Among the different psychosocial risks, the following stand out because of their importance in relation to the crisis situation and the theoretical reference model: (a) Role conflict: this is the situation in which a worker cannot simultaneously satisfy the contradictory role expectations in which he or she is involved. There is role conflict when a worker is being given work tasks without enough resources to complete them and receiving contradictory requests from different people. Previous research has shown that problematic levels of distress were 53% more likely for workers reporting role conflict (Johannessen et al., 2013). Having to teach from your own home often can bring some role conflict, since familiar conciliation might get more challenging for those teachers who also have to perform other roles, such as being parents, partners, and caregivers in general. (b) Lack of organizational justice: Lack of organizational justice refers to the extent to which employees perceive they are treated unfairly in their workplace and the perception of the absence of reciprocity in social exchanges (Moorman, 1991; Kobayashi and Kondo, 2019). Low organizational justice is known to be a potential risk factor for poor physical and psychological health among employees (Fujishiro and Heaney, 2009; Kobayashi and Kondo, 2019). (c) Workload: It assesses quantitative and qualitative workload. Quantitative workload refers to the amount of activities to be performed in a given period of time, while qualitative workload refers to the difficulty of the task and the volume of information to be processed in relation to the time available (Gil-Monte, 2016). A high workload has been associated with low levels of well-being and higher risks of health problems (Pace et al., 2019). In general, the adaptation to the current pandemic situation requires an extra load of work that teachers (and family and students) have to deal with. (d) Interpersonal conflicts: It assesses the frequency with which workers perceive conflicts coming from the school management, colleagues, students, or relatives of the students. Interpersonal conflicts have been associated to health problems, particularly to depression (Kubik et al., 2018). In the context of the COVID-19 pandemic, uncertainty has often made it difficult to reach an agreement between school, families, students, and teachers about the best way to proceed, which new measures to take in order to adapt, and for how long this measures should be maintained. (e) Emotional work: It refers to the effort, planning, and control necessary to express the organizationally desirable emotions during interpersonal transactions (Morris and Feldman, 1996; Ortiz et al., 2012). Previous research has shown that problematic levels of distress were 38% more likely for workers reporting high emotional work (Johannessen et al., 2013). In the context of a pandemic, an extra burden of negative emotions in teachers (such as worry, uncertainty, and fear) would be expected. (f) Job insecurity: the perceived threat of losing one's current job in the near future (Heaney et al., 1994), or that the employer did not comply with his or her obligations or promises (breach of psychological contract) (Vander Elst et al., 2016), can have equally serious consequences as actual job loss (De Witte, 1999). Particularly, job insecurity is considered a stressor that affects negatively the physical, psychological, and social health of the employee (Cheng and Chan, 2008; De Witte et al., 2015; De Witte et al., 2016; Selenko et al., 2017).

On the other hand, as the Karasek model points out, one of the most important resources to cope with psychosocial risk factors is the *Social support at work*. Social support at work is defined as the social climate in the work context involving the relationship between the supervisor and coworkers (Karasek and Theorell, 1990). It involves both social–emotional and instrumental support. The former refers to the degree of social and emotional integration between coworkers and the supervisor, while instrumental support refers to the collaboration between coworkers and the supervisor to carry out work tasks (Martín-Arribas, 2007).

An important potential source of social support is the emotional support of family, friends, and colleagues, which is particularly difficult to have on a confinement situation such as that originated by the COVID-19 pandemic. Social support and resilience protect individuals from threats to their mental and physical health by reducing or balancing the negative effects of the stressful events they experience in life (Woodhead et al., 2016; Sun et al., 2017).

As previously stated, a large number of demands and low resources produce a series of negative consequences for workers (Karasek, 1979), of which psychosomatic health problems and burnout syndrome are the most important due to their prevalence and associated consequences.

Psychosomatic Health Problems

The term psychosomatic refers to all those alterations in which mental processes influence areas of the organism (Montiel et al., 2016). Among the most common are various types of symptoms affecting multiple organs and systems.

Examples of these are back pain, tension headaches, sleep problems, chronic fatigue, heartburn, tension diarrhea, or heart palpitations (Jaradat et al., 2016).

Burnout Syndrome

Burnout syndrome is defined as a prolonged response to chronic emotional and interpersonal stressors at work and is defined by the three dimensions of burnout, cynicism, and inefficiency (Maslach et al., 2001).

The prevalence of burnout in education oscillates between 11 and 35.5% depending on the country and the study considered (Ratto et al., 2015; Villaverde et al., 2019). A Eurofound study (Aumayr-Pintar et al., 2020) showed that, in Portugal, 15% of educational professionals had a moderate risk of burnout, and the employees with burnout syndrome increased from 8 to 15% between 2008 and 2013. In addition, their study (King et al., 2018) with school counselors in Australia found that 45% of the sample experiences burnout.

Given this prevalence in recent years, the study of burnout in the education sector has become increasingly important (Kim and Burić, 2019; McLean et al., 2019a; Schonfeld et al., 2019). Most researches pointed out the importance of burnout on teachers (Kaur and Singh, 2014; Yerdelen et al., 2016; Schonfeld et al., 2019), considering it as a risk for teachers that can negatively affect effective teaching (Travers, 2017), their interaction with their students (Travers, 2017), and their motivation for the job (McLean et al., 2019b), resulting in absenteeism (Makhdoom et al., 2019), depression (Martínez-Monteagudo et al., 2019), insomnia (Gu et al., 2020), or a decrease in the capacity to give support to the students (Zapf et al., 1999; Jennings and Greenberg, 2009).

Despite the impact of pandemics on the health and well-being of citizens, and more specifically of workers, and their clear influence on working conditions, or more specifically on their psychosocial risks, there are hardly any studies that have addressed the effect of a pandemic on psychosocial risks. There are even fewer studies comparing these types of factors during a pandemic in Spanish-speaking countries. Although there are studies carried out within the framework of different crises, allowing for contextualization of stress situations, these do not focus on the specific case of a pandemic like the one we are facing due to COVID-19. This situation is even more limited if we consider the impact on teachers. Likewise, the few studies traditionally available have been carried out retrospectively, ignoring their perception of the pandemic, as well as the associated psychosocial risks during the times of greatest severity.

After conducting a review of the literature, we were unable to observe any studies focused on teachers that analyzed the psychosocial risks of this group and their perception of the pandemic comparing two Spanish-speaking countries at different phases or moments of the pandemic. Therefore, the study presented here aims to fill this gap in the literature by offering a first approach to the perception of COVID-19 by teachers and its relationship with psychosocial risks, comparing data from Spain and Mexico.

Aims

The main aim of this study was to analyze the perception of non-university teachers regarding measures and resources implemented by institutions and governments and its impact on their daily work. Also, to analyze the psychosocial risks of these professionals and its relation to the sanitary emergency caused by COVID-19 comparing two Spanish-speaking countries, Spain and Mexico, at a moment where the two countries were at different phases of the pandemic.

MATERIALS AND METHODS

Design, Procedure, and Participants

Data were collected from a sample of 421 non-university teachers (80.2% women and 19.8% men; 56.3% from Mexico and 43.7% from Spain) aged 24–60 years (M = 39.32, SD = 10.21) *via* a self-completed questionnaire during the COVID-19 pandemic from March to April 2020. From Spain, participants were aged 24–60 (M = 40.17, SD = 8.46), 71.1% of whom were women and 28.9% were men. From Mexico, participants were aged 20–64 (M = 38.72, SD = 811.28), 86.6% of whom were women and 13.4% were men. At the beginning of the study, the research team contacted different associations and institutions of education in order to reach non-university teachers and invite them *via* e-mail to participate in the study. In the online invitation, teachers were informed about the purpose of the study and also about how their anonymity and confidentiality were guaranteed. The time cost of completing the questionnaire was 35 min.

The eligibility criteria for participants were as follows.

Inclusion criteria:

(a) To be a teacher in an institution other than university.
(b) To be actively working during the moment of assessment.
(c) To have signed the informed consent document and confidentiality agreement within the framework of the principles of the Declaration of Helsinki.

Outcome Measures

The research included the variables and measurement instruments:

Psychosocial Risks

Different questionnaires were used to measure demands, resources, and consequences: The UNIPSICO Battery (Gil-Monte, 2016), the Burnout Assessment Tool (BAT) (Schaufeli et al., 2019), and The Job Insecurity Scale (Vander Elst et al., 2014).

The demand factors include:

Role conflict

Taken from UNIPSICO Battery (Gil-Monte, 2016). Role conflict is the situation in which a worker cannot simultaneously satisfy the contradictory role expectations in which he or she is involved. The scale is composed of five items (e.g., "I receive incompatible demands from two or more people"). Participants are asked to score the frequency with which they have experienced the

situation described in each statement on a Likert-type scale from 0 to 4 (0 = Never; 4 = Very frequently: every day), with higher scores indicating higher levels of Role conflict (scores above 1.6 are considered high, whereas scores equal to or below 0.81 are considered low). The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.84; Mexico: α = 0.80; Spain: α = 0.84).

Lack of organizational justice

Extracted from UNIPSICO Battery (Gil-Monte, 2016). Lack of organizational justice is defined as the perception of the absence of reciprocity in social exchanges. The scale is made up of five items (e.g., "I give up my skin at work compared to what I receive in return"). The response format is on a Likert-type scale from 0 to 4 (0 = Never; 4 = Very frequently: every day), with higher scores indicating higher lack of organizational justice (scores above 2.4 are considered high, whereas scores equal to or below 1.6 are considered low). The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.83; Mexico: α = 0.74; Spain: α = 0.89).

Workload

Taken from UNIPSICO Battery (Gil-Monte, 2016). It assesses quantitative and qualitative workload on a Likert-type scale from 0 to 4 (0 = Never; 4 = Very frequently: every day). Quantitative workload refers to the amount of activities to be performed in a given period of time, while qualitative workload refers to the difficulty of the task and the volume of information to be processed in relation to the time available. It consists of six items, three quantitative (e.g., "Is it possible for you to work at a relaxed pace?") and three qualitative (e.g., "When you are working, do you encounter particularly hard situations?"), with higher scores indicating higher Workload (scores above 2.17 are considered high, whereas scores equal to or below 1.51 are considered low). The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.76; Mexico: α = 0.62; Spain: α = 0.80).

Interpersonal conflicts

Extracted from UNIPSICO Battery (Gil-Monte, 2016). It assesses the frequency (0 = Never; 4 = Very frequently: every day) that workers perceive conflicts coming from the hospital management, colleagues, patients, and relatives of the patient. The scale consists of six items (e.g., "How often do you have conflicts with your colleagues?"), with higher scores indicating higher Interpersonal conflicts (scores above 1 are considered high, whereas scores equal to or below 0.6 are considered low). The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.60; Mexico: α = 0.58; Spain: α = 0.57).

Job insecurity

It was measured using the Job Insecurity Scale (Vander Elst et al., 2014). It consists of five items (e.g., "I feel insecure about the future of my job") designed to measure quantitative job insecurity (i.e., insecurity to lose the job as such). Respondents were asked to rate these items on a 5-point Likert-type scale, ranging from 1 ("strongly disagree") to 5 ("strongly agree"), with higher scores indicating higher levels of job insecurity. The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.87; Mexico: α = 0.76; Spain: α = 0.91).

The resource factors include:

Social support at work

Extracted from UNIPSICO Battery (Gil-Monte, 2016). This is defined as the availability of help from other people. It evaluates the social support offered by your head of studies, the management of the center, and by your colleagues, in all cases in the form of emotional support and technical support. It consists of six items (e.g., "How often do your colleagues help you when problems arise at work?"). This was answered on a 4-pont Likert-type scale (0 = Never; 4 = Very frequently: every day), with higher scores indicating higher Social support at work (scores above 2.83 are considered high, whereas scores equal to or below 2 are considered low). The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.88; Mexico: α = 0.88; Spain: α = 0.89).

The consequence factors include:

Psychosomatic problems

Included in the UNIPSICO battery (Gil-Monte, 2016). It assesses the frequency of occurrence of psychosomatic problems related to the perception of sources of stress at work. It consists of nine items related to different systems of the organism (e.g., "Have you been worried that, without making any effort, your breathing would be cut off?"). It was answered on a 4-pont Likert-type scale (0 = Never; 4 = Very frequently: every day), with higher scores indicating higher Psychosomatic problems (scores above 1.67 are considered high, whereas scores equal to or below 0.89 are considered low). The scale has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.90; Mexico: α = 0.90; Spain: α = 0.90).

Burnout

It was assessed using the reduced version of the BAT (Schaufeli et al., 2019). It consists of 12 items that evaluate four scales: (European Centre for Disease Prevention and Control, 2020c) exhaustion (e.g., "At work, I feel mentally exhausted"), mental distance (e.g., "At work, I have trouble staying focused"), emotional impairment (e.g., "I don't recognize myself in the way I react emotionally at work"), and cognitive impairment (e.g., "I make mistakes in my work because I have my mind on other things"). Participants are asked to score the frequency that they have experienced the situation described in each statement on a Likert-type scale from 0 to 4 (0 = Never; 4 = Very frequently: every day), with higher scores indicating higher levels of Burnout. The instrument has obtained adequate psychometric properties in previous studies and in the present research (total sample: α = 0.91; Mexico: α = 0.89; Spain: α = 0.91).

Coronavirus Disease 2019-Related Measures

This is an *ad hoc* questionnaire of 13 items constructed to measure different aspects related to the health emergency caused by the COVID-19. The aspects considered are: Available resources (provided by the health center, regional government,

and national government, e.g., "I feel that my center has put sufficient resources to deal with COVID-19 in my daily work"), information {provided by the health center, regional government, and national government, e.g., "I consider that from the regional government [e.g., state of Sinaloa (Mexico)/or Autonomous Community (Spain)] I have been given enough information to deal with COVID-19 in my daily work"}, measures (taken by the health center, regional government, and national government, e.g., "I believe that sufficient measures have been taken by the national government to address COVID-19 in my daily work"), and impact on work (workload, labor conflicts, work-related stress, and work-related concerns and fears, e.g., "The COVID-19 has increased my workload"). The subjects score on a Likert-type scale his or her level of agreement or disagreement with the statements (1 = totally disagree, 5 = totally agree). Scores range from 1 to 5, with higher levels indicating greater satisfaction with the resources available, information, and measures taken, as well as higher levels of impact on work. The scale has obtained adequate psychometric properties (total sample: available resources $\alpha = 0.90$, information $\alpha = 0.94$, measures $\alpha = 0.94$, impact on work $\alpha = 0.78$; Mexico: available resources $\alpha = 0.86$, information $\alpha = 0.93$, measures $\alpha = 0.91$, impact on work $\alpha = 0.78$; Spain: available resources $\alpha = 0.87$, information $\alpha = 0.89$, measures $\alpha = 0.90$, impact on work $\alpha = 0.78$).

Data Analyses

A descriptive statistical analysis was performed for all study variables, as well as correlations and mean comparison analysis. All analyses were carried out using the statistical package SPSS (Statistical Package for the Social Sciences, Version 25, Armonk, NY, United States: IBM Corp.).

RESULTS

Descriptive Analysis

Sociodemographic

From the total sample of 421 non-university teachers, 237 were from Mexico and 184 from Spain. The great majority worked in a public institute (84.8%); 32% taught in kindergarten, 39.5% in primary school, and 28.5% in high school. The educational level of the teachers was 65.3% university degree, 23.9% master, and 10.8% doctorate. From the participants, 7.8% had a temporary contract, whereas 92.2% had a permanent contract.

TABLE 3 | Descriptive data on COVID-19-related measures on teachers in Spain and Mexico.

		Resources	Information	Measures	Impact
Spain	Mean	2.10	2.31	2.11	2.59
	SD	1.12	1.18	1.15	1.11
	Range	1–5	1–5	1–5	1–5
Mexico	Mean	3.32	3.84	3.65	2.35
	SD	1.32	1.23	1.20	1.07
	Range	1–5	1–5	1–5	1–5

SD, standard deviation.

Psychosocial Risks

As it can be seen in **Table 2**, regarding psychosocial risks, that teachers in Spain present medium levels on all of the psychosocial risks, whereas teachers in Mexico present medium levels on lack of organizational justices and of social support and low levels on the rest of psychosocial risks.

Coronavirus Disease 2019-Related Measures

As it can be seen in **Table 3**, during the pandemic, teachers in Spain rated the resources, information available, and measures taken by the government and the hospital below the mean value of the answer scale, which points to a tendency to consider resources, information, and measures as insufficient. The highest scores from teachers in Spain are regarding the impact of COVID-19 on their jobs, although the scores in this case are also below the medium value of the answer scale. Teachers in Mexico, on the other hand, rated the resources and information available and the measures taken by government and the hospital above the mean value of the answer scale, which points to a tendency to consider resources, information, and measures as sufficient. The lowest score for teachers in Mexico is the impact of COVID-19 on their jobs.

Comparison of Mean

Analysis of the mean comparison among the variables of the study was carried out between data from teachers in Spain and Mexico (**Table 4**).

In general, it seems that the pandemic has a greater effect in the case of Spain, since there are statistically significant differences in all dimensions except social support, with higher levels of risk and consequences in the Spanish case. Likewise, there is greater satisfaction with the available information, resources, and measures in the Mexican case than in the Spanish case, and finally, there seems to be a greater impact of the pandemic on the work and life of teachers in the Spanish case in comparison with the Mexican case.

Analysis of Relations

The results of the correlation analysis among the variables are shown in **Table 5**. As it can be seen, almost all the variables are very strongly related. The only correlation that is not statistically significant is between the Impact of COVID-19 in the workplace and Social support.

When focusing on correlations among the variables in teachers from Spain and Mexico separately, the situation slightly changes (**Table 6**). In the case of teachers in Spain, many of the psychosocial risks correlate between them, except for Job insecurity that does not appear related to any of the resting variables. Also, from the COVID-19-related measures, Information and Measures are related with a higher number of psychosocial risks, whereas Impact is less related to the rest of the variables (psychosocial risks as well as the resting COVID-19-related measures). On the other hand, in the case of teachers in Mexico, variables are also very strongly related between them, although Lack of organizational justice and Job insecurity are less related to the rest of the variables. Also, in contrast with the case of Spain, Impact appears related with the rest of the COVID-19-related measures.

DISCUSSION AND CONCLUSION

The current crisis caused by the coronavirus is a challenge not only in the health field but also in all spheres of society. In this context, professionals at all levels have had to adapt to new working conditions, in addition to dealing with the pandemic in their personal lives and as members of the community. Among them, teachers of preschool and primary and secondary education have had to assume their important role in the best possible way, with limited means and resources and with the uncertainty of the moment and with the enormous responsibility that comes with educating and training children and adolescents, helping them to cope with the crisis and often providing relief as much as possible with homework and how to take school home (Boletín Oficial del Estado, 2020; Faro de Vigo, 2020). Considering that teachers are vulnerable to burnout and job stress (Zapf et al., 1999; Jennings and Greenberg, 2009; Kaur and Singh, 2014; Yerdelen et al., 2016; Travers, 2017; Makhdoom et al., 2019; Martínez-Monteagudo et al., 2019; McLean et al., 2019b; Schonfeld et al., 2019; Gu et al., 2020), and therefore the negative consequences these can have on their health and professional performance (Bergh et al., 2018; Fornell et al., 2018; Junne et al., 2018; European Centre for Disease Prevention and Control, 2020d), it is essential to study how psychosocial risks affect this group at a time of such vulnerability and general demand as the present. The literature on social risks to teachers in a pandemic context is extremely limited; however, it is critical to study the extent to which factors related to teachers' well-being may be affected during a health crisis such as the current one in order to ensure the well-being of teachers and, in turn, the children and adolescents in their care.

This study has sought to explore the extent to which teachers are affected by psychosocial risks during the pandemic and how these risks relate to teachers' perceptions of the pandemic in terms of resources, measures, information, and impact. At the same time, it compares data of teachers in Mexico with data of teachers in Spain, two countries heavily affected by the pandemic and yet at very different stages of its development: Spain in the midst of a drop in cases, Mexico in the midst of a rise (European Centre for Disease Prevention and Control, 2020d).

At the time of collecting the data, the coronavirus crisis was at its peak in Spain, while in Mexico, it was in a more initial phase. This facilitates the interpretation of some of the data found.

The main results of the study show, on the one hand, that teachers in Spain as well as teachers in Mexico inform about perceiving lack of organizational justice during the pandemic but, at the same time, to perceive social support. Teachers in Spain, however, also inform about role conflict, workload, interpersonal conflict, psychosomatic problems, and burnout. These data go in line with previous literature about the social risks that teachers are exposed to (Zapf et al., 1999; Jennings and Greenberg, 2009; Kaur and Singh, 2014; Yerdelen et al., 2016; Travers, 2017; Makhdoom et al., 2019; Martínez-Monteagudo et al., 2019; McLean et al., 2019b; Schonfeld et al., 2019; Gu et al., 2020). Regarding resources and information available about COVID-19, the impact of COVID-19 on their jobs, as well as measures taken by responsible entities (national and regional government, as well as work center), data from teachers in Spain point to a perception of insufficient resources, information, and measures and to a perception of a moderate–high impact of COVID-19 on their jobs. Regarding teachers in Mexico, data point to a perception of sufficient resources, information, and measures taken by responsible entities, as well as to a perception of a moderate impact of COVID-19 on their jobs.

When specifically comparing data from teachers in Spain and Mexico, the results highlight a difference between teachers in both countries: Spanish teachers present more role conflict, lack of organizational justice, workload, interpersonal conflicts, job insecurity, psychosomatic problems, and burnout than teachers in Mexico. At the same time, teachers in Spain inform about less resources, information, and measures than teachers in Mexico, but also about a bigger impact of COVID-19 on their jobs, than teachers in Mexico. The fact that teachers in Spain are more affected by psychosocial risks during the pandemic and are more

burned out by work could be due, on the one hand, to the phase of the pandemic at the time of data collection, as the pandemic situation was more severe in Spain at the time that the study was conducted. However, it could also be due to the fact that teachers in Spain perceive fewer resources, information, and measures taken by responsible institutions, which could in turn worsen some of the psychosocial risks and even be a direct risk factor for burnout. Specifically, in terms of the relationship between psychosocial risk factors and COVID-19-related measures, these appear to be closely related, although it is true that in the case of teachers in Spain, the relationship between COVID-19-related measures and social risks is clearer than in the case of teachers in Mexico. Of the COVID-19-related measures, the least related to psychosocial risks is the impact of COVID-19 on work, while of the psychosocial risks, the least related to the rest of the psychosocial risks and to COVID-19-related measures is Job insecurity. These data indicate that teachers' perception of the measures taken by the responsible entities, as well as the perception of sufficient information and resources, could influence the psychosocial risks to which these professionals are exposed. As mentioned above, some of the differences are due, on the one hand, to the phase of the pandemic in which both countries were and, on the other hand, to the perception of resources by teachers to face the pandemic and the challenges it poses in their professional life.

One of the main limitations of this study is that it presents an analysis of relationships between variables that does not allow for the establishment of causal relationships between them. Furthermore, it is a cross-sectional study that does not allow for observing the evolution of the data as the pandemic caused by COVID-19 progresses. Future studies could make new measurements of the variables when the different phases of the pandemic have passed, which would allow the comparison of the variables taking into account the evolution of the health crisis, as well as the evolution of the psychosocial risks of teachers and the possible development of pathologies that, based on the scientific literature, have been related to the burnout and psychosocial risks described here.

Despite its limitations, this study shows data collected in a context never before seen, where data on psychosocial risks are not collected *a posteriori* but in the midst of a pandemic crisis. Our data speak of a greater general attrition of teachers in Spain, which indicates that the pandemic may indeed be related to greater sources of stress and psychosocial risks. At the same time, data from the present study underline the importance of the perception of resources by professionals, which could prevent to some extent the burnout and the possible alterations associated with it.

It is difficult to carry out this type of study in these contexts for a number of reasons, but we believe that it is important to have data to support the fact that the measures taken by the responsible entities and the provision of information affect teachers not only directly but also indirectly by making them more vulnerable to psychosocial risks that could affect their health and professional performance, thus affecting students as well. If this is important in any context, it becomes even more important in a context where the emotional toll on society is more evident than ever.

Some of the main practical applications of this research would be to know the psychosocial risks during a pandemic in non-university teachers to discover the perception of resources, information, and measures adopted by the different public and private entities to deal with COVID-19, as well as to know the impact that this perception has had on the daily work of non-university teachers. These results can help make a difference between building resilience and developing burnout. Any data that can clarify the relationships between the variables will be data that will benefit teachers, their students, and society in general. The results obtained in the present study allow to advance and consolidate the research on psychosocial risks during a pandemic while enabling the development of policies for action to improve teachers' coping with a pandemic and occupational health, which in turn will impact the outcomes of their work and society as a whole.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation, to any qualified researcher.

ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

Public Perceptions of COVID-19 in Australia: Perceived Risk, Knowledge, Health-Protective Behaviors, and Vaccine Intentions

Kate Faasse[1]* *and Jill Newby*[1,2]

[1] School of Psychology, UNSW Sydney, Sydney, NSW, Australia, [2] Black Dog Institute, UNSW Sydney, Sydney, NSW, Australia

Widespread and sustained engagement with health-protective behaviors (i.e., hygiene and distancing) is critical to successfully managing the COVID-19 pandemic. Evidence from previous emerging infectious disease outbreaks points to the role of perceived risk, worry, media coverage, and knowledge in shaping engagement with health-protective behaviors and vaccination intentions. The aim of the current study was to examine the role of these factors in predicting recommended health-protective behaviors early in the pandemic. A secondary aim was to assess uncertainty and misconceptions about COVID-19. An online survey of 2,174 Australian residents was completed between March 2 and 9, 2020, at an early stage of the COVID-19 outbreak in Australia. Results revealed that two-thirds of respondents were at least moderately worried about a widespread COVID-19 outbreak. Worry about the outbreak and closely following media coverage were consistent predictors of greater engagement with health-protective behaviors and higher vaccination intentions. Uncertainty and misconceptions about COVID-19 were common, including uncertainty about whether people are likely to have natural or existing immunity to the virus. There was also uncertainty around whether specific home remedies (e.g., vitamins and saline rinses) would offer protection and whether the virus was human-made and deliberately released. Such misconceptions are likely to cause concern for members of the public. The findings also highlight psychological and demographic factors associated with lower engagement with health-protective behaviors, including male gender, younger age, and low levels of worry about the outbreak. These findings offer potential pathways and targets for interventions to encourage health-protective behaviors. The results relating to uncertainty and misconceptions about COVID-19 point to areas that could be usefully targeted by public information campaigns.

Keywords: COVID-19, emerging infectious disease, health behaviors, perceived risk, worry, knowledge, uncertainty, misinformation

INTRODUCTION

On December 31, 2019, the first report of a "pneumonia of unknown cause" was made to the World Health Organization (WHO) Country Office (World Health Organization, 2020c). The report came from Wuhan, China. On January 10, 2020, WHO issued its first guidance on the "novel coronavirus," with similarities to other coronaviruses such as SARS (Severe Acute Respiratory Syndrome) and MERS (Middle East Respiratory Syndrome). By the end of January 2020, the novel coronavirus had spread to countries around the world, and the outbreak was declared a Public Emergency of International Concern. The first cases of COVID-19 in Australia were identified on January 25, 2020 (Minister for Health, 2020). As of March 7, there were 63 confirmed cases, including two deaths (Australian Government Department of Health, 2020b).

Public engagement with health-protective behaviors, including social distancing and hygiene behaviors, has been highlighted as one of the most important strategies for reducing the transmission of COVID-19 (Bonell et al., 2020). Social distancing refers to minimizing the number of times people come into close contact with one another. Hygiene behaviors are those aimed at cleaning hands, surfaces, or objects that may have come into contact with potentially infectious respiratory droplets (Michie et al., 2020). Understanding the cognitive and affective factors that predict engagement with these health-protective behaviors can help inform public health strategies to encourage people to increase and sustain these behaviors.

A number of cognitive factors contribute to engagement with health-protective behaviors during disease outbreaks. Perceived risk, or perceived susceptibility to a threat, has emerged as a consistent predictor of such behaviors (Weinstein, 1988; Petrie et al., 2016). For example, higher perceived likelihood and severity of influenza A/H1N1 (swine flu), influenza H5N1 (bird flu), and SARS were associated with increased heath-protective behaviors in general population samples (Tang and Wong, 2003; Lau et al., 2007; Rubin et al., 2009). Other cognitive factors identified include more accurate knowledge about how a virus is spread (Petrie et al., 2016) and the perception that behaviors will be effective in reducing the risk of infection (Bish and Michie, 2010).

Affective factors also appear to play a role in increasing health-protective behaviors (Slovic et al., 2007). The COVID-19 pandemic has generated substantial public anxiety, uncertainty, and distrust (Asmundson and Taylor, 2020). Both heightened anxiety and trust in information provided by authorities have been shown to predict health-protective behaviors during infectious disease outbreaks (Bish and Michie, 2010).

Substantial media coverage and misinformation have been generated by the COVID-19 pandemic (Asmundson and Taylor, 2020). Media coverage about a health threat can heighten both perceived risk and anxiety (Paek and Hove, 2017). Misinformation and conspiracy theories regarding COVID-19 are also widespread and evolving (Wikipedia, 2020; World Health Organization, 2020a). Such misinformation can have lasting impacts, including reduced engagement with health-protective behaviors including vaccination, once it becomes available (Zimet et al., 2013).

The current study investigated the Australian public's perception of risk (i.e., likelihood and severity) and worry about COVID-19, viewing of media coverage, accuracy of current knowledge (and conversely, misinformation) about the virus, and health-protective behaviors. Insight into how perceptions of emerging infectious diseases influence the adoption of health-protective behaviors is important in understanding the potential health, social, and economic impact of such outbreaks and may contribute to targeting public health messaging to encourage appropriate health behaviors.

MATERIALS AND METHODS

Recruitment

Members of the Australian general population were recruited for the online survey by the use of Facebook advertisements. Advertisements were targeted at all users with current country of residence listed as Australia and age listed as 18 or above. Users meeting these criteria were shown the advertisement on their Facebook page "timeline." In addition, the advertisement was posted on the timeline of one university webpage, so that those individuals who followed this page could view the post on their timeline. Facebook users who viewed the advertisement were able to click on an embedded link that took them to the survey (hosted on Qualtrics). Advertising and data collection ran for 7 days from 4 pm Monday, March 2, to 4 pm Monday, March 9, 2020. In total, the ad was displayed to 66,210 individual accounts, with 4,353 clicks. Each response came from a unique Internet Protocol (IP) address, indicating that each response came from a separate device.

Ethical Approval

The study was approved by the UNSW Human Research Ethics Advisory Panel (File 3309), and all participants provided electronic informed consent to participate.

COVID-19 in Australia

During the week that the study was conducted, the COVID-19 virus was already in Australia, but infections were limited and were predominantly cases where individuals had contracted the virus overseas (Australian Government Department of Health, 2020a; Worldometer, 2020). At the end of day 1 (March 2), there were 33 confirmed cases; the first death from the virus occurred on this day, as did the first reported community transmissions. This number had risen to 93 by March 9, with three deaths and 18 cases that were likely to be community transmissions (no history of recent travel).

Participants

In total, 3,086 people viewed the participant information statement and consent form. Of these, 854 either did not consent or completed only some of the survey questions before discontinuing, and 2,232 submitted the survey. Nine responses were excluded because participants reported that they did not

live in Australia, and 49 responses were incomplete (48 missing demographic information, one with less than half of all responses completed). This resulted in a final sample of 2,174 participants.

Measures

See **Table 1** for survey questions and response options.

Information

Participants were asked how closely they had been following news about the outbreak, sources of information about the outbreak, and the extent to which they believe that scientists and other medical and health experts understand COVID-19 (to assess perceived scientific understanding).

Perceived Risk and Worry

Participants were asked five questions relating to their perceived risk and worry about COVID-19. The first question assessed how concerned or worried respondents were feeling about the possibility of a widespread outbreak in Australia (i.e., the virus spreading from person to person more like a typical cold or flu virus). Perceived likelihood of an outbreak, perceived likelihood of the individual catching the virus if there was an outbreak, perceived behavioral control, and perceived severity were also assessed.

Knowledge

To assess knowledge (and possible misinformation), participants were asked to respond to a series of statements about the COVID-19 coronavirus and whether (to the best of their knowledge) these statements were true or false or they were unsure of the answer. See **Table 3** for items and their correct answers (based on the state of knowledge at the time of the study). Correctly answered items were summed to generate a general virus knowledge subscale score.

Participants were asked to identify the most common symptoms of COVID-19 infection (see **Table 4**), based on information provided to the Australian public at the time: fever, cough, sore throat, and shortness of breath (Australian Government Department of Health, 2020c). More recent information includes fatigue or tiredness, which were not included in the survey. Three uncommon symptoms were included: diarrhea, vomiting, and nausea (Guan et al., 2020). The number of correctly answered items was summed to generate a symptoms knowledge subscale score.

Transmission knowledge items asked about the ways the virus can potentially be spread (see **Table 4**), including droplets spread through coughing or sneezing, touching or shaking hands with someone who is infected, and touching surfaces that have come into contact with the virus. Three other sources, which did not appear to be transmission mechanisms, were also included: water, mosquitoes, and airborne spread (Centers for Disease Control and Prevention, 2020; World Health Organization, 2020a,b). As above, the number of correctly answered items was summed to generate a transmission knowledge subscale score.

One item assessed knowledge of recommended face mask use, with advice to the public at that time being that only people who were sick should be wearing masks to stop them spreading the virus (Australian Government Department of Health, 2020c). Another item assessed knowledge of the approximate mortality rate, which at the time was estimated to be 3.4% (World Health Organization, 2020d). Responses were deemed correct if they were between 1 and 5%. A total COVID-19 knowledge

TABLE 1 | Survey questions and response options.

Survey question	Response options
Information	
How closely have you been following news about the recent outbreak of COVID-19 coronavirus?	11-point scale from 0, *not at all*, to 10, *very closely*
How have you been getting information about the COVID-19 coronavirus outbreak?	Select all that apply: news media, social media, official government websites, family members, friends or colleagues, none of the above, other (text entry)
To what extent do you believe that scientists and other medical and health experts understand the COVID-19 coronavirus?	11-point scale from 0, *don't understand at all*, to 10, *understand very clearly*
Perceived risk and worry	
How concerned or worried are you that there will be a large outbreak of COVID-19 coronavirus in Australia within the next 12 months?	5-point scale: not at all concerned, a little concerned, moderately concerned, very concerned, extremely concerned
How likely do you think it is that there will be an outbreak of COVID-19 coronavirus in Australia?	Visual analogue scale (VAS) from 0, *not at all likely*, to 100, *extremely likely*
If there is an outbreak of COVID-19 coronavirus in Australia, how likely is it that you, personally, will catch the coronavirus?	VAS from 0, *not at all likely*, to 100, *extremely likely*
If there was a COVID-19 coronavirus outbreak in Australia, how much could you personally do to protect yourself from catching the virus?	VAS from 0, *couldn't do anything*, to 100, *could do a lot*
If you did catch COVID-19 coronavirus, how serious do you think your symptoms would be?	6-point scale: no symptoms, mild symptoms, moderate symptoms, severe symptoms, severe symptoms requiring hospitalization, and severe symptoms leading to death
Knowledge	
General virus knowledge, symptoms knowledge, and transmission knowledge	See **Tables 3**, **4**
To minimize the transmission of the COVID-19 coronavirus, who should be wearing a face mask?	Four response options: sick people—to stop them spreading the virus, healthy people—to prevent infection, everyone, no one
To your knowledge, approximately what percentage of people who have been infected with coronavirus (COVID-19) have died from the virus?	VAS from 0% to 100%
Health-protective behaviors	
Distancing and hygiene behaviors	See **Table 5**
If there was a safe and effective vaccine developed for the COVID-19 coronavirus, how likely is it that you would choose to have this vaccination?	5-point scale: would definitely not get the vaccine, would probably not get the vaccine, unsure if I would get the vaccine or not, would probably get the vaccine, would definitely get the vaccine

TABLE 2 | Demographic characteristics of the sample with number (percentage) of respondents.

Demographic variables	Total *N* (%)
Gender

Not stated	7 (0.3)

score was calculated as the number of correct responses to all items assessing various aspects of knowledge about COVID-19, potentially ranging from 0 to 34.

Health-Protective Behaviors

To assess distancing and hygiene behaviors, participants were asked whether they had engaged in 13 behaviors during the previous month (see **Table 4**). Response options were *yes*, *no*, *unsure*, and *not applicable*. Items were generated based on previous research (Rubin et al., 2009; Bults et al., 2015; Petrie et al., 2016; Simpson et al., 2019) and recommended behaviors (Australian Government Department of Health, 2020c). Health-protective behavior sum scores (number of "yes" responses) were calculated, with possible scores ranging from 0 to 13.

Participants were asked to complete a single item asking about how likely it is that they would choose to have a COVID-19 vaccination. Responses were scored such that higher scores indicated higher vaccine intentions.

Demographics and Health Information

Information was collected on participants' age group, gender, ethnicity, highest level of education, and region of residence within Australia (see **Table 2**). Participants were also asked to complete three questions relating to their health. First was a single-item measure assessing their self-rated heath (Idler and Benyamini, 1997), with responses on a five-point scale from *poor* to *excellent*. Second was an item assessing whether they had received a flu vaccine in the previous year (*yes*, *no*, *unsure*). For the purposes of analysis, *no* and *unsure* responses were combined to form a dichotomous measure. Finally, participants were asked whether they, or any family members or friends, had caught COVID-19 (*yes*, *no*, and *unsure*). Only nine respondents said "yes" to this question, and these responses were included in the analysis.

RESULTS

Demographics

Demographic characteristics of the sample can be seen in **Table 2**. A large proportion of respondents were from the state of New South Wales (NSW).

Health-Related Characteristics

Respondents' mean self-rated health was 3.21 (SD = 0.98). The majority of participants rated their health as good (38.7%) or very good (29.5%). Approximately half of the sample (52.9%) reported having had a flu vaccine in the past year. Only nine respondents (0.4%) reported that they themselves, or their friends or family, had caught COVID-19. The majority had not (95.3%).

Information

Participants reported following news about COVID-19 closely (M = 7.3, SD = 2.1). Information about COVID-19 came from the news media (85.2%), official government websites (72.2%), social media (68.5%), colleagues or friends (22.7%), and family members (22.7%). Only 0.3% of respondents reported not getting information from any of these sources. Perceived scientific understanding was moderate (M = 6.1, SD = 2.0).

Perceived Risk

Concern about the possibility of a widespread outbreak in Australia was moderate (M = 3.2, SD = 1.1; scale from 1 to 5). A small proportion reported being not at all concerned (6.1%), while 24% reported being a little concerned, 31.1% were moderately concerned, 21.7% were very concerned, and 14.9% were extremely concerned. Respondents' ratings of the perceived likelihood of an outbreak of COVID-19 in Australia were relatively high (M = 71.8, SD = 24.9; scale from 0 to 100), and perceived likelihood that they would catch the virus in the case of an outbreak was moderate (M = 54.9, SD = 24.7). Perceived behavioral control was relatively high (M = 68.2, SD = 21.6).

With regard to perceived severity of symptoms in the case of infection, only 0.3% of respondents indicated that they would experience no symptoms; mild (27.5%) and moderate (46.7%) symptoms were most commonly anticipated. One in

TABLE 3 | Percentage of true, false, and unsure responses to general knowledge items, with correct answers in bold font.

	True	False	Unsure
Currently there is no vaccine to protect against COVID-19 coronavirus [T]	**95.0**	1.6	3.3
There is an effective medicine available for treating COVID-19 coronavirus [F]	5.1	**79.2**	15.6
There are ways to help slow the spread of COVID-19 coronavirus [T]	**89.7**	4.0	6.2
If COVID-19 coronavirus breaks out in Australia, it is likely that some people will have natural immunity to it [F]	29.5	**34.1**	36.3
The ordinary flu vaccine will protect me from COVID-19 coronavirus [F]	0.6	**92.7**	6.6
To date, no one in Australia has died from COVID-19 coronavirus [F*]	4.5	**91.8**	3.6
To date, no one in Australia who was infected with COVID-19 coronavirus passed it on to infect another person [F*]	4.1	**84.9**	10.9
There are other strains of coronaviruses that can infect humans, including those that cause the common cold [T]	**80.2**	4.7	15.0
The health effects of COVID-19 coronavirus appear to be more severe for people who already have a serious medical condition [T]	**97.7**	0.8	1.4
Antibiotics are an effective treatment for COVID-19 coronavirus [F]	3.4	**81.9**	14.5
Packages or letters from China can spread the virus [F]	6.8	**67.8**	25.3
Taking vitamin C or other vitamins will protect you from the COVID-19 coronavirus [F]	5.9	**74.1**	19.7
There is no evidence that vaccines against pneumonia will protect you against the COVID-19 coronavirus [T]	**67.0**	5.5	27.4
Regularly rinsing your nose with saline will protect you against the COVID-19 coronavirus [F]	2.7	**77.6**	19.6
There is no evidence that eating garlic will protect you against the COVID-19 coronavirus [T]	**82.6**	6.7	10.6
Putting sesame oil on your body will block the COVID-19 coronavirus from entering your body [F]	0.3	**95.4**	4.2
Hand dryers are effective in killing the COVID-19 coronavirus [F]	2.8	**80.2**	17.0
The virus was genetically engineered as part of a biological weapons program [F]	10.2	**57.6**	32.0
The virus was human-made and deliberately released [F]	10.2	**57.8**	31.9

**True during study design, false at data collection. Missing data from one to five respondents for each item; percentages do not always total 100.*

four respondents perceived the illness severity to be high, with 14.1% indicating they thought they would experience severe symptoms, severe symptoms requiring hospitalization (8.8%), or severe symptoms leading to death (2.3%).

Knowledge

Participants were asked to respond to a series of true–false questions to assess their more general knowledge of COVID-19. The percentage of true, false, and unsure responses (with correct answers in bold font) can be seen in **Table 3**. Total general virus knowledge subscale scores ranged from 0 (1 respondent) to 19 (129 respondents), with a mean of 14.9 (*SD* = 2.8).

Knowledge questions were also asked relating to most common symptoms and routes of transmission (see **Table 4**). Respondents were more accurate in recognizing the symptoms that have been linked with COVID-19 and less certain of whether the other symptoms (nausea, vomiting, and diarrhea) were indicative of illness. Symptoms knowledge subscale scores ranged from 0 to 7, with 32.6% of respondents correctly answering every item. The mean subscale score was 5.5 (*SD* = 1.4), indicating good recognition of the symptoms commonly mentioned in public health information provided to the Australian public at this time. Respondents typically recognized transmission routes associated with droplet spread but were less certain of whether the virus can also spread via air, water, or mosquitoes (evidence at the time indicated that these routes were unlikely). Transmission knowledge subscale scores ranged from 0 to 6, with a mean of 4.6 (*SD* = 1.0). Only 17.8% of respondents correctly answered every item.

Most respondents (79.7%) correctly identified that it was recommended (at the time) that people who were sick wear masks to stop them spreading the virus. In addition, 15.9% reported that "everyone"—both sick and healthy—should be wearing masks, and 1.3% responded that only healthy people should be wearing masks. Knowledge of the approximate mortality rate was good: 69.2% of respondents gave answers between 1% and 5%, which were deemed accurate. Percentage estimates ranged from 0 (0.5%) to 100 (0.3%), with a mean of 7.84% (*SD* = 12.31). A total COVID-19 knowledge score was calculated from responses to general, symptoms, and transmission subscales, as well as individual items about mask use and mortality. Scores ranged

TABLE 4 | Percentage of yes, no, and unsure responses to symptoms and transmission knowledge items, with correct answers in bold font.

	Yes (%)	No (%)	Unsure (%)
Symptoms			
Fever	**97.5**	0.9	1.5
Cough	**96.7**	1.1	2.0
Sore throat	**86.1**	4.0	9.7
Shortness of breath	**90.4**	2.7	6.9
Nausea	20.9	**50.4**	28.4
Vomiting	8.5	**64.4**	26.8
Diarrhea	13.9	**66.0**	19.7
Transmission			
Droplets spread through coughing or sneezing	**98.8**	0.3	0.9
Surfaces recently touched by someone who is sick	**91.2**	3.1	5.7
Touching or shaking hands with a person who is sick	**94.8**	2.1	3.1
Airborne	56.1	**28.1**	15.8
Waterborne	8.0	**64.4**	27.3
Mosquitoes	1.7	**80.0**	18.0

from 7 to 34 (out of a possible 34), with a mean of 26.48 (*SD* = 4.10).

Health-Protective Behaviors

The percentage of respondents who reported having engaged in a range of distancing and hygiene behaviors during the past month can be seen in **Table 5**. Hygiene behaviors (handwashing, using hand sanitizing gel, and cleaning and disinfecting surfaces) were the most commonly reported behaviors. The number of behaviors endorsed was summed, and scores ranged from 0 (16%) to 13 (0.3%), with most (80.5%) respondents reporting five behaviors or fewer, with a mean score of 3.29 (*SD* = 2.89).

Four in five respondents indicated that they would definitely (60.4%) or probably (20.8%) get a vaccination if one became available. Only 12.3% reported being unsure, 3.7% said that they would probably not get the vaccine, and 2.8% said that they would definitely not get vaccinated.

Predictors of Health-Protective Behaviors

Negative binomial regression with maximum likelihood estimation was conducted to assess the influence of information, perceived risk, and knowledge-related predictors on engagement with health-protective behaviors, while controlling for demographic factors and self-rated health. Negative binomial regression was chosen because it is appropriate for over-dispersed count data. The health-behavior outcome score is a count of the number of behaviors endorsed and is over-dispersed, as the variance of measures exceeds the mean score.

Demographic Predictors

To assess demographic differences in health-protective behaviors, each demographic predictor variable was entered individually into a separate negative binomial regression model. The mean (standard error) number of behaviors across demographics can be seen in **Table 6**. Demographic differences in health-protective behaviors were seen by gender ($p < 0.001$), state of residence ($p = 0.002$), age group ($p = 0.001$), and ethnicity ($p < 0.001$). Female respondents reported engaging in more health-protective behaviors than their male counterparts, and those in the youngest age group (18–29) engaged in fewer behaviors than older respondents. Behavior differences by ethnicity were also seen, with non-Caucasian respondents reporting more health-protective behaviors. Respondents from Queensland reported engaging in more behaviors than those from the category of NSW (reference category). There was not a significant effect of education level ($p = 0.339$).

Psychological Predictors of Health-Protective Behaviors During the Past Month

To assess the influence of psychological predictors on engagement with health-protective behaviors, all relevant variables were entered into a single model (see **Table 7**), controlling for demographic variables and self-rated health. The Pearson Chi-Square Goodness of Fit statistic (1.084) indicated

TABLE 5 | Percentage of yes responses relating to health-protective behaviors during the past month.

	Yes (%)
Reduce or avoid going to work or university	6.3
Reduce or avoid using public transport	18.5

B, unstandardized coefficient; SE, standard error; Exp(B), exponentiated regression coefficient.

that the model fit the data well. The omnibus test results indicate that the model was a significant improvement over a null model, $\chi^2 = 940.41$ ($df = 2$), $p < 0.001$.

More closely following media coverage, heightened worry or concern about an outbreak, higher perceived personal severity of COVID-19, and higher perceived effectiveness of health-protective behaviors were significant predictors of greater engagement with distancing and hygiene behaviors during the previous month. In contrast, stronger beliefs in scientific and medical understanding of the virus, confidence in government information, and higher COVID-19 knowledge scores predicted reduced engagement with health-protective behaviors.

Predictors of Vaccination Intentions

Respondents were asked how likely they were to get vaccinated against COVID-19. This outcome did not approximate a normal distribution; thus, ordinal logistic regression was used to assess the influence of information, perceived risk, and knowledge-related predictors on vaccination intentions, while controlling for demographic factors and self-rated health.

Demographic Predictors

To assess demographic differences in vaccine intentions, each demographic predictor variable was entered individually into a separate ordinal logistic regression model. There were

TABLE 8 | Number and percent of respondents in each age group reporting that they would definitely not, would probably not, were unsure if they would, probably would, or definitely would get a COVID-19 vaccine, if available.

	N (% of age group)				
	18–29	**30–49**	**50–59**	**60+**	**Total**
Definitely not	6 (1.2)	24 (2.8)	17 (3.5)	13 (4.3)	60 (2.8)
Probably not	14 (2.9)	31 (3.6)	22 (4.5)	11 (3.6)	78 (3.7)
Unsure	44 (9.0)	118 (13.8)	76 (15.6)	28 (9.2)	266 (12.5)
Probably would	133 (27.2)	190 (22.2)	74 (15.2)	42 (13.9)	439 (20.6)
Definitely would	292 (59.7)	494 (57.6)	297 (61.1)	209 (69.0)	1,292 (60.5)

no demographic differences in vaccine intentions by gender ($p = 0.429$), state of residence ($p = 0.832$), ethnicity ($p = 0.461$), or level of education ($p = 0.129$). Respondents did differ in their vaccine intentions by age group ($p = 0.019$). Compared to the 60-plus age group, being in the 30–49 (*ExpB* = 0.662, 95% CI [0.503 to 0.871], $p = 0.003$) or 50–59 (*ExpB* = 0.695, 95% CI [0.515 to 0.938], $p = 0.017$) age group was associated with a lower likelihood of intending to get a vaccination (see **Table 8** for percent of responses in each category by age group).

Psychological Predictors of Vaccination Intentions

Predictors entered into the full model were the same as in the previous analysis, with the addition of a dichotomous variable reflecting whether respondents had received a flu vaccine in the previous year or had not/were unsure. All variables were entered into a single model (see **Table 9**). The Pearson Chi-Square Goodness of Fit statistic (0.921) indicated good model fit. The omnibus test results indicate that the model is a significant improvement over a null model, $\chi^2 = 557.23$ ($df = 28$), $p < 0.001$.

Having received a seasonal flu vaccine in the past year predicted increased intentions to get a COVID-19 vaccine if it becomes available. With regard to psychological predictors and in line with previous results, both increased exposure to media coverage and heightened worry or concern about the outbreak predicted increased vaccination intentions. In contrast to results relating to health-protective behaviors, perceptions of greater scientific and medical understanding of the virus, confidence in government information, and higher knowledge scores predicted greater vaccination intentions.

DISCUSSION

The results of the survey provide information on public knowledge, perceived risk and worry, and health-protective behaviors in the early period of the COVID-19 pandemic in Australia. A large proportion (two-thirds) of participants were at least moderately worried about the possibility of a widespread outbreak. These rates are commensurate with past pandemics such as SARS (Bults et al., 2011; Wheaton et al., 2012). Consistent with previous findings, higher worry about outbreaks was associated with greater health-protective behaviors (e.g., handwashing; Bults et al., 2011). Recent research from China indicates that engaging in hand hygiene and other health-protective behaviors was associated with reduced psychological impact of the COVID-19 outbreak, including lower stress and anxiety (Wang et al., 2020). These findings highlight the importance of encouraging the public to engage with such behaviors not only to reduce the risk of infection but also to reduce anxiety associated with COVID-19.

This study provided important insights into what participants *expected* in terms of how serious the symptoms of coronavirus would be, should they contract COVID-19. There is a clear discrepancy between respondents' perceived severity of symptoms and current data on rates of asymptomatic infection. Only 0.3% of respondents believed that they would experience no symptoms. In contrast, emerging evidence from groups with widespread testing for the SARS-CoV-2 virus (e.g., cruise ships, repatriation flights, and overseas arrivals) indicates that between 2 and 8 out of every 10 infections may be asymptomatic (Day, 2020; Mizumoto et al., 2020; Nishiura et al., 2020). Despite being asymptomatic, those infected are still able to transmit the virus to others (Bai et al., 2020; Zou et al., 2020). In addition, people appear to be infectious and asymptomatic during the incubation period (Lauer et al., 2020). People commonly rely on symptoms to indicate illness and assume that the absence of symptoms means they are well (Diefenbach and Leventhal, 1996). Such assumptions in the COVID-19 pandemic could have serious consequences, in terms of both community transmission and reduced health-protective behaviors. Therefore, public health communication campaigns about COVID-19 need to address these misconceptions.

The results also provide insights into where Australian residents are seeking their information about COVID-19 and their level of knowledge about the virus and is transmission. While it was promising to see that 72% sourced information from official and government websites, mainstream news media was the most popular, and social media use was also high. The high usage of news media is concerning given the potential for alarming, sensationalist portrayals of the pandemic (Klemm et al., 2016). In addition, myths, rumors and misinformation can quickly spread online, particularly via social media (Vosoughi et al., 2018). Reliance on social media might have contributed to uncertainty around COVID-19, for example, about whether people have natural immunity and whether specific home remedies (garlic, vitamins, and rinsing noses with saline) help protect against coronavirus. It may also explain some uncertainty around whether the virus was human-made and deliberately released. Uncertainty and rapidly changing information may have contributed to increased worry about the virus (Han et al., 2006). These findings speak to the importance of distributing accurate health information about COVID-19 through a variety of sources (news, social media, and government websites) to reach the general population and correct misinformation.

Given the rapidly evolving situation with COVID-19 globally, the findings from this study may not be reflective of behaviors now that greater restrictions have been put in place and significant widespread messaging around social distancing, handwashing, and self-isolation has been disseminated. However,

our findings provide insights into the demographic and psychological predictors of health-protective behaviors in the early stages of a pandemic disease outbreak. The most powerful predictors were demographic factors including age, female gender, and being of non-Caucasian ethnicity, as well as risk perceptions (greater worry about outbreak and perceived severity of illness) and higher media exposure. The effect of media exposure may be related to the provision of important health information about the pandemic. Although media exposure early in the outbreak appears to have facilitated health-protective behaviors, media fatigue—where people become desensitized to ongoing messaging—may reduce this effect as the pandemic continues (Collinson et al., 2015). Repeated media exposure may also lead to heightened stress and anxiety, which can have longer-term health effects, as well as contributing to excessive or misplaced health-protective behaviors such as presenting for diagnostic testing when actual risk of exposure is low (Garfin et al., 2020).

The results of this study shed light on how many participants plan to get a COVID-19 vaccine if available. Concern about

the outbreak, greater media exposure, and higher knowledge predicted vaccination intentions. These findings are in line with previous research showing that concern and knowledge were associated with increased Ebola vaccine intentions (Petrie et al., 2016). In contrast to previous research, perceived likelihood and severity of infection were only marginally associated with intentions to get a vaccine (Weinstein et al., 2007; Bish and Michie, 2010). Previous research has typically focused on personal risk. In the case of COVID-19, the personal risk to most individuals is low, and behavior may be driven primarily by perceived risk to others, which was not assessed in the current study.

The current study is strengthened by a large sample size and a good representation of participants from different educational backgrounds. However, Caucasian women were overrepresented, as were those from NSW and those aged under 50 years. Participants were recruited through Facebook and as such are not representative of the general population. The pattern of results may not generalize to the broader population. To maximize convenience sampling, we used solely self-report measures, which may lead to biased effects. While the results of the regression analyses provide interesting starting points to identify the demographic and risk variables that predict health behaviors and vaccine intentions, they cannot establish causality and must be interpreted with caution. Given the large sample, the relationships between some of the significant predictors are likely to be small and may not be clinically meaningful.

The current results provide information on the Australian public responses to the COVID-19 pandemic, including information sources and engagement, knowledge, and perceived risk in the early stages of the outbreak in Australia, and their relationship with health-protective behaviors and vaccine intentions. The findings show that there was a critical mismatch between expected severity of symptoms versus data on how COVID-19 is experienced, which needs to be addressed in government education campaigns. Health-protective behavior was relatively low at the start of the outbreak, and these behaviors and vaccination intentions were consistently predicted by greater exposure to media and worry about outbreaks. Finally, our questions revealed significant uncertainty and misinformation, which needs to be corrected.

Without a vaccine currently available, encouraging widespread and sustained engagement with hygiene and distancing behaviors is critical to successfully manage the COVID-19 pandemic, flatten the curve of infections, and protect vulnerable individuals and overburdened healthcare systems. The results of the current study provide important insights into psychological and behavioral responses early in the outbreak of this novel coronavirus. The findings point to types of information that may be particularly effective and groups that may benefit from clear and targeted messaging to promote engagement with health-protective behaviors.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the UNSW HREAP-C (Behavioral Sciences) File 3309. The patients/participants provided their written informed consent to participate in this study.

The novel coronavirus disease (COVID-19) has affected hundreds of millions of people worldwide. Data collection in the ascending phase is crucial to address a rapidly evolving crisis by helping us understand the uncertain relationship between risk communication and psychological responses. Data were collected from 26 January 26, 2020, until February 17, 2020, with a mean test–retest interval of 16 days. A total of 846 adults from four residential communities in high-risk areas (Wuhan city) and low-risk areas (Zhengzhou city) were invited to complete a set of Internet-based questionnaires measuring the adoption of preventive behaviors, appraisal of risk communication, anxiety level, and susceptibility to emotional contagion. At the baseline assessment (Wave 1), 58 withdrew from the study, and 788 (433 females) completed the questionnaires. At the Wave 2 survey, 318 (185 females) adults from Wave 1 were retained. The results from cross-lagged models demonstrated reciprocal negative associations between anxiety and risk communication and between the appraisal of risk communication and the adoption of preventive behaviors. In addition, a higher appraisal of risk communication in the initial period of the outbreak mitigated the respondents' susceptibility to emotional contagion later on. Susceptibility to emotional contagion was positively associated with preventive behaviors taken. Furthermore, multiple-group structural equation modeling suggested that risk communication was more likely to affect the susceptibility to emotional contagion of people on the frontline of the outbreak than people living in low-risk areas. This study demonstrated the importance of risk communication aimed at encouraging appropriate countermeasures against virus outbreaks.

INTRODUCTION

On March 11, 2020, the World Health Organization declared coronavirus disease 2019 (COVID-19) a pandemic. As of March 28, 2020, a total of 571,678 confirmed COVID-19 cases, and 26,494 deaths had been reported worldwide. Medical interest in COVID-19 has been considerable [e.g., (1)]. Mental health issues that coincide with emerging epidemics and the appropriate behaviors to adopt to avoid infection are rarely examined (2).

Viral disease infections usually come from ordinary contact with people, and outbreaks can trigger severe public panic. In particular, novel, exotic threats raise anxiety levels higher than more familiar threats do (3, 4). Studies during the severe acute respiratory syndrome (SARS) epidemic in 2003 showed that diagnosed patients, suspected patients, and normal people experienced intense fear or nervousness about the event, and their anxiety increased significantly (5). Moreover, emotions are extremely vulnerable during public health emergencies (6), and the fear of a vague and terrifying new illness might spiral into dangerous skepticism through emotional contagion, which refers to the phenomenon of having one person's emotions directly trigger similar emotions in other people [c.f., (7)]. It was predicted in 2018 that the next major outbreak might not be due to a lack of preventive technologies but to emotional contagion, which could erode trust in government, causing serious economic and social disruption (8).

Although many studies have pointed out that high risk perception may lead to excessive preventive behavior and bring more emotional problems (9), in the early stages of major public health emergencies, increasing the level of risk perception is still a necessary means to combat viral spread. A recent study estimates that improving the rates of handwashing by travelers passing through only 10 of the world's leading airports could significantly slow a global disease by 69% (10). It is noteworthy that preventive behavior is also affected by emotional state. A survey of earthquake victims indicated that preparedness behavior could be predicted by fear and anxiety (11). Leung et al., studying public health emergencies, reached a consistent conclusion, finding that anxiety level is positively correlated with preventive measures taken (12, 13). It may be that individuals with higher levels of anxiety hold higher risk perceptions (14), so they take preventive measures as a means of coping with anxiety in risk events (15). Similarly, individuals with high susceptibility to emotional contagion are also more likely to be affected by risk information (16), thereby alleviating emotional problems through preventive measures (17).

Risk communication refers to the exchange of real-time information, advice, and opinions between experts and people facing threats to their physiological, economic, or social well-being. On the one hand, effective, timely and credible risk communication is essential to containing fear and public threats (18) as well as promoting preventive behaviors, especially in the early phase of risk events, because this increases perceived risk (19). On the other hand, psychological traits may in turn give rise to bias against the local crisis management system. For example, people with higher levels of anxiety may be more likely to overreact to policies (20). Individuals who are susceptible to negative emotions may more easily hold beliefs that conflict with government advice or regulations, thus jeopardizing public health measures [e.g., (7)]. Governments have the hard job of explaining dangers and advising people how to act without raising alarm, and the uncertain relationship between risk communication and psychological response needs to be investigated.

Some recent studies have also discussed the relationship between anxiety and emotional contagion. Anxious individuals tend to catch emotions from others, and emotional susceptibility has the unfavorable effect of making the person more anxious [e.g., (21); for review, (22)]. In summary, the existing research cannot accurately explain the interaction between multiple factors and their multidimensional causality. COVID-19 is an unprecedented experience for many people. Therefore, in the early stage of the epidemic, public emotions and behaviors in response to the epidemic may change rapidly with the exponential growth rate of the outbreak while being influenced by risk communication. What is the public reaction to epidemic outbreaks in the early phase? How does the effective exchange of real-time risk information impact them over time? What are the characteristics of these effects under different risk intensities? The present study examined the temporal relationships among behavioral and emotional responses to COVID-19 and the attitudinal responses to risk communication. A 2-way design was employed. We hypothesized that the adoption of preventive behaviors, emotional anxiety, and susceptibility to catch emotions were associated with the appraisal of risk communication as the pandemic developed.

MATERIALS AND METHODS

Sampling and Data Collection

Three research assistants and five residential community staff members participated in the survey distribution. Invitations containing links to this Internet-based survey and quick response codes were sent to local communities in Wuhan and Zhengzhou via messenger apps with the group function. Data were collected from January 26, 2020 (at which time 30 provinces launched their first-level response to this major public health emergency in China, and 20 cases had been confirmed in Zhengzhou, China, making it a low-risk area, while 63 deaths and 698 cases had been confirmed in Wuhan, China, making it a high-risk area), with 4-day duration until February 17, 2020 (154 cases had been confirmed in Zhengzhou; 1,381 deaths and 42,752 cases had been confirmed in Wuhan), with 3-day duration. The mean test–retest interval was 16 days ($SD = .82$), with a range of 14 to 18 days. The data collected by these surveys thus covered the ascending phase of the outbreak (23).

A total of 846 adults from four residential communities (i.e., two communities in Hanyang, which is an urban administrative district of Wuhan, and two communities in Erqi and Zhongyuan, which are also the main administrative districts of Zhengzhou) were invited to complete a set of questionnaires. Wuhan and Zhengzhou, as the China national central cities, are at a similar level in terms of leading, developing, and performing tasks in

politics, economics, and culture (24). Sociodemographic data were collected on sex, age, education, current health status, diagnosis with COVID-19, suspicion of COVID-19, having contact with a confirmed patient, and having contact with a suspected patient.

The questionnaires used a forced response mode that required respondents to answer all the questions before proceeding, but respondents could withdraw from the study at any time. Participants completed the questionnaires after giving online informed consent. The last six digits of the participant's phone number were used as their unique ID. We used the phone numbers, IP addresses recorded by the network server, and manual verification as the means of data matching. To ensure participant confidentiality, we purposely analyzed the data only in aggregate and did not perform individual program analyses.

At the baseline assessment (Wave 1), 58 withdrew from the study, and 788 (433 females, $\text{mean}_{\text{age}} = 34.66$; $SD = 7.34$, 500 from Zhengzhou and 288 from Wuhan) completed the questionnaires. At the Wave 2 survey, 318 adults from Wave 1 were retained. Of these respondents, four participants gave arbitrary answers on age in both waves (e.g., 888), which were treated as missing data and handled by mean imputation. The final samples of Zhengzhou and Wuhan were different in age, $t\,(316) = -5.31$, $p < 0.01$; and education, $\chi^2(4) = 38.99, p < 0.01$. This is mainly manifested in the fact that the Wuhan group is older and the Zhengzhou group has more people with a master's degree or above. In addition, a suspected case was reported in Wuhan (**Table 1**). Those who we were unable to retrospectively follow up fell into attrition. In many longitudinal studies, observations across waves can be missing for various reasons, and the attrition rate for web-based surveys is especially high (25). Another reason for our high attrition rate may be that we use the forced response mode; people will stop working on the survey if they are asked questions they do not wish to answer (26), although some of our questions included a "no answer" option.

Several analyses were performed to test whether there was a systemic pattern to the participant loss. The chi-square test showed a significant linear-by-linear association ($p < 0.001$), suggesting that the attrition rate decreased with increasing education level. Attrition at Wave 2 was lower among the younger participants, $t(624) = -7.65$, $p < 0.01$ [Levene's test indicated unequal variances ($F = 9.09$, $p = 0.003$), so the degrees of freedom were adjusted from 786 to 624]. Higher age may be regarded as a predictor of withdrawal due to less frequent Internet usage [(27); c.f., (28)]. The difference between the attrition and retained proportions by sex, $\chi^2(1) = 2.42$, $p > 0.05$, current health status, $\chi^2(4) = 1.92$, $p > 0.05$, and all other studied variables did not reach statistical significance, $ps > 0.05$ for all.

Measures

Adoption of Preventive Behaviors (APB)

Eight questions based on recommendations from the China Center for Disease Control and Prevention (CDC) guidelines were developed. Sample items of preventive measures included "Did you wash your hands after sneezing, coughing, or cleaning your nose in the past three days?" All eight behavior items were rated on a four-point scale, ranging from 1 "Not at all" to 4 "Always." The total frequency of APB was calculated by summing the scores of all 8 items. APB had Cronbach's alpha values of 0.75 and 0.81 for the Wave 1 and Wave 2 data, respectively.

Appraisal of Risk Communication (RMC)

A six-item scale was used to assess appraisal of risk communication. It was designed to reflect opinions on information distribution and openness of information [(29), e.g., "With regard to the distribution of information by the health authorities to the public in your country, do you agree or disagree that it has generally been sufficient?" Or "Do you agree or disagree that you have had the chance to express your personal views and concerns to the authorities if you wanted to?"]. The items are scored on a six-point scale, with higher scores indicating more positive appraisal (based on these replies: "strongly disagree," "disagree," "not sure but probably disagree," "not sure but probably agree," "agree," "strongly agree"). The questionnaire was shown to have acceptable validity and high internal consistency. Cronbach alpha values in our sample were 0.87 for both waves.

Anxiety Level

Anxiety were assessed using the Zung Self-Rating Anxiety Scale (SAS) (30), which consists of 20 items. Questions 1–5 represent the emotional symptoms of anxiety of which question 5 is a reverse-scored item, while questions 6–20 represent the physical symptoms of anxiety [e.g., (31)]. Responses to each item range from 1 ("a little of the time") to 4 ("most of the time"), with higher scores indicating increased levels of anxiety. Emotional symptoms of anxiety were the main concern in this study (e.g., "I feel more nervous and anxious than usual"). Reliability coefficients were good for both Wave 1 (Cronbach $\alpha = 0.82$) and Wave 2 (Cronbach $\alpha = 0.83$) samples in the current study.

Susceptibility to Emotional Contagion (SEC)

The Emotional Contagion Scale for Public Emergency (ECS-PE) (32) is a self-report scale for assessing the susceptibility to catch emotions, especially generated in public emergency events (e.g., When public emergency happens, I panic if others around me panic). It is a revised version of the Emotional Contagion Scale (33) and consists of 15 items that a person endorses on a five-point scale (ranging from 1 "strongly disagree" to 5 "strongly agree"). Scores are generated by adding the item scores. This scale had Cronbach α values of 0.90 and 0.91 for the Wave 1 and Wave 2 data, respectively.

PLAN OF ANALYSIS

Repeated-measures analyses of variance (ANOVAs) were conducted to determine time and risk effects over the two waves of the study. We also computed descriptive statistics for all study variables and bivariate correlations among them using SPSS 20.0. Then, cross-lagged models were tested by structural equation models with the robust maximum likelihood estimation using MPlus version 7 (34). Finally, to additionally assess whether the cross-lagged associations varied by group (i.e., Zhengzhou vs. Wuhan, which represents risk level), we ran multigroup structural equation models. The following steps were conducted: (1) unconstrained multiple-group model, in which the same correlation of paths was tested without constraints across groups; and (2) constrained multiple-group model, where correlation paths were constrained to be equal across groups.

Model fit was examined by the chi-square statistic (χ^2), the comparative fit index (*CFI*), the Tucker–Lewis Index (*TLI*), the root mean square error of approximation (*RMSEA*), and the standardized root mean square residual (*SRMR*). Good model fit is indicated by a nonsignificant χ^2 (35), a *CFI* and/or *TLI* between.90 and 1.00 (36), an RMSEA of.10 or lower (37), and an SRMR of.10 or lower (35).

RESULTS

Descriptive Statistics and Bivariate Correlations

Inspection of Mahalanobis d^2 values indicated that there were six outliers in our sample. Omitting the outliers gave the same results as not. Repeated-measures ANOVA revealed a significant main effect of time on APBs, $F_{(1, 316)} = 48.67$, $p < 0.001$, $\eta_p^2 = 0.13$, and a significant main effect of risk level (i.e., Zhengzhou vs. Wuhan) on APBs, $F_{(1, 316)} = 10.83$, $p < 0.01$, $\eta_p^2 = 0.03$, and on anxiety level, $F_{(1, 316)} = 31.94$, $p < 0.001$, $\eta_p^2 = 0.10$. A significant risk × time interaction on susceptibility to emotional contagion (SEC) was found, $F_{(1, 316)} = 7.26$, $p < 0.01$, $\eta_p^2 = 0.02$. Simple effect analyses revealed that SEC decreased significantly for participants in Zhengzhou, $F_{(1, 317)} = 4.34$, $p < 0.05$, $\eta_p^2 = 0.02$, but did not change with the development of the epidemic for participants in Wuhan. Although the ANOVA showed that the means were significantly different, the effect size was small to modest. **Table 2** presents bivariate correlations among Wave 1 and Wave 2 variables, which indicated considerable stability in autoregressive correlation between all studied variables, and revealed cross-lagged relations between appraisal of risk communication and anxiety. The cross-sectional intercorrelations among all variables were similar across Wave 1 and Wave 2.

Cross-Lagged Model

The model with full cross-lagged paths demonstrated an acceptable fit to the data. Given the sensitivity of the χ^2 statistic to sample size (35), it was not surprising that the test was significant ($\chi^2 = 39.781, p < 0.001, df = 16$). However, Wheaton et al. (38) maintain that a χ^2/df ratio below five supports a favorable conclusion about fit in large sample models. In this study, this criterion is solidly met, $\chi^2/df = 2.49$, $p < 0.01$; *CFI* = 0.97, *TLI* = 0.92, *RMSEA* (90% CI) = 0.07 (0.04–0.10), *SRMR* = 0.05. The autoregressive paths between Wave 1 and Wave 2 for APB, $\beta = 0.58$, $SE = 0.06$; RCM, $\beta = 0.61$ $SE = 0.05$; anxiety, $\beta = 0.63$, $SE = 0.04$; and SEC, $\beta = 0.81$, $SE = 0.02$, were all significant, $ps < 0.01$. After controlling for demographic variables (i.e., gender, age, education level and health status), one positive pathway from RCM to later APB, $\beta = 0.13$, $SE = 0.05$, and one negative path from Wave 1 RCM to Wave 2 SEC, $\beta = -0.10$, $SE = 0.03$, were revealed. Two reciprocal associations between RCM and anxiety, $\beta s = -0.11$ for both directions, and RCM and ABP, $\beta = 0.10$ and 0.13, for two directions respectively, $ps < 0.05$, were also detected. The whole model accounted for 47.9, 48.1, 49.2, and 67.5% of the total variance in Wave 2 APB, RCM, anxiety, and SEC, respectively. The standardized path coefficients are presented in **Figure 1**. Age and gender have an effect on the susceptibility to emotional contagion (SEC). The older the age, the greater the SEC, $\beta = -0.08$, $SE = 0.03$, and women hold more susceptibility than men, $\beta = -0.07$, SE=0.03.

Multigroup Structural Equation Model

The chi-square of the baseline model (unconstrained) is 0 because it is a saturated model. A significant difference in chi-square indicates non-equivalence across groups, $\Delta\chi^2 = 38.75$, $\Delta df = 22$, $p < 0.05$, suggesting that one or more paths are different across group from areas in different risk level. Further, Wald tests were used to examine differences among the cross-lagged paths between the two groups and revealed that the

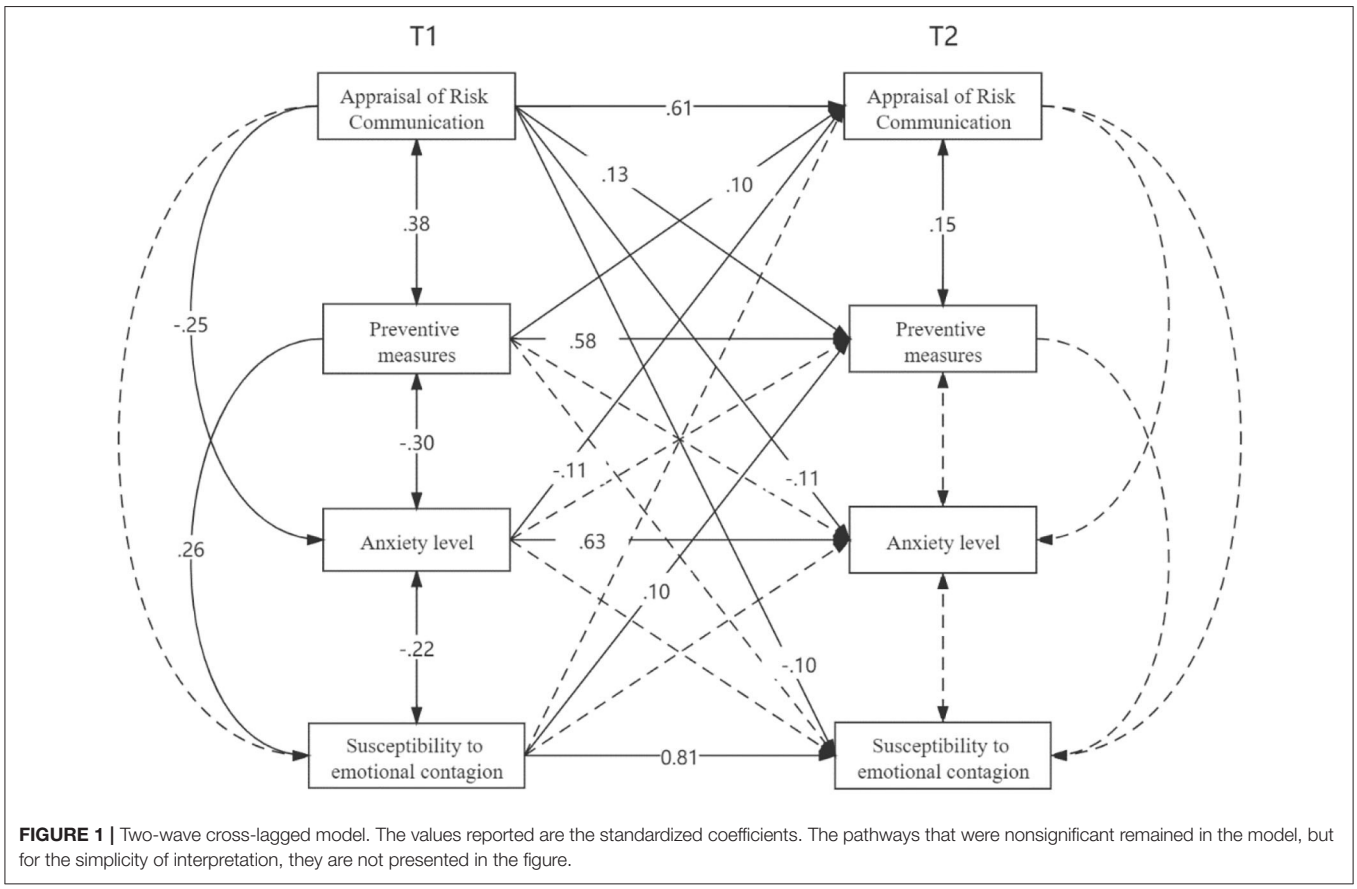

FIGURE 1 | Two-wave cross-lagged model. The values reported are the standardized coefficients. The pathways that were nonsignificant remained in the model, but for the simplicity of interpretation, they are not presented in the figure.

coefficient of the paths from Wave 1 RCM to Wave 2 SEC was significantly higher for Wuhan than those in Zhengzhou, Wald(1) = 7.14, $p < 0.01$. The association of RCM with SEC reached a significant level for Wuhan, $\beta = -0.20$, $p < 0.001$, but not for Zhengzhou, $\beta = -0.05$.

DISCUSSION

This study sought to gather a snapshot of the attitudinal and behavioral responses during the early stages of the COVID-19 epidemic. The results showed that the level of anxiety of people

in high-risk epidemic areas is significantly higher than that in low-risk areas. A virus that is thought to be highly contagious, lockdown control, and disturbances in people's living conditions are all factors that cause mental problems in epidemic areas in the short term. It is not surprising that as the epidemic progressed, respondents adopted more preventive measures, and people in high-risk epidemic areas also took preventive measures to a greater extent, indicating a high-risk perception.

Without information, people may start speculating and "filling in blanks" on their own. This often results in increased susceptibility to emotional contagion (SEC), which is a catalyzer that accelerates the spread of rumors [e.g., (39)]. The finding that the susceptibility was significantly lower in low-risk areas suggests to some extent that the increased susceptibility caused by the emergency was alleviated by the gradually disclosed information, even though participants living in high-risk areas did not change in any way. This suggestion was further verified by cross-lagged panel analysis. The initial appraisal of risk communication was predictive of later susceptibility to emotional contagion, and such an association exhibited a greater impact on people of the frontline of the outbreak (i.e., Wuhan). Previous studies have pointed out that effective risk communication can mitigate susceptibility and is an important means to relieve public anxiety [e.g., (40)]. However, this study demonstrated a reciprocal association between anxiety and risk communication, reflecting that the emotional aspect may create resistance to risk communication.

Some previous research that has focused on responses to other respiratory infectious disease epidemics (RIDEs) has examined factors that motivate people to adopt preventive measures. For example, Lee-Baggley and colleagues found that people high in empathic responsiveness (e.g., listening to others' feelings about SARS) were more likely to take health precautions (41). Consistent with these findings from cross-sectional studies, individuals who were more susceptible to emotional contagion early on were more likely to engage in preventive behaviors later. However, not all mood states affect behavior. Compared with susceptibility, initial anxiety did not predict later adoption of preventive measures. A possible explanation is that in the early stage of an epidemic, when the threat is highly uncertain, cognitive risk responses may be optimal for driving increasingly suitable behavior as the epidemic evolves (42). Emotional contagion occurs at more conscious levels [for review, (43)]. Anxiety generally involves less intense cognitive components than susceptibility to emotional contagion and thereby is less likely to predict behavioral change.

The respondents' appraisal of risk communication predicted the extent to which they would engage in preventive behaviors, which indicates that preventive measures are undoubtedly closely related to the effective and timely transmission of epidemic-related information. The results also revealed the effect of changes in behavior on the changes in the appraisal of risk communication. If an action is believed to reduce risk, people who take the action will lower their perceived risk (19, 44), leading to decreased sensitivity to risk information. We did not find any correlation between anxiety and susceptibility to emotional contagion, although it is evident from various findings that anxious individuals tend to catch negative emotions from others [e.g., (21)]. Given the evidence presented in this study, however, it seems clear that anxiety was unrelated to susceptibility to emotional contagion as measured on a bipolar scale that measures reactions to both positive and negative emotions. In addition, we extracted emotional symptoms of anxiety from the more general Zung Self-Rating Anxiety Scale (SAS) for screening anxiety, which is different from the State Trait Anxiety Inventory (STAI) used in some previous epidemic studies [e.g., (45)]. In line with these studies, the anxiety level remained low throughout the pandemic, suggesting that a low level of anxiety has little effect on behavioral or emotional responses toward COVID-19.

A few limitations to this study are worth noting. First, with regard to the measurements we used, a set of questions measuring the extent to which a respondent adopted preventive behavior may not fully reflect all the preventive measures required to prevent infections. Second, the results may have limited generalizability because this community sample was limited in its diversity, as a majority of the sample consisted of middle-aged and healthy people. Lastly, this study used district (i.e., Wuhan and Zhengzhou) as an indicator of risk. Although some demographic variables were controlled, there are some unobserved heterogeneity (e.g., income and occupation) may limit conclusions of the study. Nevertheless, to our knowledge, these data provide some of the first follow-up data regarding mental health during the COVID-19 outbreak. Data collection in the ascending phase is crucial to deal with a rapidly evolving crisis. More harm is done by officials trying to avoid panic by withholding information or overreassuring the public than is done by the public acting irrationally in a crisis. Precrisis planning should assume that an open and honest flow of information will be established. This study demonstrates the importance of the disclosure of information aimed at encouraging appropriate countermeasures against virus outbreaks.

DATA AVAILABILITY STATEMENT

The datasets presented in this article are not publicly available due to the fact they containing sensitive information that could compromise research participant privacy/consent. However, they are available on reasonable request from the corresponding author. Requests to access the datasets should be directed to psychlab@zznu.edu.cn.

ETHICS STATEMENT

The study protocol, including questionnaires, was reviewed by the Ethics Committee of Zhengzhou Normal University (approval no. 2020EM-01) and Institutional Review Boards of University of California at Davis (IRB ID 1561876-1).

AUTHOR CONTRIBUTIONS

ZJ conceived of the presented idea and planned the experiments. ZJ took the lead in writing the manuscript with input from all authors. K-bZ and Y-yX analyzed the data and contributed

equally to this article. Y-MS, R-jC and ZY contributed to sample preparation. GYP provided financial support that are necessary for this study. All authors read and approved the final version of the manuscript.

FUNDING

This study is sponsored by Program for Science & Technology Innovation Talents in Universities of Henan Province (HASTIT) (2017-cx-023) and Youth Backbone Teacher Training Project of Henan Province (2017GGJS180).

ACKNOWLEDGMENTS

We would like to acknowledge all the frontline doctors fighting this pandemic. We thank Dr Jeffrey Sherman (University of California at Davis) for support on online academic journal databases access and his help on protocol setup.

Emotional, Behavioral, and Psychological Impact of the COVID-19 Pandemic

*Ana Luisa Pedrosa†, Letícia Bitencourt†, Ana Cláudia Fontoura Fróes, Maria Luíza Barreto Cazumbá, Ramon Gustavo Bernardino Campos, Stephanie Bruna Camilo Soares de Brito and Ana Cristina Simões e Silva**

The emergence of SARS-CoV-2 in December 2019 prompted consternation in many parts of the world. Due to its fast dissemination, the World Health Organization declared a pandemic in March 2020. Aiming to contain the spread of the virus, leaders of many countries restrained social movement, targeting to flatten the curve of contamination with social distancing. This review aimed to analyze how human behavior has changed throughout this period. We also approached the key components of the emotional reaction to the pandemic, how internal and external factors, such as personality traits, gender, the media, the economy and the governmental response, influence the social perception of the pandemic and the psychological outcomes of the current scenario. Moreover, we explored in depth the groups at increased risk of suffering mental health burden secondary to these circumstances. These include the healthcare professionals, elderly individuals, children, college students, black subjects, latin and LGBTQ+ communities, economically disadvantaged groups, the homeless, prisoners, the rural population and psychiatric patients. We also discussed several measures that might minimize the emotional impact derived from this scenario. It is crucial that the health authorities, the government and the population articulate to assist the vulnerable groups and promote emotional and psychological support strategies. Moreover, it is fundamental that the population is provided with accurate information concerning the COVID-19 pandemic.

INTRODUCTION

In December 2019, a cluster of pneumonia cases was reported in the province of Hubei, China (Lu et al., 2020). It was then discovered that the infection was caused by a virus, named SARS-CoV-2. Subsequently, the illness caused by this virus was termed Coronavirus disease 2019 (COVID-19). Data from the World Health Organization (WHO) Guidelines indicate that by January 14th 2020, 1 day after the first recorded case outside of China, only 41 cases were confirmed (World Health Organization [WHO], 2020b). At the present, statistics taken from the WHO Coronavirus Disease (COVID-19) Dashboard by September 5th announce 26.5 millions of

confirmed cases worldwide, with over 871 thousand deaths (World Health Organization [WHO], 2020c).

Restricting measures have been implemented in several countries as an attempt to slow down the dissemination of the SARS-CoV-2. China (Wang C. et al., 2020), Italy (Briscese et al., 2020), and the United Kingdom (UK) (Holmes et al., 2020), for example, carried out strict "lockdown" regulations, while other countries, including the United States of America (US) (Imperial College of London, 2020) and Brazil (Simões e Silva et al., 2020), have delivered "stay home" recommendations. In many places, means of transportation were shut down, public spaces were closed and only essential services kept functioning; albeit with restrictions and preventive measures.

However, as the world authorities seem to focus on the infectious aspect of the pandemic, a rise has been observed in mental health disorders (Brooks et al., 2020; Holmes et al., 2020). Indeed, during this ongoing health crisis, those affected by emotional, behavioral and psychiatric disorders tend to be more numerous than those affected by COVID-19. As a matter of fact, the fear of contracting COVID-19 seems not to be as high as concerns about the psychological and social impact of the pandemic, as reported in a United Kingdom survey (Mental health Covid-19, 2020). Particular groups appear to be at higher risk for this kind of mental health impact, including frontline healthcare workers, the elderly, children, college students, the LGBTQ+ community, homeless individuals and those in economic vulnerability, rural community, foreigners and psychiatric patients (Holmes et al., 2020; Khan et al., 2020; Salerno et al., 2020; Wood et al., 2020). Indeed, the emotional stress linked to the current scenario may potentially aggravate previous psychiatric conditions or may precipitate its symptomatology (Yao et al., 2020). A critical aspect of this context is that, due to physical distancing, many elective appointments have been canceled and mental health support systems have been suspended, even though remote assistance is rapidly increasing (Holmes et al., 2020).

This review aims to discuss the impact of COVID-19 for the mental health of the overall world population, in addition to its causes and ramifications. The topics of greater relevance in the scientific literature so far have been included, most of which concern not only the healthcare professionals and authorities, but the entire population as well. Furthermore, some measures that ought to be taken to minimize the emotional burden of the pandemic were debated.

METHODS

Data were obtained independently by six authors, who carried out a comprehensive and non-systematic search in the PubMed, Cochrane, Scopus, SciELO, and Google Scholar databases. Search strategies included terms as: "COVID-19," "SARS-CoV-2," "anxiety," "depression," "psychiatric disorders," "social isolation", "behavior changes", "psychiatric patients", "mental health", "suicide", "media", "racism", "healthcare workers," "elderly," "domestic violence," "sleep," "LGBT community," "homeless," "foreigners," "rural community," "informal settlements." The search was conducted between May 14th and May 26th. This article was subsequently updated between May 26th and September 5th. The search emphasized recent articles, published case series, consensus statements, guidelines, meta-analyses, systematic reviews and prospective cohort studies, critically reviewed and selected by the authors. Research has also been made in informative official website public domains and in the references contained in the previously data collected.

RESTRICTING MEASURES DUE TO THE PANDEMIC

Terminology on Quarantine, Social Isolation, and Social Distancing

In the context of COVID-19 pandemic, the terms "social distancing," "social isolation," and "quarantine" have been used mostly as synonyms in the media, in communication with the public and even in scientific papers (Brooks et al., 2020). However, there are great differences between these designations, even though there is not always an agreement on the terminology. "Quarantine" refers to extreme restrictions of movement of those exposed or potentially contaminated by the virus, in order to minimize the spread of the pathogen. Moreover, the term "quarantine" ought to be used in the context of groups or at community level (Dsouza et al., 2020; Sánchez-Villena and de La Fuente-Figuerola, 2020). "Social isolation" refers to the restriction of social movement of those infected with the disease (Dsouza et al., 2020; Sánchez-Villena and de La Fuente-Figuerola, 2020). Meanwhile, "social distancing" is a preventative measure recommended to the general population to flatten the curve of the contagious disease. In this scenario, people are advised to stay at home and use services as little as possible, as well as to avoid agglomerations, maintain the recommended distance of one meter from each other and take precautionary measures to avoid infection (Covid-19, 2020). Nevertheless, the use and the comprehension of these terms should not be so inflexible. In fact, the term "social isolation" has also been used to express the source of subjective feelings of solitude that may accompany the social distancing measures, especially for those who are already at enhanced risk of suffering from loneliness. Notwithstanding, the term "social disconnection" is used in this review to encompass this framework.

Source of Psychological Impact Related to the Restricting Measures

It is undeniable that the restricting measures imposed to contain the COVID-19 pandemic have a severe impact on the mental health of the population. Nonetheless, it is yet unclear what promotes such negative effects. It is possible that these repercussions derive directly from the restrictive strategies and reduced social mobility (Bavel et al., 2020; Brooks et al., 2020; Pfefferbaum and North, 2020; Wang G. et al., 2020). However, the emotional and psychological outcomes of the pandemic may also be secondary to the intrinsic changes that the restricting measures

cause in lifestyle habits and socioeconomic scenario (Brooks et al., 2020; Zhu et al., 2020).

KEY COMPONENTS OF THE EMOTIONAL AND BEHAVIORAL RESPONSE TO COVID-19 PANDEMIC

The emotional and behavioral response to COVID-19 pandemic is multifactorial. It relies not only on external components, but on personal and innate ones as well. Nonetheless, the reaction to the current circumstances seem to have predominant elements in the overall population. A significant increase in feelings of functional impairment, boredom, stigma, worry, phobia, frustration and anger has been observed (Ahmadi and Ramezani, 2020; Brooks et al., 2020; Pfefferbaum and North, 2020; Restubog et al., 2020; Sher, 2020a; Teufel et al., 2020). In this topic, some selected factors must be discussed thoroughly due to its pivotal influence on the mental health impact of the pandemic.

Fear and Uncertainty

Unlike other virus outbreaks of the 21st century, such as SARS and MERS, which were primarily disseminated in hospital environments (Bai et al., 2004; Cauchemez et al., 2016), COVID-19 is unique in the way that it has spread far beyond health centers' borders. With the entire population at risk, the necessary restricting measures have created an unparalleled scenario, dominated by fear and uncertainty. Even though fear is an essential adaptive mechanism that humans and other species have developed to cope with threats in the environment, it can only be supportive for those who feel capable of dealing with the menaces presented specifically to them. To those who consider themselves as unable to handle such risks, fear can trigger defense responses (Bavel et al., 2020). And so, in a conjuncture where the fear is not only of death but also of the repercussions in a myriad of different spheres, including family organization, schools closure, social isolation and economic consequences, it is vital that close attention is paid to the mental health of the individuals (Ornell et al., 2020). In fact, previous studies showed that fear positively associates with depression, anxiety, perceived infectability and germ aversion (Ahorsu et al., 2020). Furthermore, another detrimental consequence of fear is the stigmatization and discrimination of those infected or exhibiting symptoms of COVID-19 (Ahorsu et al., 2020).

Although fear has several destructive outcomes, one of the most maleficent one is suicide. In the COVID-19 pandemic, there have been numerous reports of suicidal behavior due to fear-related issues, for instance, fear of being infected (Dsouza et al., 2020; Mamun and Ullah, 2020), fear of infecting others (Mamun and Griffiths, 2020), fear of being quarantined (Dsouza et al., 2020) and fear of the mental health impact (Sher, 2020b). A particular illustration of this is a Bangladeshi 40-year old woman who took her own life in a hospital bathroom after being refused medical care due to the staff's fear of SARS-CoV-2 infection (Mamun et al., 2020a).

Finally, it must be observed that the adjustment to the new life of social distancing may differ according to age groups, gender and other variables surrounding the individuals. Therefore, given the importance of fear in the pandemic context, scales addressing this feeling have been developed and might be helpful to the comprehension and management of this emotional component (Ahorsu et al., 2020; Sakib et al., 2020).

Stressors

In the pandemic background, stressors must also be considered in the assessment of the emotional and neuropsychological impact. These mainly include COVID-19-related circumstances, such as potential exposure to the virus and loss of loved ones, as well as secondary adversities due to economic difficulties, unavailability of food, psychosocial effects, disruption of future plans and underlying physical and psychological conditions (Islam et al., 2020; Pfefferbaum and North, 2020).

Economic Factors

The ongoing pandemic caused by COVID-19 has set off a distinguishable economic crisis in considerable domains of work and business, including manufacturing, retail, travel and trade (Restubog et al., 2020). Unemployment is in the rise and even the most stable and former professionals are having their work threatened. The International Labor Organization estimates that there will be 25 million new unemployed individuals by the end of the second quarter of 2020 (Restubog et al., 2020). In addition, surveys with US workers before and after previous economic downturns state that unemployment is not the only possible detrimental outcome, since pay cuts, reduction in work hours, increased work demand and challenging working conditions are possibly part of a contingency plan for this pandemic (Restubog et al., 2020). Financial loss has been profoundly linked to psychological distress and is considered a risk factor for mental health disorders, with long lasting effects. The disruption or even bankruptcy of business, unpaid debts, stress of losing job, poverty, inability to provide support to the family and food insecurity are only a few examples that portray the extremely harsh scenario regarding the financial impact secondary to this pandemic (Bhuiyan et al., 2020; Dsouza et al., 2020; Mamun and Ullah, 2020). Indeed, the lack of basic supplies, including water, food, clothes and accommodation, seems to be a particularly deleterious source of frustration, anxiety and anger (Brooks et al., 2020).

Additionally, a disturbing matter is that the economic impact represents one of the main risk factors for suicidal behavior (Conejero et al., 2020; Vandoros et al., 2019). During the pandemic, cases of suicide due to financial downturns have been reported in several countries, particularly in those experiencing more severe crises than developed countries, such as India (Dsouza et al., 2020; Griffiths and Mamun, 2020), Bangladesh (Bhuiyan et al., 2020; Griffiths and Mamun, 2020) and Pakistan (Mamun and Ullah, 2020). Using the data available in the International Labor Organization's press release in March 2020, a study has estimated that, in the best-case scenario, the rise in unemployment rates will provoke an increase of about 2,135 suicides in a year worldwide (Kawohl and Nordt, 2020).

Therefore, the number of individuals who might seek help from mental health services is expected to substantially increase in the context of the COVID-19 pandemic (Kawohl and Nordt, 2020).

Domestic Violence

As a matter of fact, as the "stay home" recommendations remain, it is crucial to remember that home is not always a safe place for everyone. It can also be a residence for distortion of power and abuse, which is supported by studies that suggest that forced proximity, along with economic stress and disaster-related instability, are risk factors for aggression and domestic violence (Bavel et al., 2020; Usher et al., 2020). Furthermore, distancing measures also represent, for those living in violent places, diminished access to community-based and familial support, with fewer opportunities to ask for help (Usher et al., 2020). Fear of COVID-19 and threats about contamination can even be used as a coercive mechanism to maintain the abuse. As a consequence, for example, those suffering from domestic violence may be less inclined to go to the hospital on account of fear of infection. Ultimately, the social distancing, albeit essential to contain COVID-19, may exacerbate the violence and maintain it less visible (Usher et al., 2020).

Indeed, in the United Kingdom, a domestic abuse organization reported that calls to its domestic violence helpline increased by 25% in the 7 days following the announcement of tighter social distancing and lockdown measures by the government (Bradbury-Jones and Isham, 2020). In Australia, some police departments reported a 5% increase in domestic violence-related calls, while Google announced a 75% growth in internet searches for domestic abuse support (Usher et al., 2020). Additionally, there was a 32–36% increase in domestic violence complaints in France and a 21–35% increase in the US after the implementation of the social distancing measures (Usher et al., 2020). This pattern is equivalent to what has already been observed in previous epidemics (Usher et al., 2020).

Changes in Daily Habits

Analysis on sleep quality during the SARS-CoV-2 pandemic also indicated that there has been a rise in sleep disturbances, a critical condition associated with anxiety, depression, and suicidal behavior (Sher, 2020a). Furthermore, diminished sleep quality promotes short temperament and, as a consequence, complicates family cohabitation (Islam et al., 2020).

Another interesting inquiry was related to news monitoring: a study suggested that higher averages of time ($\geq$ 3 h) spent focusing on the virus outbreak was positively correlated to the development of anxiety symptoms (Huang and Zhao, 2020), but also with social responsibility values and compliance to social distancing recommendations among US adolescents (Oosterhoff et al., 2020). Contrarily, less engagement in risk prevention behaviors was observed in individuals who were apparently prone to "optimism bias," the belief that they are less likely to acquire the disease than others. This principle is also seen in other diseases, including lung cancer (Soofi et al., 2020).

Moreover, an Italian survey performed in April 2020 assessed the changes in eating and lifestyle habits of 3,533 individuals, aged between 12 and 86 years. It was observed that 34.4% of responders had increased appetite during this period, whereas 17.8% had less appetite. As a result, nearly half of the participants of the study perceived weight gain during the pandemic. Additionally, it was observed that although there were no differences in physical activity in the group of individuals who did not play any sports before the COVID-19 lockdown, the training frequency has increased amongst those who were physically active. Around 3% of smokers have quit smoking in this period, probably due to the fear concerning increased risk of respiratory distress and mortality from COVID-19 (Di Renzo et al., 2020).

Individualized Response to Stress

In times of psychological distress, emotional reactivity is deeply influenced by individual differences and stress-mediated contexts. A study with the Italian general population aimed to observe the gender and personality traits that more substantially associated with psychological impact during the COVID-19 pandemic (Moccia et al., 2020). The results showed that individuals with anxious, cyclothymic and/or depressive temperaments are predicted to suffer greater emotional impact secondary to the current scenario. Meanwhile, male gender, as well as secure and avoidant adult attachment style were protective for the risk of higher psychological burden (Moccia et al., 2020).

Moreover, in a different line of research, a Chinese study proposed to understand the differential psychological distress among distinct populations affected by the pandemic. It was observed that individuals who had experienced SARS-CoV-2 infection had significantly increased prevalence of depressed mood, somatic symptoms and anxiety-like behavior (Zhang W.R. et al., 2020). Post-traumatic stress disorder (PTSD) was found to affect 96.2% of hospitalized patients with COVID-19, whereas depression was also higher in COVID-19 patients (Vindegaard and Benros, 2020). Furthermore, having an infected friend or family member has been associated with higher anxiety levels (Duan L. et al., 2020).

PSYCHOLOGICAL DISORDERS SECONDARY TO THE COVID-19 PANDEMIC

The COVID-19 pandemic may intensify psychological disorders or precipitate others, for instance, anxiety, depression, PTSD, alcohol misuse, obsessive-compulsive behaviors, panic and paranoia (Dubey et al., 2020; Islam et al., 2020). A nationwide survey in China with over 52 thousand participants had almost 35% of the respondents experiencing psychological distress due to the SARS-CoV-2 (Qiu et al., 2020). In this study, women appeared to be more vulnerable to stress than men, although this result is not consistent in literature (Huang and Zhao, 2020). Therefore, some of the most cited psychological consequences of the pandemic will be further addressed.

Anxiety and Depression

Anxiety, one of the main evaluated subjects, has been significantly increasing in society during this pandemic (Huang and Zhao, 2020; Li et al., 2020; Qiu et al., 2020; Teufel et al., 2020). A research

group in China analyzed the online posts from about 18,000 Chinese social media users before and after the declaration of COVID-19 in China on January 20, 2020 and found an increase in words that mirror negative emotions including anxiety, depression, and anger (Li et al., 2020). One particular kind of anxiety is worth mentioning: health anxiety. It is characterized mainly by catastrophic misinterpretations of bodily sensations, dysfunctional beliefs about health and illness and maladaptive coping behaviors. Harmful consequences can derive from this condition, including excessive hand washing, social withdrawal, panic purchasing and overspending in resources such as hand sanitizers, medications and protective masks (Asmundson and Taylor, 2020b). In fact, especially for the suspected cases of COVID-19, the development of obsessive-compulsive symptoms may be a consequence of anxiety related to their health status (Dubey et al., 2020). The same rising tendency has been seen for depressive symptoms (Bavel et al., 2020; Pfefferbaum and North, 2020; Restubog et al., 2020; Sher, 2020a). Interestingly, groups with less education seem to be more susceptible to these manifestations in an epidemic context, especially due to unreliable access to information and apprehension to its academic formation (Pfefferbaum and North, 2020).

Post-traumatic Stress Disorder

Another alarming condition that can be expected to increase is post-traumatic stress disorder (PTSD) (Brooks et al., 2020; Dutheil et al., 2020; Gunnell et al., 2020), similar or worse to what happened in previous epidemics, such as H1N1 Influenza and Ebola (Xu et al., 2011; Cénat et al., 2020). The adverse effects of this illness are not manifested immediately and mental health support must be prepared to deal with this issue in a few months. PTSD is more likely to take place after longer periods of social disconnection and it is associated with increased suicide risk by 2–5 times (Thibodeau et al., 2013; Brooks et al., 2020). PTSD patients are also less prone to seek help from authorities, possibly due to few available information about this subject, fear of stigmatization, beliefs that symptoms may disappear over time and concerns about the cost of mental healthcare (Dutheil et al., 2020).

Alcohol Addiction

During the lockdown, some countries also prohibited alcohol sales. The arguments to sustain the restricting conditions included impaired ability of those under the influence of alcohol to implement the preventive measures, the influence of drinking in domestic violence, its impact to the immune system and, finally, the high cost of acute drinking for the emergency services (Nadkarni et al., 2020). Nevertheless, higher numbers of abstinence syndrome appeared as a consequence within patients who suffer from addiction (Narasimha et al., 2020). In a psychiatry emergency service in Bangalore, India, twice the number of severe abstinence syndrome (seizures, delirium tremens, and hallucinations) occurred per day after lockdown (Narasimha et al., 2020). Furthermore, rise of the black marketing of alcohol, consumption of non-consumable alcohol and even suicide in those suffering from addiction have been reported in India (Nadkarni et al., 2020). In fact, it has been suggested that alcohol consumption is an important risk factor for the decompensation of psychiatric disorders and, ultimately, may favor individuals to commit suicide, particularly the fragile and more vulnerable ones (Conejero et al., 2020).

Another complex consequence of such measures concerns those in recovery or wanting to recover from alcohol abuse. Since autonomy is crucial to sustain behavioral changes that result in the discontinuation of drinking, and since the patients have, during this period, restricted access to services such as Alcoholics Anonymous, prohibiting alcohol sales can be detrimental to recovery (Nadkarni et al., 2020). Additionally, the social distancing, the anxiety and the negative thinking that have been exacerbated in the pandemic situation may trigger relapse (Nadkarni et al., 2020). In fact, in other countries where alcohol sales were not prohibited, such as in the United Kingdom, the consumption of alcohol during lockdown significantly increased (Nadkarni et al., 2020). It is important, then, that countries prohibiting alcohol sales carefully address its impact for those who suffer from addiction.

MENTAL HEALTH VULNERABILITY

Several groups are more vulnerable to greater emotional, behavioral and psychological impact of the COVID-19 pandemic. The most cited ones will be addressed in this discussion. Nevertheless, other groups at increased risk for the mental health repercussions of the pandemic include those with pre-existing health conditions, those living in care homes, domestic caregivers and COVID-19 patients and their family members (Dubey et al., 2020; Khan et al., 2020).

Healthcare Professionals

One of the main groups in this category is the one with the healthcare providers during the pandemic, specifically frontline workers. In the alarming context of this health emergency, these professionals are put through different circumstances and afflictions, which include fear of being infected and infecting others, higher workload, significant pressure, pain of losing patients and colleagues, the yet unpredictability nature of the virus, inadequate testing, limited treatment options and disruption of regular routine, along with insufficient personal protective equipment and other medical supplies, especially in developing countries (Chew et al., 2020; Lancet, 2020; Mamun et al., 2020c; Pfefferbaum and North, 2020). Evidence reports that such conditions might make them more vulnerable not only to physical symptoms, including headache and sore throat (Chew et al., 2020), but also to mental health burden, with an increase in rates of anxiety, depression, stress, irritability, insomnia, anger, and frustration (Brooks et al., 2020; El-Hage et al., 2020; Pfefferbaum and North, 2020; Zhang J. et al., 2020). Having an organic disease appeared as an independent risk factor for these outcomes in previous studies (Zhang J. et al., 2020). As an illustration, a study in China concluded that half of the frontline healthcare professionals had symptoms of depression and anxiety, 70% had psychological distress and many also reported insomnia (Mesa Vieira et al., 2020). Previous epidemics

had a similar pattern, as 29% of the healthcare workers may have had emotional distress after the SARS epidemic in 2003 (Holmes et al., 2020). This group is also at risk for the development of PTSD (Dutheil et al., 2020).

Moreover, as the COVID-19 pandemic is currently at the center of the news broadcast, the public gains access to the scientific data practically at the same time that it becomes available to the medical community. Therefore, in the midst of fear and anxiety, there is great pressure on healthcare professionals to be constantly updated on the release of new studies, as well as to prescribe the experimental treatments for their patients, in spite of insufficient high-quality evidence (González-Padilla and Tortolero-Blanco, 2020).

The extent of mental health vulnerability seems to vary amongst different populations within the healthcare staff. It has been reported that young women are at higher risk for adverse psychological repercussions than men (El-Hage et al., 2020; Lai et al., 2020). Moreover, nurses are also more likely to be affected than physicians (El-Hage et al., 2020; Lai et al., 2020; Tsamakis et al., 2020). Interestingly, one study observed that non-frontline nurses were more prone to emotional impact than the frontline group, which seems to be due to their greater working experience and psychological preparation (Ghaffari et al., 2020). Although results from other researches evidenced the opposite (Lai et al., 2020), it brings attention to the importance of providing psychological preparation and assistance to healthcare professionals during the COVID-19 outbreak.

Elderly

As part of an important risk group for COVID-19, the elderly are currently being instructed to remain at home and self-isolate (Armitage and Nellums, 2020). Nonetheless, it has been demonstrated that older adults are at higher risk for anxiety and depression when put in situations of social disconnection (Armitage and Nellums, 2020; Conejero et al., 2020). To those who do not have close family or friends and to those whose only social contact is out of the home, these can be particularly dawning times. Many individuals within this group rely solely on community centers, places of worship, voluntary work and social care, activities which have been severely restrained by the COVID-19 outbreak (Armitage and Nellums, 2020). In addition, many older individuals have smaller access and/or literacy to social networks, which prevents them from maintaining virtual connection with others (Mesa Vieira et al., 2020). Therefore, the psychological and emotional impact is tremendous. The social disconnection causes and aggravates loneliness, neglect, depression and anxiety, all of which can produce long-term health consequences (Banerjee, 2020; Bavel et al., 2020). Moreover, the context of this pandemic might increase suicide behavior amongst older adults. As an example, after the SARS epidemic in 2003, suicide rates among elderly individuals were increased by 30% (Holmes et al., 2020). The solitude in the elderly has also been suggested to be accompanied by biological modifications that make this group more vulnerable to commit suicide, which includes the elevation of inflammatory markers and expansion of peripheral blood mononuclear cells (Conejero et al., 2020). Furthermore, it has also been suggested that social disconnection may worsen neurodegenerative disorders, such as Alzheimer's disease (Conejero et al., 2020; Plagg et al., 2020).

An additional topic of discussion that further elucidates the emotional impact of the pandemic among the elderly is the phenomenon of "ageism". In the early phases of the COVID-19 outbreak, the disease had been predominantly portrayed as an illness that affects almost exclusively the older adults (Ayalon, 2020). At present, this stereotype has been proven erroneous, as age itself is not a reliable criterion to predict the health impact of SARS-CoV-2 infection (Ayalon, 2020). Notwithstanding, albeit the scientific evidence of such a statement, the social marginalization and segregation of the elderly persists throughout the population (Ayalon, 2020; Colenda et al., 2020). Indeed, in some countries, the gradual relaxation of the social distancing recommendations does not seem to apply to the older adults, who are consistently advised to self-isolate (Ayalon, 2020). Moreover, there is a general belief that the safety of this group should be sacrificed for the greater good of society, particularly in detriment to the economy (Ayalon, 2020; Colenda et al., 2020). In this scenario, the aggravation of the intergenerational tension can be observed in social media content. As an illustration, the offensive hashtag #boomerremover appeared in over 4,000 posts in Twitter in a 10-day period following the pandemic declaration of WHO in March (Jimenez-Sotomayor et al., 2020). In this framework, there is a destructive increase in the mental health burden of senior citizens, which must be urgently addressed.

Children

Children, especially the young ones, are also in a position of vulnerability during the pandemic. This happens because, at home, they suffer with limited social connection, crucial for identity and well-being at young ages, reduced physical activity, loneliness and boredom (Fegert et al., 2020; Jiao et al., 2020; Loades et al., 2020), which may result in long-term effects. Indeed, the mental and physical health, as well as productivity in adult life, is deeply rooted in the childhood years (Loades et al., 2020; Wang G. et al., 2020). Data from previous epidemics demonstrate that children who experienced isolation measures were five times more prone to demand mental health services and more inclined to experience PTSD (Loades et al., 2020). It has also been demonstrated that children who are out of school (i.e., weekend and summer holidays) tend to have longer screen times, irregular sleep patterns and less favorable diets (Wang G. et al., 2020), which can be exceptionally harmful in longer periods of time such as the yet unknown duration of this pandemic. Furthermore, the economic recession, the restricting measures and the overall family stress may be accompanied by an increase in domestic violence and child maltreatment, situations that impact the mental health of children (Fegert et al., 2020). Adolescents with previous mental health disorders require particular attention since disruption of school routine can decline their mental health status (Khan et al., 2020). Moreover, the current events have further prompted the expansion of remote work, whereas schools and daycare centers had to interrupt their activities. In this setting, family and work environment have

merged and decreased performance can be seen in both spheres, as stress intensifies (Mental health Covid-19, 2020).

Following the distancing measures, social media has become an important resource to maintain social interaction. Even though its use might alleviate some of the mental health impact of the isolation, it is essential to analyze its negative impact in children and adolescents (Deslandes and Coutinho, 2020; Ni et al., 2020). First, consuming indiscriminate information about the pandemic may trigger stress, anxiety, panic and depression. This effect is even more intense in younger individuals that do not have the discernment to filter information (Deslandes and Coutinho, 2020). Second, the excessive use of the Internet might create an addiction, compromising the development of a healthier routine during the pandemic, which is also composed by study, leisure, and exercise activities (Deslandes and Coutinho, 2020). Third, digital social networks are extremely based in the virtual construction of a self-image and visibility, which, especially for the youngest, might mediate self-esteem through the pursuit of social approval. Simultaneously, social media can be a violent place. As a consequence, its excessive use may contribute to self-harm actions through virtual challenges, in which the participant has assignments related to self-mutilation and even suicide that should be filmed and posted. The online search for the term "challenges online" has increased since the implementation of the restricting measures (Deslandes and Coutinho, 2020). Ultimately, elevated Internet use is associated with behavioral problems such as neglecting personal life, relationship disorders, mood dysfunction and sleep disturbances, as well as increased anxiety and depression levels during the pandemic (Duan L. et al., 2020).

College Students

Since universities have temporarily closed during this world health emergency, college students are also vulnerable to major changes in their routine and, as a consequence, to the psychological impact of the pandemic (Khan et al., 2020). As a matter of fact, having the graduation affected by the pandemic has already been significantly associated with increased depression rates (Duan L. et al., 2020). Factors that may aggravate this situation include living away from family, instability of family income and insufficient access to technology in order to attend online classes (Cao et al., 2020; Khan et al., 2020). In fact, the mental health impact of online classes is a topic that deserves further evaluation, since it might lead to overburden (Dubey et al., 2020). As an extreme example, a suicide pact related to online classes has been reported between a private university student and his mother. Similarly, suicides due to depression after an exam postponement and due to inability to access online classes have also been announced (Mamun et al., 2020b).

LGBTQ+ Community

LGBTQ+ individuals, in general, have worse mental health and well-being compared to non-LGBTQ+ peers, especially for the persons of color (Fish et al., 2020; Salerno et al., 2020). As a consequence, during the COVID-19 pandemic, they face particular stressors that can trigger deleterious psychological outcomes (Fish et al., 2020; Phillips et al., 2020; Salerno et al., 2020).

For the LGBTQ+ youth, for instance, the social distancing measures might lead to confinement in unsupportive homes, increasing their exposure to discrimination, violence and rejection from their family (Fish et al., 2020). Previous researches have demonstrated that one third of the LGBTQ+ youth undergo family rejection and that these individuals are six times more prone to depression and eight times more prone to suicide (Salerno et al., 2020). Simultaneously, the LGBTQ+ youth, during the pandemic, experience less access to essential social connections, identity-based alliances and school-based mental health services (Fish et al., 2020; Salerno et al., 2020). As a result, this group is more vulnerable to anxiety, depression, suicide behavior, PTSD, substance abuse and self-harm (Fish et al., 2020; Salerno et al., 2020). For this reason, online communities have emerged as important support resources for this group (Fish et al., 2020).

Moreover, the LGBTQ+ elders are twice as likely to live alone, four times less prone to have children and more inclined to be segregated from their family (Salerno et al., 2020). Therefore, social distancing measures may exacerbate loneliness and previous mental health conditions (Salerno et al., 2020). Finally, the levels of poverty, lack of health-insurance and unemployment are higher amongst LGBTQ+ individuals, which aggravate the impact of the pandemic in their mental health (Phillips et al., 2020; Salerno et al., 2020).

Black and Latin Communities

Structural racism imposes unequal access to healthcare and protective resources among different racial and ethnic populations. For instance, many individuals of color do not have adequate housing, a main social determinant of health. Additionally, nearly one third of the black Africans and one fourth of Black Caribbean in the United Kingdom are workers in essential services without the possibility of working from home (Farquharson and Thornton, 2020; Liu and Modir, 2020). Furthermore, there is an insufficient amount of well-resourced hospitals in many primarily black and latin communities (Liu and Modir, 2020). As a result, the COVID-19 pandemic has an increased impact on the individuals of color, which may lead to enhanced fear of infection and worse mental health outcomes (Farquharson and Thornton, 2020; Liu and Modir, 2020). In fact, black Americans have the highest COVID-19 mortality rate among the racial groups in the United States and early data reported that 33% of all deaths were of black people, even though this group composes 13% of the United States population (Liu and Modir, 2020).

Furthermore, in the course of the pandemic, the stigmatization of racial minorities exacerbates, causing rejection, social disconnection and physical violence (Farquharson and Thornton, 2020). As an example, the early recommendation to wear face masks in public resulted, for the black community, in increased racial profiling and police violence (Liu and Modir, 2020). Therefore, the narrative "we're all in this together" regarding the COVID-19 outbreak has been proven inaccurate, and the communities

of color are a vulnerable group for the mental health repercussions of the pandemic (Farquharson and Thornton, 2020; Liu and Modir, 2020).

Foreigners

The continuous threat of SARS-CoV-2 has aggravated ethnic prejudice and intolerance toward stigmatized groups, especially toward Chinese people (Asmundson and Taylor, 2020a; Bavel et al., 2020). This is not unprecedented in History: Jewish people were linked to the Black Death, HIV was believed to be disseminated by the LGBTQ+ community and the western African population was discriminated against during the Ebola outbreak (Coates, 2020). In this pandemic, it is likely that the novelty of the virus and the uncertainty surrounding its potential outcomes in several spheres of society have triggered fear and anxiety that endorse the xenophobia behavior (Asmundson and Taylor, 2020a). There have been reports of discrimination within social and political contexts: Chinese restaurants having to shut down due to reduced number of costumers (Asmundson and Taylor, 2020a), Chinese individuals being barred from entering certain establishments and even the United States President referring to COVID-19 as the "Chinese virus" (Devakumar et al., 2020). Moreover, immigrants have decreased access to healthcare services, adequate housing and clean water, especially if undocumented (Liu and Modir, 2020; Mesa Vieira et al., 2020). To manage such reality, multidisciplinary measures are necessary to correctly inform the population on public health risks, to notify discriminatory acts and to support those affected by harmful misconceptions (Rzymski and Nowicki, 2020).

Individuals in Economic Vulnerability

As in natural hazards, the economically disadvantaged people seem to be more susceptible to the threat and more likely to be minced by it (Bavel et al., 2020). For instance, a study has shown that groups with lower income may have been performing less physical exercises during this period, due to less access to Internet and technological tools. This is evidence that, besides the economic impairment, these individuals are also more vulnerable to physical and psychological repercussions of social isolation (Peçanha et al., 2020). Furthermore, there has been correlation between socioeconomic deprivation and ability to adopt preventive measures, enhancing the risk inequality (Atchison et al., 2020).

Those living in informal settlements have particular stressors that decline their mental health. For instance, space constraints, violence and overcrowding implicates in decreased capability to adhere to the social distancing measures and, as a consequence, in increased fear of contamination (Corburn et al., 2020). Furthermore, basic needs such as access to water, waste collection, sewers and adequate housing may not be available. Moreover, most of the individuals living in slums are informal workers and, therefore, are more vulnerable to the economical impact of the pandemic (Corburn et al., 2020). Finally, racism, xenophobia and stigmatization of the poor have raised during the pandemic, which implicates in even worse outcomes regarding the mental health of these populations (Corburn et al., 2020).

Homeless Individuals

Homeless individuals compose another vulnerable group for contracting COVID-19 and for the psychological impact of the pandemic (Hsu et al., 2020; Khan et al., 2020; Mesa Vieira et al., 2020). First, this group faces difficulties in taking preventive measures for COVID-19, such as hand washing and self-isolation. Conversely, they are more prone to risky behaviors such as substance abuse and the sharing of needles (Wood et al., 2020). Second, many individuals have an increased prevalence of comorbidities and chronic diseases compared with people of similar age, including mental health disorders like bipolar disorder and schizophrenia (Khan et al., 2020; Mesa Vieira et al., 2020; Wood et al., 2020). Third, they face enhanced obstacles to receive treatment for previous medical conditions, especially considering their reduced accessibility to telehealth services (Wood et al., 2020).

Prisoners

The vulnerability of the prison population in the COVID-19 pandemic does not seem to be thoroughly explored by the scientific community (Hewson et al., 2020). Notwithstanding, this group of individuals comprise numerous risk factors for worse mental health outcomes secondary to the current circumstances. This magnified emotional impact is a result of several aspects. The frequency of pre-existing psychological disorders, neurodevelopmental health, substance misuse, suicide and self-harm is already increased in this group compared to the rest of the population (Hewson et al., 2020; Kothari et al., 2020). Moreover, as consequences of the COVID-19 pandemic, these individuals have been suffering with diminished social interaction with other inmates and outside visitors, suspension of jury trials and delay of court hearings, and recreational and occupational prison activities (Fovet et al., 2020; Hewson et al., 2020; Tozzo et al., 2020). This group is also more vulnerable to the infection of SARS-CoV-2, as prisons tend to be overcrowded, have poorly ventilated environments and low compliance to hygiene rules (Tozzo et al., 2020). In light of this scenario, prisoners are more likely to suffer from anger, depression, anxiety, irritability, frustration, paranoia, fear of contamination, psychosis, exacerbation of underlying mental illness and suicidal behavior (Fovet et al., 2020; Hewson et al., 2020; Tozzo et al., 2020).

Rural Communities

The individuals living in rural communities experience more loneliness, lack of belonging and perceived burdensomeness than those living in urban centers. They are, therefore, at elevated risk for unsatisfactory mental health and even suicide (Monteith et al., 2020). During the COVID-19 pandemic, the social distancing measures, often not accompanied by virtual connections due to diminished access to the Internet, may exacerbate mental health symptoms and increase suicide behavior in this population (Monteith et al., 2020). Furthermore, intimate partner violence tends to be more intense in rural communities, whereas access to mental healthcare tends to be deficient. All of these circumstances may exacerbate during the pandemic and might result in

poorer mental health outcomes and increased suicide rates (Monteith et al., 2020).

Psychiatric Patients

In psychiatric patients, the COVID-19 pandemic might trigger an even worse outcome regarding mental health. As previously discussed, the uncertainty, fear and social distancing may exacerbate pre-existing psychiatric diseases and precipitate its symptomatology (Holmes et al., 2020; Vindegaard and Benros, 2020; Yao et al., 2020). Added to their higher vulnerability to many stressors (Yao et al., 2020), they face worsen medical follow-up due to the suspension of some elective appointments and redirection of health professionals to face the pandemic (Holmes et al., 2020). Furthermore, they tend to have more severe forms of COVID-19 due to comorbidities, immunosuppression (Fontenelle and Miguel, 2020; Yao et al., 2020) and, possibly, worst access to medical care because of discrimination (Yao et al., 2020).

Depression and Anxiety

When performed several scales to assess the psychological impact of COVID-19 pandemic in China on 76 psychiatric patients (with major depressive disorder, anxiety disorders and mixed anxiety and depressive disorder patients) and 109 healthy controls, the patients group had worst outcomes on almost all variables addressing depression, anxiety, stress and insomnia (Hao et al., 2020). As for other psychiatric symptoms referred during the survey, the patients group had more worries about their physical health, more moderate to severe anger and impulsivity and more suicidal ideation (Hao et al., 2020). However, it is important to mention that the control group was evaluated simultaneously to the patients group. Control group was composed of individuals without psychiatric disorders that were evaluated before COVID-19 pandemic. For this reason, results of the study can be contestable.

Moreover, patients with generalized anxiety have increased health anxiety. As a result, they are more prone to confound normal feelings with COVID-19 symptoms, generating even more anxiety and distress (Dubey et al., 2020).

Obsessive-Compulsive Disorder

Many patients with obsessive-compulsive disorder (OCD) already excessively worry about having a disease or contaminating others. During this world health emergency, these feelings may intensify (Fontenelle and Miguel, 2020). Also, some signs and symptoms of OCD are very similar to important preventive measures for COVID-19, such as compulsive hand washing and avoiding physical contact (Fontenelle and Miguel, 2020). Therefore, this overlap may cause difficulty for physicians to diagnose and treat new cases of OCD. Finally, the stressors associated with the pandemic might increase the number of new OCD patients, especially among those "at risk" for COVID-19 (Fontenelle and Miguel, 2020).

Schizophrenia

In psychiatric patients, excessive attention to media or social networks might precipitate an acute phase of the disease or change its manifestations (Fischer et al., 2020). For example, a 43-year old German patient with schizophrenia had delusions and hallucinations related to the pandemic (Fischer et al., 2020). He believed he contracted the disease through a WhatsApp video from COVID-19 patients in China and started having acoustic hallucinations, anxiety and depressing humor. Therefore, equilibrated communication, based on scientific facts, is essential to minimize this possible damage (Fischer et al., 2020).

Furthermore, schizophrenic patients were less likely to vaccinate, adhere to social distancing, wash their hands and use masks during influenza pandemic (Maguire et al., 2019). This reality is also true for patients with other psychiatric conditions, such as addiction (Narasimha et al., 2020). Therefore, they are a vulnerable group for contracting COVID-19, especially if their mental health is worse than usual (Yao et al., 2020).

Hospitalized Patients

Stress experienced during COVID-19 pandemic is probably even higher for psychiatric patients hospitalized for severe illness. In China, these patients had to stay in closed wards without family visits or electronic equipment (Li and Zhang, 2020). These conditions exacerbated their distress and mental symptomatology (Li and Zhang, 2020). Additionally, the patients in these facilities tend to make group activities, share dining and bathroom spaces, interact closely and practice less preventive measures because of their mental state (Bojdani et al., 2020; Xiang et al., 2020). Therefore, they are more vulnerable to the transmission of SARS-CoV-2 (Bojdani et al., 2020; Xiang et al., 2020).

EXTERNAL INFLUENCE

Culture

As a multi-dimensional psychosocial construct that shapes the perception of the world, culture has the ability to influence several aspects of daily life. In the framework of the pandemic, cultural components affect how the population will perceive, for instance, the implementation of hygienic greetings etiquette, the recognition of health symptoms and the fear of stigmatization (Bruns et al., 2020; Furlong and Finnie, 2020). For this reason, it can be challenging to encourage individuals to comply with some of the necessary precautions, such as avoidance of cultural activities (i.e., worship meetings) and submission to the restricting measures, particularly if these strategies are divergent to the customary social norms (Bruns et al., 2020; Furlong and Finnie, 2020). For example, in Asia, where the COVID-19 outbreak started, discipline is highly valued in society, as well as punishments for deviance. Therefore, the sense of community can be vital in motivating individuals to comply and respect the measures imposed. Contrarily, countries who value freedom and individual expression, including the United States, Italy, and Brazil, may exhibit more difficulties in renouncing personal desires in order to oblige to a common good (Bavel et al., 2020). As a result, the mental health outcomes derived from

this pandemic rely deeply on the level of cultural impact in the community (Furlong and Finnie, 2020).

Media and Access to Information

As a worldwide unprecedented health issue, COVID-19 pandemic has drawn massive attention from the media. Nonetheless, the supply of information regarding the disease has heavily surpassed the demand from the population (Liu and Liu, 2020). This phenomenon has two main repercussions in respect to the mental health impact.

First, the manner by which media vehicles have been portraying the current situation to the community might be causing great harm in terms of psychological implications. This can be easily translated as an analogy with vicarious traumatization, a process suffered by the health staff in command when listening to the victims' narration of traumatic events they experienced (Liu and Liu, 2020). Similarly, the negative exposure of individuals to ruthless details concerning the COVID-19 pandemic has the potential to promote great psychological distress in the society. During these times, pessimistic reports have prevailed in the correspondence with the public, including daily updates on the number of those infected and number of deaths, economic impact and uncertainty about the future. This consequently increases negative emotions throughout the community and makes people more susceptible to panic. An illustration of this matter is the display of images of empty shelves and panicked shoppers during the first months of the pandemic. Even though this may have been used as a critic, it induced viewers to look out after themselves and foster individuality and competitiveness (Bavel et al., 2020).

Secondly, as information travels at an uncontrollable speed, it is virtually impossible to control the accuracy and authenticity of the majority of news in circulation. As expressed by the Director-General of the WHO, in addition to the fight to the SARS-CoV-2 virus, the world is currently facing an "infodemic" (Dubey et al., 2020; Zarocostas, 2020). It is characterized not only by the massive frequency of fake and inaccurate news (Irwin, 2020), but also conspiracy theories and misinformation, which puts the public through the distress of having to distinguish between scientific evidence and unreliable information (Depoux et al., 2020). The repercussions of this phenomenon are numerous and deleterious, particularly to the mental health of the population, given it is a potential source of anxiety, phobia, panic, depression, obsession, irritability, and COVID-19-related paranoia (Dubey et al., 2020).

Social Network

In this topic, social networks present twofold effects. On one hand, it is one of the main vehicles of the misinformation and inaccurate information reported. Moreover, people can be adversely influenced by what they see in social networks, which may alter risk perceptions, encourage unhealthy behaviors and reassure the non-compliance with preventative measures (Gao et al., 2020). On the other hand, as the current situation demands physical distancing, remote communication has become an indispensable resource to have social connection (Bergman et al., 2020), as well as to find inspiration on healthy habits and behaviors (Brooks et al., 2020; Gao et al., 2020). In fact, particularly in the scenario of this unprecedented crisis, social networks have been suggested to play a fundamental role in social support, tension release and emotional catharsis (Liu and Liu, 2020).

Government

In the midst of the pandemic disarray, the government of each country is in the position to guide the population and to execute the necessary interventions to minimize the propagation of the virus. Some strategies consisted of school closures, limited commercial activities, requests that individuals work from home and reduced freedom to use public spaces (Briscese et al., 2020). This kind of leadership has powerful repercussions, with surveys indicating that trust in the government increased from the day the restrictive measures were implemented (Teufel et al., 2020) and that positive behavioral changes were made in response to authorities' guidance (Atchison et al., 2020). Indeed, it has been demonstrated that government's interventions of disease prevention and control have significantly increased the likelihood of adoption of protective measures (Duan T. et al., 2020). Moreover, a study showed that, in the United Kingdom, the inclusion of altruism in government's health messages possibly had a positive effect on wellbeing compared with compulsory orders to stay at home (Holmes et al., 2020).

Nonetheless, in regard to the governments' strategy to mitigate the emotional and behavioral impact of the pandemic, the results may not be as optimistic. During health crises, there seems to be a special focus from authorities in epidemiological and biomedical data (Atlani-Duault et al., 2020). Indeed, a Chinese study investigated the government's communication with the public through social media and observed an overall inadequate responsiveness to the public's concerns. The majority of posts consisted of reports on the epidemic situation, disease-related questions, guidelines and prevention advice. Although these are tremendously relevant topics, there seemed to be insufficient instrumental and emotional support for the community (Liao et al., 2020).

Moreover, an interesting phenomenon is the "heroization" process (Atlani-Duault et al., 2020; Liao et al., 2020). It can be illustrated by the fact that, in any disaster, there seems to be a social need for attribution of blame, in which certain groups or individuals may be considered heroic figures (Liao et al., 2020). Therefore, in order to balance the complex geographies of hope and blame (Atlani-Duault et al., 2020), the government must be aware of this phenomenon in order to modulate the community's emotional response to the pandemic, as well as to counteract fake news and misinformation (Atlani-Duault et al., 2020).

Another key component to examine in the government's influence over the population is the establishment of deadlines to the end or the loosening of restricting measures. While the lack of an end date to protective efforts may increase the perceived severity of the situation, which, in turn, may build up compliance to such measures, it is also possible that the absence of a deadline might increase anxiety and other psychological complications over the uncertainty of the future (Briscese et al., 2020). The opposite may also apply: a deadline

may also create the impression that the emergency is limited in time and not particularly serious. In addition to that, deadlines may develop expectations in the population that, if not met, might reduce people's acceptance to the necessary procedures, trust in authorities and compliance to social distancing, a result which is called "social isolation fatigue" (Briscese et al., 2020).

MEASURES ADOPTED TO MINIMIZE BEHAVIORAL AND PSYCHOLOGICAL CONDITIONS FACING COVID-19 PANDEMIC

In light of all the harmful ramifications that derive from the current COVID-19 pandemic, it is essential that the government, the health authorities and the population articulate to endorse preventive and supportive measures, not only for the transmission of the disease, but also for emotional, behavioral and psychological impact. In this context, it is important to include mental health professionals managing the pandemic more broadly (Sani et al., 2020). Their knowledge and experience are crucial to monitor the situation and to coordinate supportive measures in order to prevent an even higher increase in psychological disorders, including panic, OCD, addiction and PTSD (Fiorillo and Gorwood, 2020; Sani et al., 2020). Finally, considering that poor mental health is associated with lower adherence to preventive measures for SARS-CoV-2, improving well-being might even decrease the rates of infection (Adhanom Ghebreyesus, 2020).

Telepsychology Services

As mentioned, worse medical follow-up is one of the most important features to understand the mental health impact of COVID-19 pandemic to mentally ill patients. Demand for telepsychology services, therefore, has increased markedly during the pandemic, and managers have accordingly tried to keep up with this abnormally high demand (Perrin et al., 2020). In fact, psychologists performed 7.07% of their work through telecommunication technologies before the COVID-19 pandemic, whereas, during the pandemic, this number increased to 85.53%, with 67.32% of the mental health professionals executing their work solely via telepsychology (Pierce et al., 2020). The United States government has pursued some actions to enlarge the role of telepsychology, such as allowing the possibility of some drugs to be prescribed in appointments via the Internet, and the expansion of Medicare and Medicaid to cover telepsychology and telemedicine consultations (Perrin et al., 2020; Pierce et al., 2020). Furthermore, online training with experienced trainers, along with tools and resources prepared by psychology organizations, are available in order to instruct the professionals for this new demand (Pierce et al., 2020). These learning opportunities are remarkably important, since lack of self-efficacy is one of the main reasons that explain the small use of telepsychology preceding the pandemic (Pierce et al., 2020).

Concerning its efficacy, Internet-delivered therapy, such as cognitive behavior therapy (CBT), was not less effective than face-to-face CBT in health anxiety disorders, while resulting in lower treatment costs in previous studies (Axelsson et al., 2020). Therefore, even though the evidence base is still limited, these therapeutic modalities may have an important role for facing mental health issues during COVID-19 pandemic (Bilder et al., 2020; Fegert et al., 2020). Nevertheless, telepsychology uptake in more complex cases with severe symptomatology, such as antisocial personality disorder, behavioral issues and bipolar disorder, had a lower increase during the pandemic, indicating difficulty to treat the conditions via the internet or insufficient specialized training for psychologists. The same pattern was observed with testing and evaluation, which could signal insufficient tests adapted for telepsychology (Pierce et al., 2020). Furthermore, technology issues are among the main barriers to the implementation of telehealth. For instance, the elderly may lack familiarity with the platforms, while those from a lower socioeconomic background or those living in rural areas may deal with deficiency of technological devices or Internet connections (Bilder et al., 2020; Monteith et al., 2020).

Finally, mental health professionals should be prepared to address some particularities of minority groups, such as the LGBTQ+, black and latin communities, with cultural responsiveness (Liu and Modir, 2020; Phillips et al., 2020). For the black community, psychologists can use racial socialization in order to enhance awareness about the reality of racism and to promote coping mechanisms (Liu and Modir, 2020).

Hotlines

It has been recommended that people under quarantine should have access to hotlines with trained healthcare providers to receive guidance regarding possible symptoms or doubts. Such communication channels would reassure and comfort distressed people, providing a sensation that they have not been forgotten. Online support groups for people who are quarantined at home might also be helpful in reducing levels of fear and anxiety (Brooks et al., 2020).

People with suicidal tendencies or previous mental illnesses need special support. Some of them will search for help, and, in this case, it is necessary to increase the volunteer team and to prepare individuals to deal with the situation, including resources through the Internet or phone call. For those who will not search for help, it is important to be attentive to their signs, such as social disconnection and humor flows (Gunnell et al., 2020). Monitoring the mental status of the population is crucial to guide new interventions and improve the overall wellbeing (Holmes et al., 2020).

Digital Technology Monitoring and Assistance

The global issue of misinformation and social media panic is a crucial topic to be addressed during this pandemic. In order to avoid misleading media reports, the main news outlets should assign professionals to moderate the information that is passed on to the public, in the interest of verifying if it is in line with the current guidelines and scientific evidence (Gunnell et al., 2020). Furthermore, news broadcasts should use simple

language when communicating with the public, which means avoiding complex and scientific terms. It is also recommended that they offer practical and specific advice instead of vague or complex guidance (Lakhani et al., 2020; Mesa Vieira et al., 2020). This facilitates the comprehension of the information and also promotes social inclusion of the more vulnerable groups (Mesa Vieira et al., 2020).

Moreover, there is a serious need for online platforms that clarify the available data concerning COVID-19, as well as demystify the fake and inaccurate news in circulation (Depoux et al., 2020). An illustration of this strategy is the "Mythbusters" dashboard in the WHO website, which carries this exact purpose (World Health Organization [WHO], 2020a). Additionally, the use of social media must be conducted with responsibility. The users should avoid the sharing of information that it is either not followed by a reliable source or that may cause panic or anxiety. Medical advice ought to be provided solely if it is backed by evidence (González-Padilla and Tortolero-Blanco, 2020).

Moreover, as the Internet has become an indispensable tool to foster social connections and perform numerous activities, online access, as well as reliable connection, is imperative and must be provided particularly for the vulnerable groups (Bavel et al., 2020). For instance, in order to nurture belonging, webinars, meetings and virtual extracurricular activities can be implemented for the black, latin and LGBTQ+ communities (Liu and Modir, 2020; Salerno et al., 2020). Furthermore, those with limited literacy concerning the use of digital technologies ought to receive special consideration.

Financial Support

As for the financial stress experienced during the COVID-19 pandemic, the government of each country should offer financial support for the vulnerable population in this context, including the self-employed and those with lower income. It is also crucial to prepare an economical plan during and after the quarantine, in order to reduce stress about the uncertainty of the future (Gunnell et al., 2020). Moreover, aiming to alleviate the economic burden faced particularly by numerous groups throughout the community, medical expenses of COVID-19 confirmed and suspected patients should be subsidized by the government. This strategy may also ensure that individuals seek medical care and, therefore, promotes health equity and disease control amongst the more vulnerable groups (Wang and Tang, 2020).

Personal Strategies to Improve Mental Health

In light of this difficult scenario, there are ways in which individuals may personally attempt to improve their well-being. Undoubtedly, maintaining interest and motivation is difficult for those suffering from mental health disorders or for those struggling financially (Mental health Covid-19, 2020). Nonetheless, studies have suggested that nourishing adaptive mindsets regarding stress may exert positive effects on how people deal with their emotions. It may also reduce adverse physical symptoms and boost physiological functioning under acute stress (Bavel et al., 2020). In fact, stress and loss of life satisfaction have been associated with higher levels of inflammation, which increases the odds of contracting the disease (Mesa Vieira et al., 2020).

Moreover, a study with employed students observed that there are multiple emotion regulation strategies that might be helpful during this period. They include seeking and reaching out to social connection, such as friends or family, or even volunteering, as reducing the feeling of loneliness and enhancing belongingness is crucial to prevent suicide (Holmes et al., 2020). Keeping oneself committed to other things (i.e., hobbies, music, reading, film, and television and home improvements) and engaging in enjoyable activities to improve one's mood have also been suggested (Restubog et al., 2020). As complex and multicomponent activities, arts and crafts have been highly associated with diminished risk of developing mental health disorders (Conejero et al., 2020). It is suspected that they modulate several neurotransmitters, as well as cortisol levels, and stimulate neuroplasticity. Therefore, they offer the possibility of emotional expression and regulation (Conejero et al., 2020).

As the COVID-19 outbreak severely restricted people's movement, outdoor activities have been limited, which does not mean, however, that physical activity needs to be limited as well. Physical exercises have been strongly associated with positive effects regarding mental and physical health (Jiménez-Pavón et al., 2020; Lyons et al., 2020). Therefore, exercising at home is an accessible and easy alternative, which includes not only walking and running, but also several online and free classes of different sport modalities (Chen et al., 2020; Jiménez-Pavón et al., 2020; Mental health Covid-19, 2020).

Several other strategies can contribute to improve the mental health status during the current situation. They include mediation, faith, prayers, playing and listening to music, cooking and baking, caring for a pet or gardening (Lades et al., 2020; Lyons et al., 2020; Mental health Covid-19, 2020). The importance of maintaining a routine or daily plan has also been emphasized (Lyons et al., 2020; Mental health Covid-19, 2020). The management of information intake, keeping news monitoring to a minimum in order to reduce levels of anxiety (Holmes et al., 2020; Mesa Vieira et al., 2020) or simply following official guidelines to stay safe and to respect social distancing are also fundamental strategies to diminish the stress response (Mental health Covid-19, 2020). Furthermore, sleep has a significant impact in mental health and stress response and the population should be constantly informed of its importance, particularly during the COVID-19 pandemic (Holmes et al., 2020).

Specific Measures for Certain Vulnerable Groups

Healthcare Professionals

Considering the emotional and psychiatric risk that healthcare workers are exposed to, actions must also be taken to protect and support this group. Healthcare managers should offer proactive steps to help their workers deal with this situation, reinforcing teams as needed, being honest about the situation and monitoring their staff more closely (Greenberg et al., 2020).

Support measures such as psychologists and psychiatrists' appointments, psychological assistance hotline, support groups and reading materials illustrating coping mechanisms to deal with stressors should also be provided without stigma (Santarone et al., 2020; Zaka et al., 2020). Since many professionals are afraid of going home and infecting their families, it is important to inform them about the safety measures that can minimize the chances of infection (Mamun et al., 2020c). Hospitals can also provide a place where the workers can rest and, if possible, record their hospital routine in order to share with their family (Zaka et al., 2020). Furthermore, the family members of the healthcare professionals should receive special access to testing and treatment, if necessary (Dutheil et al., 2020; Mamun et al., 2020c).

Moreover, an adequate work environment is essential to diminish the mental health impact of the pandemic in healthcare professionals. In that matter, there should be sufficient PPE availability and detailed rules about its use, limited hours in each shift, dissemination of medical information through multiple platforms and languages, education about skills to deal with the patients psychological concerns, delaying of elective appointments and surgeries and, if possible, assembly of a backup force composed of capable retired workers and college students about to graduate for the times of higher patient volume (Dutheil et al., 2020; Santarone et al., 2020; Zaka et al., 2020). Special attention must be paid to preventive strategies of PTSD and its related risk of suicide in the upcoming months (Dutheil et al., 2020).

Finally, it is important to acknowledge that targeting the psychological impact of the pandemic in healthcare professionals is also important to control the COVID-19 itself, since impaired mental health affects their attention, understanding and decision-making (Zaka et al., 2020).

Elderly

Considering the particularly detrimental consequences of social disconnection among the elderly, the benefits and damage of such restriction must be thoroughly and continuously weighed (Plagg et al., 2020). In institutions and nursing homes, this group should be allowed the visit of healthy relatives and friends, as long as the hygienic measures are adequately taken. If possible, these relatives and friends might be tested for SARS-CoV-2 infection (Mesa Vieira et al., 2020; Plagg et al., 2020).

Moreover, the family should be encouraged to contact these individuals more frequently, as well as voluntary organizations and community projects should provide similar support for this group (Armitage and Nellums, 2020). Indeed, the phone call outreach program promoted by the Northwestern University in Chicago, Seniors Overcoming Social Isolation, has been developed with the purpose of minimizing social disconnection among the elderly and providing significant engagement with the community (Office et al., 2020). Older adults must also be stimulated to leave their room or even perform outdoor activities when possible (Plagg et al., 2020). Online cognitive behavioral exercises and therapy should also be provided (Armitage and Nellums, 2020).

At last, the community should be encouraged to not comply with ageist content and to recognize the immense value and contribution of the senior citizens to the society (Jimenez-Sotomayor et al., 2020). Furthermore, intergenerational contact ought to be stimulated, as it promotes mental health benefits for both the parties involved (Jimenez-Sotomayor et al., 2020; Office et al., 2020).

Children

It has been recommended that the children maintain a healthy routine with adequate sleep cycle and physical activity, and videos can be used to encourage them to exercise and to play (Deslandes and Coutinho, 2020; Wang G. et al., 2020). In order to prevent loneliness, families might seize the opportunity to establish better bonds with their kids, providing them a sense of belonging in the family (Loades et al., 2020). Additionally, social networks should be used to allow interaction with their peers (Loades et al., 2020). Nevertheless, it is suggested that the parents monitor and control the screen time and the content visualized in the Internet (Deslandes and Coutinho, 2020). Parents should always talk to children about the current circumstances clearly and directly, in order to minimize the negative feelings and to help the kids better comprehend the pandemic and the information received from the Internet (Deslandes and Coutinho, 2020; Dubey et al., 2020; Wang C. et al., 2020). Interestingly, an effort that has already been made is the creation of the book *My Hero is You* (Storybook for Children on Covid-19, 2020) by the United Nation in conjunction with other agencies. This book was designed to help children aged 6 to 11 coping with the stress and anxiety generated by the pandemic. Furthermore, online services provided by psychologists can be useful, especially due to domestic conflicts, harassment, abuse and other types of violence (Wang C. et al., 2020).

Domestic Violence

Domestic violence is a complex issue with strong cultural components (Gunnell et al., 2020). Therefore, it requires a combination of multiple measures in order to protect the victims (Gulati and Kelly, 2020).

To improve the reporting of domestic violence, it is important to ensure constant availability of hotlines and digital reporting systems (Sacco et al., 2020; Sharma and Borah, 2020). However, since the victims may be isolated with their perpetrators, other alternatives must be adopted. For instance, family, friends and neighbors have an essential role revealing domestic violence, and advertising campaigns should encourage the community to report the cases (Marques et al., 2020; Sacco et al., 2020; Sharma and Borah, 2020; Usher et al., 2020). A positive message, focusing on solutions, is more effective in these circumstances (Sharma and Borah, 2020). Furthermore, code-based systems to report abuse situations could be implemented in pharmacies, supermarkets or even with toll-free phone numbers (Sacco et al., 2020; Usher et al., 2020). Finally, healthcare workers should be aware of the signs of domestic violence and of the risk factors involved, such as substance misuse by family members (Gulati and Kelly, 2020).

After reporting, the speed of the response is critical, especially since the victims and their perpetrators are probably

sharing spaces during the pandemic (Sharma and Borah, 2020). Accordingly, domestic violence must be included in the policymaker's response to the pandemic, guaranteeing financial funding, human resources and protective measures for the victims (Marques et al., 2020; Sharma and Borah, 2020). Moreover, the population should be communicated about the speed of the arrest, since it increases the chances of the victim and bystanders to report the crime (Sharma and Borah, 2020). Finally, encouraging initiatives to provide social support, advocacy and psychological and physical healthcare for the victims is crucial (Gulati and Kelly, 2020; Marques et al., 2020).

Some victims will not report the domestic violence for several reasons, such as fear, economic dependency and protection of the perpetrator. In these cases, friends and family assistance and support groups are especially important to reduce the mental health impact of the abuse (Sharma and Borah, 2020).

Informal Settlements and Homeless Individuals

For those living in informal settlements and for the homeless, it is essential that the police avoid top-down forced directives and that committees are created in order to improve communication between the population and the government. Along with financial support, food assistance and adequate water, sanitation and hygiene should be provided for this population (Corburn et al., 2020; Dubey et al., 2020). In this context, non-governmental organizations such as community-based organizations and faith-based groups are also extremely important (Corburn et al., 2020; Dubey et al., 2020). Furthermore, shelters can be created in sports installations, closed universities and military lands to shelter the homeless or to the de-densification of the settlements (Corburn et al., 2020). It is also crucial that psychologists and psychiatrists are available for those demanding specific support (Dubey et al., 2020). Ultimately, all individuals require their basic rights protected to diminish the mental health impact of the pandemic.

Prisoners

In light of the increased risk for worse mental health outcomes due to the pandemic, prisoners must receive special consideration and support. Prison management should explore the development of strategies that promote the well-being among the incarcerated community. It has been recommended that the inmates should receive telehealth support, substitute recreational activities, for instance, puzzles, coloring and playing cards, as well as other communication methods, such as writing letters and obtaining increased access to telephone landlines and social networks (Fovet et al., 2020; Hewson et al., 2020; Kothari et al., 2020). They must also be encouraged to practice physical exercise, even if it is inside the cell (Fovet et al., 2020; Hewson et al., 2020). Although access to hygiene measures can be difficult, the prisoners should be constantly informed about the social distancing precautions and provided with accurate information about the pandemic, in order to reduce anxiety and improve adherence to the restricting measures (Hewson et al., 2020; Tozzo et al., 2020).

CONCLUDING REMARKS

COVID-19 pandemic brings novel challenges to human beings. Not only virus' spread and disease mortality for risk groups, but also emotional, behavioral and psychological impact to the population. Measures to contain disease transmission, including quarantine, social isolation and social distancing may affect the population's behavior and may lead to psychological disorders. Several emotional and psychological conditions including fear, anxiety, depression, and suicide ideation are triggered by the pandemic itself as well as by the adopted preventive measures. Special attention should be paid to vulnerable groups both in regard to prevent harmful emotional repercussions of the pandemic, but also to provide the necessary assistance. The health authorities and the governments should strategize to alleviate the mental burden of COVID-19 pandemic by providing emotional support to the entire population, but particularly to the vulnerable individuals.

AUTHOR CONTRIBUTIONS

ALP and LB equally contributed to this article as first authors, both authors made the literature revision and selection of main articles for this review, defined the topics of this review, and wrote the first draft. ACFF, MLBC, RGBC, and SBCSB helped in writing specific topics of the review and helped in search and analysis of clinical trials included in this review. ACSS conceptualized the study, made general supervision, revised the manuscript, and submitted the final version of the manuscript, which is approved by all authors.

FUNDING

The authors acknowledge the Brazilian National Funding Agencies, CAPES and CNPq (Grant # 302153/2019-5) for financial support.

All We Need Is Trust: How the COVID-19 Outbreak Reconfigured Trust in Italian Public Institutions

The central focus of this research is the fast and crucial impact of the COVID-19 pandemic on a crucial psychological, relational, and political construct: trust. We investigate how the consequences of the pandemic, in terms of healthcare, state intervention and impositions, and daily life and habits, have affected trust in public institutions in Italy, at the time when the contagion was rapidly spreading in the country (early March 2020). In this survey, addressed to 4260 Italian citizens, we analyzed and measured such impact, focusing on various aspects of trust. This attention to multiple dimensions of trust constitutes the key conceptual advantage of this research, since trust is a complex and layered construct, with its own internal dynamics. In particular, the analysis focuses on how citizens attribute trust to Public Authorities, in relation to the management of the health crisis: with regard to the measures and guidelines adopted, the purposes pursued, the motivations that determine them, their capacity for involvement, and their effectiveness for the containment of the virus itself. A pandemic creates a bilateral need for trust, both in Public Authorities (they have to rely on citizens' compliance and must try to promote and maintain their trust in order to be effective) and in citizens, since they need to feel that somebody can do something, can (has the power to) protect them, to act at the needed collective level. We are interested to explore how this need for trust affects the attributional process, regarding both attitudes and the corresponding decisions and actions. The most striking result of this survey is the very high level of institutional trust expressed by respondents: 75% of them trust Italian public authorities to be able to deal with the COVID-19 emergency. This is in sharp contrast with the relatively low levels of institutional trust characteristic of Italy, both historically and in recent surveys. Moreover, the survey allowed the discrimination of several potential predictors for trust, thus emphasizing factors that, during this crisis, are exhibiting an anomalous impact on trust.

Keywords: COVID-19, trust, public authorities, risk management, social norms, socio-cognitive dynamics

INTRODUCTION

The great societal challenge presented by the COVID-19 pandemic has prompted extraordinary efforts to meet such a challenge, from public authorities, civil society, and the scientific community. Extreme policies for containment, mitigation, and co-existence with the virus have been implemented by the governments of most afflicted countries, as well as by relevant international institutions (e.g., the WHO and the EU). At the same time, scientific research worldwide has focused on tackling the many facets of this dramatic phenomenon, including its impact on social relationships and psychological well-being, as well as the key socio-cognitive factors in promoting effectiveness of the proposed countermeasures. Several of these studies have highlighted the crucial and complex role of trust in dealing with the COVID-19 pandemic.

Llewellyn (2020) puts it very succinctly and effectively: "in times of crisis, trust is the most important thing to consider if you want to communicate health advice." This blanket pronouncement is well-supported by previous evidence: in their systematic review on the importance of trust when preparing for and during a pandemic, Siegrist and Zingg (2014) found confirmation that "trust in health agencies positively influenced people's willingness to adopt recommended behavior." In addition, among the five recommendations for crisis communication highlighted by the authors' survey, two directly concern trust management: "the focus should be not only on trust but also on confidence, and establishing trust in health authorities before a pandemic occurs is important." This latter point is also stressed by Lewnard and Lo (2020), with reference to the current pandemic: "The effectiveness and societal impact of quarantine and social distancing will depend on the credibility of public health authorities, political leaders, and institutions. It is important that policy makers maintain the public's trust through use of evidence-based interventions and fully transparent, fact-based communication." It is worth noting that this emphasis on evidence and transparency, albeit crucial, describes only part of the relevant socio-cognitive dynamics that affect trust in public institutions: in particular, it collapses trust to confidence in information sources and their credibility, while a crucial problem is also trust in the institution's power to intervene, as well as trust in collective compliance with the proposed measures. Finally, in specific circumstances, interesting inversions in cognitive cause–effect relationships can occur, as widely studied in cognitive sciences and social psychology (e.g., Festinger, 1957; Koller, 1988; Kunda, 1990; Epley and Gilovich, 2016).

In fact, the relevance of trust for dealing with health emergencies is also linked to the limits of direct enforcement of the required behavioral change: without the active cooperation of the population, any drastic intervention is doomed to fail, because the desired behaviors (e.g., frequently sanitizing one's hands, wearing a facemask, and keeping a safe distance from others) cannot be effectively monitored on the required scale and with sufficient frequency. In a broad and comprehensive survey of social and behavioral results to support COVID-19 pandemic response, Van Bavel et al. (2020) highlight how most measures needed to contain an epidemic are, by their very nature, difficult to enforce directly: this, in turn, makes trust in public authorities all the more relevant. Based on scientific evidence gathered during previous outbreaks, Van Bavel et al. (2020) argue that "trust in institutions and governments (. . .) may play an important role." For example, trust in the Liberian government was correlated with decisions to abide by mandated social distancing policies and utilizing clinics for care during the Ebola outbreak. Trust was also related to decisions to adopt preventive measures such as Ebola vaccinations in the DRC. Conversely, a lack of trust in public health officials may lead to negative effects on utilization of health services. Reliable information and public health messages are needed from national leaders and central health officials. However, local voices can amplify these messages and help build the trust that is needed to spur behavioral change (Van Bavel et al., 2020).

These expectations on the positive role of trust in promoting adherence and compliance with preventive regulations and guidance are finding ample confirmation also in recent studies on the ongoing crisis, both within and across various countries. In a nationally representative survey conducted in Denmark during the COVID-19 pandemic (N = 1782), Olsen and Hjorth (2020) measured the respondents' willingness to apply social distancing in order to reduce contagion: they found that both lower levels of political trust and lower generalized social trust are negatively associated with willingness to distance and that younger male respondents with the lowest levels of education and least political trust report lower willingness to distance. In a nationally representative survey of Italian adults (N = 3452) conducted between the 18th and 20th of March 2020, Barari et al. (2020) observed high levels of understanding and self-reported compliance with containment measures, and noted that "even those who do not trust the government, or think the government has been untruthful about the crisis believe the messaging and claim to be acting in accordance."

Trust acts as a precious commodity both for institutions and for scientists, both of which are crucial actors in the public response to the COVID-19 pandemic. In a large-scale background analysis of European Social Survey data on 25 European countries (N = 47,802) focused on the COVID-19 epidemic from January 22 to April 14, 2020, Oksanen et al. (2020) found that institutional trust acts as a protective factor: countries with low levels of institutional trust prior to the outbreak (including Italy) experienced significantly higher mortality rates during the crisis; moreover, their governments introduced restrictions against contagion later than countries with higher levels of institutional trust (calculated as the delta between the date when the restrictions came into effect and when the first confirmed COVID-19 death was reported in that nation), which in turn contributed to the severity of their death toll. These results on the relevance of trust as a protective factor are in line with previous studies on other epidemics, e.g., Ebola, showing how people with higher institutional trust are more likely to follow the advice and guidelines given by the health authorities (Blair et al., 2017; Vinck et al., 2019), as well as investigating the interplay between scientific and non-scientific sources in modulating people's trust in healthcare information (Falade and Coultas, 2017). As for trust in science,

its role has been highlighted in a recent study by Plohl and Musil (2020): using structural equation modeling (SEM) on a sample of 525 international, English-speaking respondents, the authors investigated whether and how risk perception and norm compliance for the COVID-19 pandemic may be affected by several constructs, i.e., religious orthodoxy, conspiracy ideation, intellectual curiosity, and trust in science, all measured with validated scales. Their results indicate that trust in science is by far the most important factor in producing appropriate risk assessment and high level of norm compliance. At the same time, trust in science, as opposed to the tendency to believe in alternative non-official sources, has been observed to be deeply affected by polarization and homophily (Bessi et al., 2016).

Looking at the specifics of the COVID-19 pandemic, so far the most insidious threat posed by the virus has been the combination of the rapidity of its spread with the high number of patients requiring treatment in intensive care, resulting in unprecedented strain on the healthcare system of affected countries. This in turn has prompted an increasing number of national governments to adopt extreme measures to limit the spread of the virus, often imposing very demanding limitations on citizens' basic rights (e.g., social isolation, lockdown, and quarantine) and with dire socio-economic consequences (e.g., job insecurity, rising unemployment, loss of revenues, and inequalities). In such a unique scenario, the relevance of studying citizens' trust in public institutions is manifold: on the one hand, the effectiveness of these measures and the collective ability to overcome their costs is conditional on the compliance of the population, which in turn is affected by trust in institutions; for this same reason, institutions actively seek to promote citizens' trust, as a means to achieve their prevention goals; on the other hand, the very nature of the current crisis is likely to affect and shape how citizens conceptualize trust, and such socio-cognitive impact of the COVID-19 pandemic needs to be understood. Indeed, the current crisis acts as a magnifying glass in highlighting the essential role of trust in our societies (trust as "vinculum societatis," the bond of society, to borrow John Locke's famous expression), both for the psychological well-being of individuals and for the effective functioning of institutions.

The study presented in this paper contributes to this fast-growing body of knowledge on the interplay between trust in institutions and the COVID-19 pandemic, by discussing the results of a large scale survey (N = 4260) conducted on Italian citizens between March 9 and March 14, 2020. At that time, Italy had the most active outbreak of the virus worldwide, and its death count was growing at alarming rates; at the same time, extreme prevention measures were still relatively recent and rapidly changing in nature, sometimes from day to day (e.g., on March 11 new restrictions were introduced by the Government, closing public places such as restaurants, pubs, and most shops). Thus, our data offer insight into a time window in which the phenomenon was already in its acute phase in medical terms, yet still novel and unexpected for the population: this offers a privileged vantage point to observe how a pre-existing construct, trust in institutions, was affected by a sudden and profound change in the everyday functioning of the whole country, by a complete (albeit hopefully temporary) re-representation of one's role in society and in personal relationships, as well as in the relationship between citizens and institutions.

The survey was theoretically inspired by the socio-cognitive model of trust developed by Castelfranchi and Falcone (2010): we chose this theoretical framework because it provides a rich and nuanced description of various *reasons for trust*, thus allowing us to probe not only the degree by which Italian citizens expressed trust toward the relevant public authorities engaged in the response to COVID-19 but also on what grounds such attitude was based. Our purpose, however, was not to look for direct validation of the theoretical model, but rather to collect as many detailed data as possible on the rapidly evolving Italian response to the COVID-19 emergency, from the standpoint of institutional trust: in this sense, this study was mostly intended as explorative. In particular, we wanted to compare our results with the well-documented low levels of trust in institutions exhibited by Italians before the onset of the crisis, which some have associated with tardiness in responding to the COVID-19 emergency across various European countries (Oksanen et al., 2020): we intended to see whether such widespread distrust toward public institutions would be confirmed or subverted during the initial stages of the COVID-19 outbreak in Italy and to offer some insights and suggestions regarding the original and peculiar nature of any discontinuity in institutional trust that may be associated with the current pandemic.

Moreover, we intended to take a closer look at the cognitive and social factors responsible for trust toward public institutions in the face of pandemic threats: the survey was designed both to discriminate several potential predictors for trust, so that subsequent analysis would allow us to individuate the most relevant ones, and to facilitate comparison with the underlying theoretical model, thus emphasizing factors that, during this crisis, are exhibiting an anomalous impact on trust—either because they determine trust more intensely than usual (overcharged factors) or because their impact is minimal or non-existent (anesthetized factors). Indeed, a key hypothesis that we wanted to test concerns the impact of COVID-19 on the very nature of the institutional trust construct: not only the overall trust in public institutions is affected by the pandemic and how these institutions respond to it, but also *the determinants of trust in institutions change and adapt to this crisis*, in comparison with other situations. Desperate times require desperate measures, and desperate measures induce a drastic reconfiguration of the cognitive underpinnings of trust in institutions. Our survey was designed to collect data on such paradigm shift in how institutional trust was conceptualized by Italian citizens during the early stages of the national response to the COVID-19 pandemic.

MATERIALS AND METHODS

Sample

We used a snowball sampling method to determine the respondents: we collected a large sample (N = 4260, 57% women, mean age = 46 years, range = 18–85 years, SD = 13.42),

relatively well-balanced in terms of geographical provenance (33% Northern Italy, 39% Central Italy, and 28% Southern Italy and main islands), with a significant portion of respondents (30%) residing in the regions most affected by COVID-19 at that time (Lombardy, Veneto, Emilia-Romagna, Marche, and Piedmont). The relatively uniform geographical distribution of the sample among the three macro-areas of Italy, as well as the significant proportion of respondents from highly affected regions, allows interesting comparisons based on participants' residence. Moreover, the introduction of more drastic restrictions by the Italian Government at the end of March 11, 2020, invites considering also this temporal dimension in analyzing the data: in this respect, it is important that a fairly large set of participants (N = 829) completed the survey after those new restrictions had been introduced. Finally, it should be noted that the mean educational level of participants is very high: almost three quarters of respondents have a degree (38%) or post-graduate specialization (34%). The main characteristics of the sample are synthetized in **Table 1**.

Survey Structure

Data were collected with a 57-item questionnaire, using a five-point Likert scale for most items: an English translation of the whole questionnaire is available in the **Supplementary Materials**. The questionnaire was based on the socio-cognitive model of trust developed by Castelfranchi and Falcone (2010) and explored participants' opinions on five main dimensions, in relation to the current COVID-19 crisis in Italy:

1. The *competence* of public authorities, both in implementing the appropriate safety measures and in issuing behavioral guidelines for their citizens;
2. The *intentions* of public authorities regarding the containment of the Coronavirus, by means of both security measures and behavioral guidelines;
3. The *purposes and effectiveness* of the safety measures implemented by PAs; the perceived impact of safety norms on the participant's life, and his/her perception of other citizens' compliance to the norms;
4. The participant's *overall trust toward public authorities* and their motivations, the factors that determine the participant's trust; the sources of information he/she most uses and their perceived trustworthiness;
5. The participant's *expectations on the crisis' long-term effects on trust*, i.e., citizens' trust toward public authorities, scientists, and modern societies' development model, as well as trust between peer citizens.

The questionnaire was administered online using the Google Forms platform. The questionnaire fully complied with ethical guidelines for human subject research and participation was conditional on the preliminary approval of an informed consent by each subject; the compilation took an average time of 10 min. Data analysis was performed using the SPSS (version 22) statistical software: the collected data were first analyzed through correlation analyses (given the asymmetric distribution of most variables, we considered Spearman correlation values); secondly, given the high number of items in the questionnaire, we conducted a principal component analysis (PCA) on each sub-section of the questionnaire prior to running regression analyses on the aggregated data.

RESULTS

Descriptive Statistics

Full details on descriptive statistics for each item in the questionnaire are included in the **Supplementary Materials**, differentiating also based on geographical factors (Northern, Central, and Southern Italy; more affected vs. less affected regions) and temporal boundaries (before vs. after the March 11 announcement of new restrictions by the National Government). Here, we report only the most relevant findings, prior to more in-depth analysis, and only in terms of aggregate data, since no significant differences emerged at this level between different areas and different dates (albeit some interesting patterns were detected via regression analysis, see Section "Regression Analyses").

Relevant Public Authority

When asked to indicate which public authority is the most adequate to take decisions concerning the COVID-19 emergency (item 14 in the questionnaire), 72.8% indicated the National Government, 13.3% indicated the Civil Protection, 4.2%

indicated the Presidency of the Republic, 3.6% indicated the Regional Government, 0.9% indicated the municipal authority, and 5.2% indicated others. Hence, the overwhelming majority (90.3%) of respondents consider pandemics as a matter of national concern, which should be primarily addressed by national authorities. This should be taken into account while interpreting all other results, since most of the attitudes expressed by participants regarding features of public authorities (competence, intentionality, trust, etc.) should be understood with reference to national institutions, unless otherwise specified. Moreover, it is remarkable that the Presidency of the Republic, which is mostly a moral authority, is seen as having a greater role than Regional Governments, in spite of their leading role in the healthcare system, which in Italy is organized on a regional basis. Equally significant is the fact that only 0.1% of respondents (within the broader category "Others") indicated any kind of international entity, including the European Union, as having a primary role in facing a pandemic outbreak. In short, at this stage of the COVID-19 emergency, Italian citizens strongly believed that this pandemic was not to be prominently addressed by either regional or international authorities, but was rather mostly a matter of national concern.

Institutional Trust

When asked to rank their overall trust in public authorities for the management of the COVID-19 emergency (item 33 in the questionnaire), 75% of respondents manifested either extreme (23.8%) or high (51.2%) levels of trust, 17.7% were non-committal, and only 7.3% expressed distrust (see **Figure 1**, left panel). As we will see in the section "Discussion and Conclusions," these numbers are in sharp contrast, to say the least, with the average institutional trust reported for Italian citizens prior to the COVID-19 crisis, especially considering that the main target of this newfound trust was national public authorities (see above).

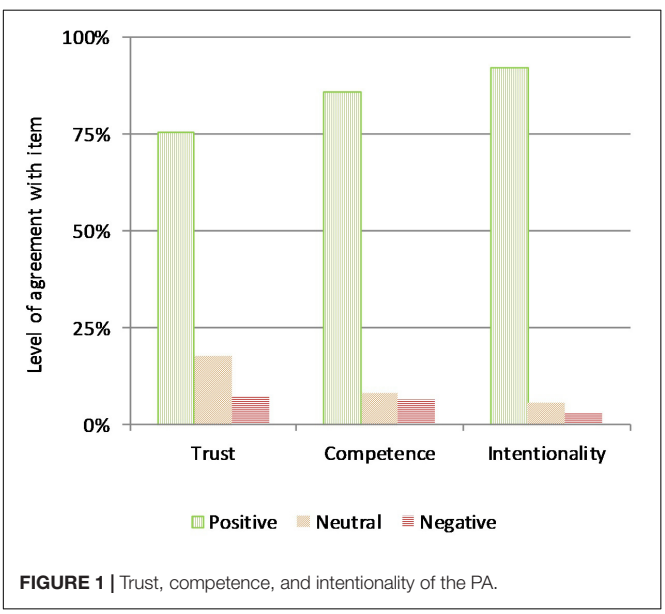

FIGURE 1 | Trust, competence, and intentionality of the PA.

Competence

The competence of public authorities was assessed as their ability in planning both the right prescriptive measures (e.g., lockdown) and the appropriate behavioral guidelines (e.g., personal hygiene recommendations). On both counts, the majority of respondents expressed a positive belief in the public authorities' competence (79.3% for measures, 82.7% for guidelines), whereas only a relatively small minority was either undecided (14.4% for measures, 11.4% for guidelines) or skeptical (6.3% for measures, 5.8% for guidelines). Moreover, correlational analysis indicates that competence scores for measures and guidelines are strongly and positively related ($R = 0.738$, $p < 0.0001$), suggesting that respondents did not really discriminate between prescriptive measures and behavioral guidelines, at least with respect to trust in public institutions: for this reason, in subsequent analyses, we collapsed these two items into a single competence value, calculated as the mean response for each subject to items 2 (competence on measures) and 3 (competence on guidelines) of the questionnaire (these are also the data reported in **Figure 1**, central panel). Other items in this section of the survey were designed to investigate the reasons behind participants' beliefs on the public authorities' competence: in summary, the overwhelming majority of the sample (91.8%) believed that it was the public authorities' proper prerogative to take action and issue containment measures against the pandemic (item 4), and most respondents (71.7%) positively evaluated the use of experts' advice by the public authorities during the COVID-19 crisis (item 5); there was instead less confidence in the organizational capacity demonstrated by public authorities in the early stages of the emergency (item 7: 44.8% expressed a positive evaluation, 33.6% were undecided, and 21.6% were critical), and the majority of the sample (54.3%) agreed that institutional communication on the COVID-19 presented some contradictions, either between different authorities or over time (item 6). In spite of these partial concerns, a significant majority of the sample (63.3%) did not express any skepticism on the competence of the public authorities in handling the emergency (item 8).

Intentionality

As for the competence, we inquired on the intentionality of public institutions separately for prescriptive measures and behavioral guidelines, asking participants whether they believed either type of intervention was both actively and honestly aimed at containing the COVID-19 pandemic. Again, respondents expressed an overwhelmingly positive belief in the good faith of public institutions, both in promulgating prescriptive measures (90.2%) and in issuing behavioral guidelines (89.1%): only a small minority was either undecided (7.1% for measures, 8.1% for guidelines) or skeptical (2.7% for measures, 2.8% for guidelines). Correlational analysis reveals again that intentionality scores for measures and guidelines are strongly and positively related ($R = 0.794$, $p < 0.0001$), further confirming that respondents did not really discriminate between prescriptive measures and behavioral guidelines, when it comes to assessing the public authorities' trustworthiness in this emergency: hence, these two items on intentionality were collapsed into a unique intentionality value in subsequent analyses, using the mean

response for each subject to items 9 (intentionality on measures) and 10 (intentionality on guidelines). Other items in this section of the survey were designed to investigate the reasons behind participants' confidence, or lack thereof, in the nature of the public authorities' intentions: in summary, we found confirmation of the fact that most respondents (72.1%) did not doubt that the intentions of the public authorities were consistent with their public statements (item 13), whereas a smaller majority (55.9%) considered the economic investment mobilized by the Italian public authorities sufficient to fight the pandemic (item 11: notice that only 16.4% considered it insufficient, with a significant portion of the sample, 27.7%, remaining undecided). Finally, asked whether other interests, e.g., political or economic, were at stake (item 12), the larger part of the sample (43.1%) answered in the negative, whereas 34.1% acknowledged the presence of such ulterior motives and 22.7% were unsure: as we will discuss further on, this question was probably easy to interpret in two markedly different senses—either negatively, as an accusation of having some hidden and problematic agenda, or positively, as the capacity to take into account all the key ramifications of the COVID-19 crisis, including its political and socio-economic aftermath. Overall, we registered strong confidence in the good faith of the intentions manifested by public institutions (**Figure 1**, right panel): this parallels the belief in the public authorities' competence, and together, these attitudes support the high levels of institutional trust expressed by this sample.

Purposes and Effectiveness of the Public Authorities' Intervention

Part of the survey was focused on the measures issued by public authorities as a response to the COVID-19 pandemic, in order to estimate both their perceived usefulness and the goal attributed to these interventions by the participants. The vast majority of our sample (85%) perceived these measures as being either useful (38.5%) or very useful (46.5%) in fighting the pandemic, whereas only a tiny minority was skeptical (2.6%), with the remaining 12.3% being undecided (item 15). When asked to assess the adequacy of the public authorities' intervention (item 32), a more abstract notion involving a counterfactual comparison with alternative strategies, the majority rated current measures as adequate (53.8%), 33.2% were undecided, and only 13% considered them inadequate. In terms of the motivations associated with these measures, we asked participants to express agreement on three potential, non-mutually exclusive aims: reassuring the population (item 16), curbing the spread of COVID-19 (item 17), and creating unmotivated alarm (item 18). The vast majority (89%) agreed that the rationale of the public authorities' intervention is indeed to contain the pandemic, whereas only 16.9% attributed to the public authorities the goal of reassuring citizens, and even fewer respondents (6%) regarded the proposed measures as a way of spreading unnecessary panic.

Impact of Containment and Beliefs on Compliance

When rating the personal burden of the proposed restrictions on their own lives (item 19), 39% of participants expressed to feel a high level of impact, whereas 29.6% indicated little discomfort for the current situation and the remaining 31.4% reported medium levels of distress. However, regardless of the perceived impact on the public authorities' intervention, the overwhelming majority of respondents agreed that such sacrifices were crucially beneficial for themselves and their families (item 20, 92.7% of agreement), for the society as a whole (item 21, 95.3%), and for both (item 22, 94.7%). Moreover, when asked to assess the usefulness of one's personal contribution to these preventive measures, since they were intended for the whole population (item 23, a question aimed at implicitly measuring any "free-riding inclination" in our sample), as many as 96.6% of the participants considered their personal role relevant for the collective effort. Taken together, these data show that, albeit different people suffered more or less because of the containment measures, almost all agreed on their usefulness and on the necessity of personal sacrifice to deal with the pandemic: this suggests a mindset in which the shared goal of public safety trumps any individual concern, including personal discomfort, fear, and anxiety (an interpretation later confirmed by regression analysis, see section "Regression Analyses"). In terms of expectations on compliance with the sanitary restrictions by other fellow citizens (items 24–27), we observe a fairly varied pattern of response (see **Figure 2**): the most widespread belief (48.6% of agreement) is that enough Italian citizens, albeit not all, will comply with the regulations, thus making them effective (item 25); in contrast, there is skepticism both on the most optimistic scenario, i.e., full compliance (item 24, 36.9% of disagreement), and on the bleakest outcome, i.e., insufficient compliance (item 27, 56.9% of disagreement), although it is worth noting that pessimism is rejected much more strongly than optimism. The possibility that only few people will comply, and yet their efforts will be useful (item 26), is also rejected by the relative majority of the sample (46.9% of disagreement), yet interpreting this result requires caution, since it could either express skepticism on

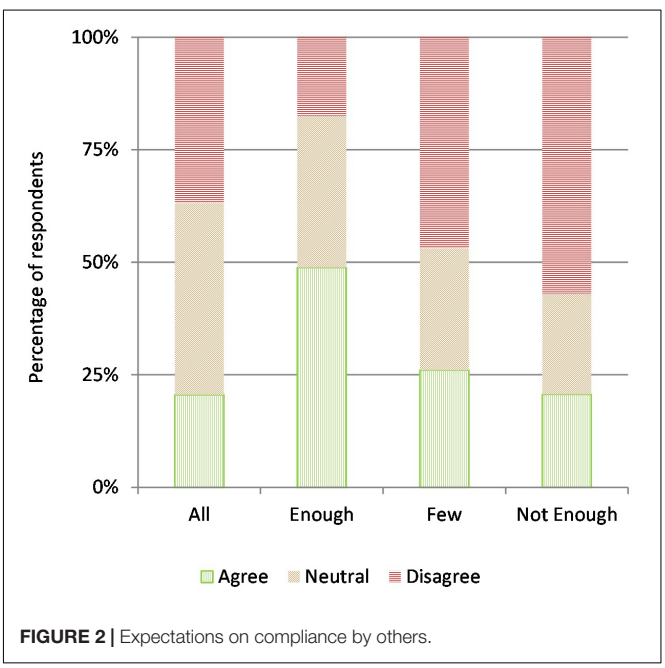

FIGURE 2 | Expectations on compliance by others.

how many people will comply, or on the chances that limited compliance may indeed be useful. Regarding the motivations useful to induce compliance, we asked participants to express agreement on four possible motivational triggers: the expectation that everybody else will follow the new regulations (item 28), a personal concern for dangers (item 29), a spirit of collaboration in the face of the emergency (item 30), and trust in the fact that public authorities are doing everything in their power (item 31). All four motivations engendered significant levels of agreement, with the highest being the feeling of a common cause against a shared threat (90%), followed by trust in maximum effort by the public authorities (83.8%), concern for the associated risks (80.6%), and expecting others to comply as well (79.2%). It is interesting to note that a motivation tied to the collaborative dimension of trust in civil society, i.e., being united in pursuing a common goal, shows more than 10 percentage points of distance from a motivation inspired instead by the sanctioning view of trust, i.e., being able to monitor compliance by others, possibly to punish free-riders, as well as from fear of personal harm: this suggests that emphasizing collaborative motives (a strategy employed quite consistently by the Italian Government in its public communications during the early stage of the COVID-19 outbreak) may be more effective in promoting compliance than stressing individualistic goals.

Reasons for Trusting Public Authorities

This section of the survey asked respondents to provide a meta-cognitive evaluation of the most relevant factors promoting their trust in how public institutions are handling the COVID-19 crisis. Of the eight factors explored, the type of measures adopted by the authorities was the most frequently cited as important (item 41, 80.2%), followed by the information received on the crisis (item 36, 71.4%), the capacity of public authorities to actually enforce protective measures (item 35, 52.2%), the respondent's profession (item 37, 46.9%) and his/her health condition (item 38, 40.6%), the opinions expressed by social relations such as friends and relatives (item 40, 37.3%) or colleagues (item 39, 35.9%), and the political connotation of the relevant authorities (item 34, 18.4%). Later on, we will use regression analysis to investigate the extent by which these self-reported data correspond to the relative weight of the actual factors affecting participants' trust in institutions. For now, it appears that participants self-describe their theory of trust in fairly objective terms, giving priority to the factual nature of the proposed measures, the information they gathered (apparently with the exception of social channels; see below), and the extent by which public authority is able to enforce their recommendations; in contrast, relatively little weight is given to personal factors and social networks, and none at all to political partisanship. This last result suggests that the public response to the COVID-19 crisis was initially perceived as a matter of shared concern of all political parties, which in turn prompted a temporary truce in the usual partisanship characteristic of Italian politics; moreover, in their efforts to deal with the emergency, public authorities were regarded mostly for their institutional role, with little attention to their political affiliation (even when such authorities were the expression of certain political parties, as it was the case with the National Government). This interpretation also helps to explain the extremely high level of trust in public institutions with respect to the COVID-19 emergency during those few days, in a population well-known for its deep-seated distrust of politicians in general, and of political parties in particular: further analysis of this interesting anomaly will be presented in the section "Discussion and Conclusion."

Information Sources

This section of the survey investigated both frequency of use (items 42–47) and perceived trustworthiness (items 48–52 and 54) of various types of information sources in relation to the COVID-19 pandemic, to get a better sense of what channels were most influential in affecting participants' opinions on this topic; in addition, we collected data on the trustworthiness directly assigned to public institutions as information sources (item 53), which was high for 77.6% of the sample, average for 17.7%, and low only for 4.6% of respondents. With respect to other information channels, the data summarized in **Table 2** highlight four main findings: (i) official online channels, e.g., the website of the Civil Protection, and scientists are both frequently used and considered reliable as information sources; (ii) in contrast, traditional media, albeit often consulted, are regarded as reliable only by less than half of our sample; (iii) family physicians are in general considered trustworthy, yet they are rarely used as information sources; (iv), finally, both social relationships and unofficial online sources, e.g., social media, are neither frequently used, nor widely believed. The result on unofficial online channels is especially surprising: whereas the very low credibility associated to these sources is understandable and even commendable, the fact that only one respondent out of four admits to using them frequently is hard to swallow, especially at a time in which personal contact was severely limited in Italy, thus making social media an even more attractive outlet for users. Besides, recent national statistics on Internet use in Italy do not agree with the picture painted by these data: according to the 2019 Global Digital Report[1], compiled annually by WeAreSocial and Hootsuite, in 2019, 58% of Italian citizens were active social media users (with a growing trend with respect to 2018), and the average time spent on social media every day was a little less than 2 h per person. Besides social desirability effects (respondents may have been reluctant to admit gathering information via unofficial channels on such delicate topics), a possible explanation for this anomaly is in a common misperception of the role of social media as gatekeepers: someone who finds on Facebook a link to an article on a traditional newspaper, or is made aware by a post on Twitter of the latest press release on the official website of the Civil Protection, may be inclined to disregard the role of the social media in bringing these information to the user's attention. Yet, this is how we use social media as information sources, often without even realizing it: we take advantage (or succumb, depending on the circumstances) of their agenda setting algorithms, which allow these platforms to act as powerful information brokers, rather than information producers.

TABLE 2 | Use and reliability of information sources.

Source	Use			Reliability		
	Frequent	Average	Infrequent	Trustworthy	Neutral	Untrustworthy
Traditional media	78.7	11.9	9.2	41.7	38.7	19.6
Official online channels (e.g., institutional websites)	77.8	12.2	10	89.6	8.1	2.3
Unofficial online channels (e.g., social media)	25.6	18	56.5	4.3	17.7	78
Family physicians	24.6	20.1	55.2	63	26.3	10.7
Scientists	70.6	15.6	13.8	92.6	6.2	1.2
Friends, relatives, acquaintances	16.6	29.2	54.2	7.3	33.2	59.5

Expectations on Long-Term Impact on Trust

The final section of the survey intended to probe participants' expectations on the long-term impact of the COVID-19 crisis on trust relationships between citizens and public institutions (item 55), between citizens and the dominant economic model of development (item 56), between citizens and the scientific community (item 57), and among citizens as peers (item 58). Here, the big winner is expected to be science: 72.8% of respondents believe that the current crisis will strengthen the trustworthiness of scientists as public figures. Expectations on the impact of trust toward public institutions and among citizens are less triumphant, yet still positive: 54.4% predict an increase in institutional trust after the COVID-19 pandemic, whereas 57% make the same prediction with respect to social trust, i.e., trust among peers. Finally, on future trust in the dominant model of economic development, our sample is evenly divided: 34% think that we will trust it more than before, 33.6% are undecided, and 32.4% expect an increase in distrust toward that model.

Principal Component Analysis

As a preliminary step before running regression analyses, we used PCA to identify strongly correlated items in the data set and simplify the variables' structure, in order to avoid multicollinearity issues in our regression models. Since the survey was theoretically motivated by the socio-cognitive model of trust (Castelfranchi and Falcone, 2010), we performed separate PCA on 10 subsets of items, to preserve relevant theory-based distinctions in the participants' responses. Item 33, degree of trust toward public authorities in relation to the COVID-19 pandemic, was not included in the PCAs, since it was intended to act as the target of the regression models; we also excluded items 8 (doubts on public authorities' competence) and 13 (doubts on public authorities' intentions), since these were included in the survey merely as control questions for, respectively, items 2–3 and items 9–10; moreover, we kept separate from the PCAs item 19 (personal discomfort associated with public authorities' measures), item 23 (usefulness of one's own personal contribution to the collective effort), and item 32 (overall adequacy of public authorities' measures), since we wanted to test their role as individual predictors in the regression models; finally, item 26 (expectation of very limited yet useful compliance by other citizens) was excluded for the PCA and regression analysis, due to the ambiguity in its interpretation already mentioned in Section "Descriptive Statistics." The remaining 49 items led to the individuation of 21 principal components, as summarized in **Table 3** (full details on the PCAs methods and results are provided in the **Supplementary Materials**). In order to be considered satisfactory, each PCA had to explain at least 50% of the cumulative variance, and further components were added only if they improved by more than 15% the explained variance.

Regression Analyses

In order to test our main hypotheses, we performed a multivariate regression model on raw data using IBM-SPSS 22 software. The dependent variable to be predicted was the overall trust manifested by participants toward public authorities involved in the COVID-19 response, i.e., item 33 in the survey. After some explorative iterations and based on theoretical considerations, we decided to include 22 independent variables in the final model: 15 principal components identified via PCAs (indicated with an asterisk in **Table 3**), 3 individual items that were conceptually independent from the other sections of the survey (personal discomfort associated with public authorities' measures, usefulness of personal contribution to the collective effort, overall adequacy of public authorities' measures), and 4 socio-demographic variables—age (coded as 1 = 18–40, 2 = 41–55, 3 = 56–85 years of age), educational level (coded as 1 = High school diploma or lower, 2 = University degree or higher), region of residence (coded as 1 = most affected regions, i.e., Lombardy, Emilia-Romagna, Veneto, Marche, and Piedmont, 2 = all other regions), and time of data collection (coded as 1 = before, 2 = after the March 11 new restrictions were announced). Preliminary analyses indicated that the respondent's profession did not affect responses, so we excluded it from the model; as for gender, preliminary regressions showed no difference in the predictors of institutional trust between male and female respondents, so we excluded it from the final regression model and performed a separate set of analyses to assess its impact in our data (see Section "Gender Effects").

We first run the regression analysis on the whole sample: the model had a good fit (R = 0.8) and explained 64% of the variance in the overall trust evaluation; 15 out of 22 independent variables were significantly correlated with trust ($p < 0.05$), and the most powerful predictors were positive indicators of competence of public authorities ($\beta = 0.31$, $p < 0.001$), perceived adequacy of the adopted measures ($\beta = 0.174$, $p < 0.001$), trustworthiness of official information sources ($\beta = 0.145$, $p < 0.001$), public authorities' intention to

The numbering used for items follows the order of presentation in the survey: the relevant items are from 2 to 58, since item 1 was the informed consent, whereas items 59–63 asked for demographic information. The asterisk (*) indicates principal components that were later used for regressions.

contain the pandemic ($\beta = 0.137$, $p < 0.001$), and perception that public authorities' efforts were focused on public safety, with no other agenda ($\beta = 0.101$, $p < 0.001$). All other significant predictors had an absolute value of β equal to or lower than 0.05. The non-significant predictors were personal discomfort due to the adopted measures, perceived usefulness of personal sacrifice, expectation of sufficient compliance (but notice that expectation of universal compliance was positively correlated with trust, whereas expectation of insufficient compliance was negatively correlated with it, both $p < 0.005$, suggesting an "all or nothing" attitude toward compliance), individualistic reasons for compliance (while collectivist reasons for compliance were strongly and positively associated with trust, $p < 0.001$), educational level, time of data collection, and age (the last one showed a marginally significant negative correlation, $\beta = -0.018$, $p = 0.06$).

We also applied the same regression model to subsets of participants, distinguishing first geographically (most afflicted regions vs. all other regions), then temporally (before and after the announcement of new restrictions by the Italian Government on March 11), in order to detect differences in how trust was processed depending on the severity of the sanitary emergency in various areas, and the strictness of the measures implemented by public authorities while the pandemic was still progressing. We already knew from descriptive statistics that no overall change in trust toward public authorities was observed across these contexts, yet we wanted to probe for more subtle differences, e.g., different predictors of trust, or different contribution of the same predictors, depending on region of residence and time of data submission. All β and *p*-values for the various multiple regressions are reported in **Table 4**; in what follows, we will focus only on the most relevant results.

Applying the model only to participants from the most affected regions in Italy at that time (Lombardy, Emilia-Romagna, Veneto, Marche, and Piedmont) revealed again a good fit ($R = 0.825$), explaining 68.1% of variance in trust assessment; the same model also had a good fit when applied only to participants from all other Italian regions ($R = 0.788$, 62.1% of explained variance). In both cases, the strongest predictors remained the same as in the whole sample, and also their order of importance was identical across regions, regardless of current outbreak severity ($p < 0.001$ for all the following predictors): positive indicators of competence (most affected: $\beta = 0.352$; other regions: $\beta = 0.289$), adequacy of the adopted measures (most affected: $\beta = 0.146$; other regions: $\beta = 0.184$), trustworthiness of official information sources (most affected: $\beta = 0.134$; other regions: $\beta = 0.149$), PA's intention to contain the pandemic (most affected: $\beta = 0.119$; other regions: $\beta = 0.146$), and perception that public authorities' efforts are focused on public safety, with no other agenda (most affected: $\beta = 0.113$; other regions: $\beta = 0.96$). In spite of the substantial similarity in how trust in public authorities was attributed by respondents in different areas of the country, some fine-grained distinctions emerge looking at those factors that were significant in one context but not in the other—and also exercising due caution, since a difference in significance does not necessarily imply a significant difference. In the most affected regions, we observed eight non-significant predictors, whereas there were only six in the other regions: four of these factors were irrelevant across both contexts (personal discomfort, perceived usefulness of the sacrifices, individualistic reasons for compliance, and time of data collection), whereas negative factors

TABLE 4 | Multiple regression analysis: β and *p*-values for the whole sample, for region of residence (most affected vs. others), and for time of data submission (before vs. after new restrictions were announced on March 11).

	All		Most affected		Other regions		Before new restrictions		After new restrictions

Predictors are clustered based on their thematic similarity.

affecting competence of public authorities, intention to downplay the emergency, impact of personal effort, and trustworthiness of unofficial information sources were immaterial for respondents from the most affected areas, whereas they acted as significant predictors (albeit weak ones) for participants from other regions of Italy; in contrast, an expectation of sufficient compliance from other people had a significant negative correlation with trust in the most affected regions ($\beta = -0.047$, $p = 0.02$), whereas it had a marginally significant positive correlation with it elsewhere ($\beta = 0.026$, $p = 0.05$). Taken together, these results suggest that participants living in areas that were currently experiencing very severe outbreaks of COVID-19 had a more focused mindset when deciding whether to trust public authorities to deal with the emergency: less factors were considered relevant, and in particular, it was probably taken for granted that some inconsistency in public communication and intervention may occur, without necessarily jeopardizing trust (negative factors on competence), and that unofficial sources were not to be taken seriously when deciding whom to trust; at the same time, expecting that only a sufficient number of people would comply with the emergency measures had a negative impact on trust in public authorities, probably highlighting the fact that, in those regions, people believed that "enough is not enough"—that is, either everybody cooperates in facing the crisis (universal compliance) or we will not be successful in overcoming it. This extreme mindset is confirmed by the fact that the relevance of one's own personal contribution did not affect trust attribution to public authorities in the most affected regions, whereas it did in other areas: this indicates again that collective compliance, not personal efforts, are perceived as the key to success by people currently facing the worst of the COVID-19 pandemic.

Looking instead for short-term shifts in trust assessment over time, in relation to relevant public events (i.e., the introduction of new measures by the Italian Government on March 11), we divided our sample based on time of data submission: before or after the public press release when the Prime Minister Giuseppe Conte announced the new restrictions to be implemented nationwide, to contain the COVID-19 outbreak. The model performed well across both time windows (before: $R = 0.799$, 63.8% explained variance; after: $R = 0.806$, 64.9% explained variance) and the strongest predictors remained the same, as well as their relative order of importance ($p < 0.001$ for all the following predictors): positive factors affecting competence of public authorities (before: $\beta = 0.311$; after: $\beta = 0.293$), perceived adequacy of the adopted measures (before: $\beta = 0.171$; after: $\beta = 0.183$), trustworthiness of official information sources (before: $\beta = 0.149$; after: $\beta = 0.117$), attributing to public authorities the intention to contain the pandemic (before: $\beta = 0.143$; after: $\beta = 0.108$), and the perception that their efforts were focused on public safety, with no other agenda (before: $\beta = 0.103$; after: $\beta = 0.096$). Again, we observed substantial stability over time in how trust in public authorities was attributed, with minor differences emerging only by comparing the significance and direction of some secondary variables.

In general, the introduction of more severe restrictions had the effect of simplifying the metrics used to assess trust toward public authorities: before the March 11 announcement, only four variables failed to correlate significantly with trust, whereas after it, the number of irrelevant predictors increased to 8, indicating a more narrowly focused mindset in assessing the trustworthiness of the institutions in charge of dealing with the emergency. In particular, intention to downplay the emergency, personal discomfort associated with the proposed measures, and trustworthiness of unofficial information sources became irrelevant for trust in public authorities; unfortunately, the expectation of universal compliance also became equally irrelevant (before: $\beta = 0.043$, $p = 0.001$; after: $\beta = -0.006$, $p = 0.81$), while the negative correlation between expectation of insufficient compliance and trust was much stronger after the March 11 announcement (before: $\beta = -0.024$, $p = 0.04$; after: $\beta = -0.083$, $p = 0.001$). This suggests a turn for the worst in people's expectations: before the new restrictions, trust was positively supported by expectation of universal compliance (the more I believe all others will behave responsibly, the more I trust the authorities), whereas after them, the influence of pessimistic fear became dominant (the more I doubt enough people will comply, the less I trust the authorities). As a possible reaction to this shift, it is worth noting that the positive correlation between impact of personal efforts in the COVID-19 response and trust in public authorities became significant only after March 11 (before: $\beta = 0.023$, $p = 0.09$; after: $\beta = 0.062$, $p = 0.03$), suggesting that the new measures strengthened in Italian citizens a sense of personal responsibility for the collective reaction to the virus. Finally, region of residence was a significant (albeit weak) predictor of trust before, but not after, the announcement of new restrictions by the Italian Government (before: $\beta = -0.035$, $p < 0.001$; after: $\beta = -0.01$, $p = 0.65$): this shows a stronger tendency to trust public authorities in the most affected regions before March 11, whereas this was no longer true after that date. Since overall trust in public authorities did not decrease after March 11 in the whole sample, this indicates a leveling in trust attribution across the country after the introduction of new measures, which in turn could be interpreted as a shift in the perception of the emergency: whereas in early March, a significant part of the Italian population still believed the outbreak to be somehow contained to specific regions, and thus a local problem unlikely to affect everybody in the same way, the nationwide interventions announced on March 11 made it crystal clear to all that COVID-19 was indeed a national concern.

Overall, these regression analyses show that, in Italy, trust in the capacity of public authorities to deal with the COVID-19 emergency was attributed in a fairly consistent manner during the time window of this survey (March 9–14, 2020) across different areas of the country, giving central prominence to positive indicators of competence in public institutions, assessing the adequacy of the proposed measures, verifying that proper intentions supported their application, and paying attention mostly to official information sources. All considered, this suggests a fairly reasonable and well-balanced judgment-making process for trust attribution, while the true anomaly remains the high levels of trust in public authorities recorded during the early stages of this emergency (see Section "Descriptive Statistics"), which are in sharp contrast with both long-term trends and recent surveys on institutional trust in Italy, prior to the COVID-19 pandemic. At a more fine-grained level, region of residence and time of data completion did reveal some interesting shifts in trust assessment, yet these insights should be interpreted carefully, since they concern relatively minor changes in the significance of secondary predictors, within a regression model with a high number of independent variables.

Gender Effects

Comparing male and female respondents, a χ^2 test revealed a small but significant difference ($p = 0.004$) in institutional trust in relation to the COVID-19 emergency: in particular, men were more likely to express high levels of trust toward public authorities involved in contrasting the outbreak (76.1% men vs. 74.3% women), whereas women were more often neutral (19.1% women vs. 15.7% men). Running the regression model described in Section "Regression Analyses" separately on male and female respondents showed that, although the main predictors remained the same (positive indicators of competence, adequacy of the measures, trustworthiness of official information sources, public intention to contain the pandemic, and institutional focus on public safety), age and region of residence were significant predictors only for women and not for men (AGE: women $\beta = -0.026$, $p = 0.05$, men $\beta = -0.009$, $p = 0.516$; REGION: women $\beta = -0.052$, $p < 0.001$, men $\beta = 0.001$, $p = 0.964$). To further investigate this interaction between gender and other socio-demographic factors influencing institutional trust during the COVID-19 emergency, we run a trivariate analysis on, respectively, gender × age × trust and gender × region × trust. The first analysis revealed that gender effects on institutional trust are significant ($p = 0.038$) only in the age range 56–85 years, which is also the most vulnerable to the virus: among respondents in this age range, the majority of those that expressed low levels of institutional trust were male (60%), whereas most of those neutral or highly trustful were female (59.4 and 53.8%, respectively). It is also worth noting that, after performing a bivariate analysis on the impact of age on trust, we found a highly significant effect ($p < 0.001$), with 86.1% of elderly respondents (56–85 years old) expressing high trust in public authorities, whereas this percentage drops to 69.6% for participants in between 18 and 40 years of age: this further confirms the role of vulnerability to the COVID-19 virus in eliciting higher attributions of trust, and it is consistent with previous findings on a negative correlation between age and willingness to comply with social distancing measures during the COVID-19 pandemic (Wirz et al., 2020). The second analysis showed that the relationship between gender and institutional trust is significant ($p = 0.027$) only in those regions that were most affected by the COVID-19 outbreak: in these areas, most of the respondents that manifested distrust in public authorities were men (55.5%), while the majority of the neutral and trustful participants were women (60.1 and 55.4%, respectively). Taken together, these results suggest that, whenever the situation was most critical (i.e., for the most vulnerable age range and in the most affected regions), men were overrepresented in the (small) group of people expressing distrust

toward public authorities, whereas women were overrepresented among those neutral or trustful. Although this may suggest an interesting gender effect on resilience under extreme stress (women seem more likely than men to suspend judgment or look on the bright side, precisely when the situation is the most dire), it is worth noting that, regardless of gender, only a small minority of respondents were expressing distrust toward public authorities, even in the most affected age range (men 6.7%, female 3.8%) and in the most affected regions (men 10.8%, female 7.1%). Thus, these gender effects invite further investigation, but on their own, they do not justify any hasty conclusion on how different genders may react against health emergencies.

DISCUSSION AND CONCLUSION

The most striking result of this survey is the very high level of institutional trust expressed by respondents: 75% of them trust Italian public authorities to be able to deal with the COVID-19 emergency. This is in sharp contrast with the relatively low levels of institutional trust characteristic of Italy, both historically and in recent surveys: according to the DEMOS & PI 22nd annual report on "The Italians and the State"[2], based on a large representative sample (N = 1212) of Italian citizens over 15 years of age interviewed in December 2019, only 22% respondents trusted the State, whereas both Regional Governments (30%), European Union (34%), and municipal authorities (38%) fared better, while political parties were in the worst shape, with only 9 Italians out of 100 willing to trust them; in fact, of the main national institutions, the only one with decent levels of trust was the Presidency of the Republic (55%, still in sharp decline with comparison to 10 years before, in 2009, when it was as high as 70%). Also international estimates indicated relatively low levels of institutional trust: according to the Eurofound report on Eurofound (2018), Italians' trust in the national government has been declining in the last few decades and is now below 20%, while the more recent data of the Eurispes Report–Italy 2020[3], presented in February 2020, indicated trust in institutions at 14.6% (6.2 points lower than in 2019). Institutional trust in Italy in recent years is extremely weak not only in absolute terms but also in relation to other European countries: in their comparison of 25 EU states, based on data from the 2016 European Social Survey, Oksanen et al. (2020) reported very low levels of institutional trust in Italy, measured by respondents' trust in five institutions (Parliament, politicians, political parties, the police, and the legal system); in fact, only Cyprus, Poland, Slovakia, and Bulgaria expressed stronger institutional distrust than Italy.

Moreover, this trend toward widespread distrust of public institutions is not a particularly recent feature of Italian politics: while in recent decades, it developed mostly against the backdrop of increasing tensions between populist movements and traditional political parties (Urbinati, 2019), massive erosion of public confidence in political figures was already ongoing in Italy well before the recent resurgence of populism worldwide—in the last decade of the 20th century, following the corruption scandals of Tangentopoli and its media resonance (Giglioli, 1996; Vannucci, 2009), and with the largely failed shift toward bipolarism during the Berlusconi age (Viroli, 2011). Even before that, a longitudinal analysis reveals that the confidence gap between electors and political institutions, characteristic of many post-WWII democracies, appeared in Italy much earlier than in other countries (Segatti, 2006)—so much so, that already in the 1960s LaPalombara (1965), a highly influential political scientist, described Italians' attitudes toward politics with three emblematic words: alienation, fragmentation, and isolation.

Such a deeply rooted tradition of distrust in public institutions underscores the importance of the opposite trend registered in our survey, i.e., a sudden boost in institutional trust prompted by the COVID-19 crisis—a significant result that is also supported by other data collected in this survey, as seen in the "Results" section. Moreover, insofar as this newfound trust is grounded on trust in the expertise of the scientific authorities involved, it is also at odds with the widespread anti-scientific sentiment considered to be on the rise at the global level, variously stigmatized as "the death of expertise" (Nichols, 2017) and the crisis of epistemic deference (Marconi, 2019).

Surprising as it may be, there are several reasons to consider this finding on trust as reliable:

(i) Internal consistency: as discussed in Section "Results," all other responses to the survey are consistent with a high attribution of trust to public authorities and indeed provide justification for such attribution.

(ii) External validation: just a few days after data collection for this study was concluded, a survey on a representative sample of Italian citizens (N = 1028, 16–17 March 2020) was conducted by the independent research center Demos & Pi[4], providing substantial support to our main results: e.g., 71% trust both the Italian Government and the current Prime Minister, with 94% approval of the adopted measures, strong endorsement for the sanitary system (94%), the Civil Protection (88%), and the National Government (82%), coupled with lower levels of confidence in political parties (none of them above 30% of approval) and a rising skepticism toward the European Union (80% of respondents believe the Italian response to the COVID-19 emergency to be better than that of other EU countries, and only 35% consider the role played by the EU as positive in this crisis).

(iii) Low chances of social desirability effects: as demonstrated by the very low levels of institutional trust recorded in previous surveys, including recent ones, Italians have no qualms expressing public distrust toward public authorities—quite the opposite, in fact. Thus, there is no reason to assume that the current data on trust are inflated by social desirability effects.

Thus, there is a genuine phenomenon to be explained here: a veridical "trust boom" during the early stages of the COVID-19 crisis in Italy. The socio-cognitive theory of trust (Castelfranchi and Falcone, 2010) that inspired our survey provides the tools needed to craft a tentative interpretation of this remarkable fact, although the questionnaire itself was designed to record such a phenomenon, rather than explain it. Thus, the speculative nature of our interpretation cannot be stressed enough: our study revealed a highly significant and surprising phenomenon, for which now we look for an explanation. The interpretation we favor is the one that, to the best of our knowledge, appears more adequate to account for the pattern of results obtained in this survey; later on, we will contrast it with other alternative explanations and argue in favor of its superiority. Nonetheless, such interpretation remains tentative, and it is intended as a springboard and an inspiration for further studies that may either confirm or falsify it, rather than as something set in stone.

With this in mind, let us focus on the fact that trust, at its cognitive core, entails the decision to delegate to someone else (the trustee) the realization of a goal that is important to the agent who is expressing trust (the trustor). As a result, being able to choose not to trust someone requires either having alternative means to achieve the desired goal (e.g., "I will do it myself" or "I will delegate it to someone else") or being ready to forsake that goal. However, neither of these options are available in the face of a pandemic: the relevant goal is personal and public safety, which is non-negotiable, i.e., it is not something we can decide to forget about, and the only course of action that offers reasonable chances of achieving it is to put our collective trust in public authorities, since there are no other available agencies we might appeal to (indeed, the only choice we have concerns the level of public authority we should confide in, and our sample clearly indicated the national level as the most pertinent one).

In other words, a pandemic like COVID-19 creates the preconditions for a collective case of *necessary trust in public authorities*, or institutional trust by force majeure: not in the sense that we are being manipulated by some hidden power, as some conspiracy theorists may be prone to believe, but because the very nature of the health crisis leaves us with no other option than to put our trust in public authorities (that is why we emphasize a need, a necessity for trust). It is worth noting that these pressures toward trust between citizens and public authorities in times of sanitary crisis are symmetrical: citizens have no alternatives to reliance in the relevant public institutions, yet these institutions themselves cannot help but trust in civic compliance to the proposed regulations, on pain of failure in containing the contagion, due to the limits of enforcement already emphasized in previous studies (Siegrist and Zingg, 2014; Lewnard and Lo, 2020; Olsen and Hjorth, 2020; Van Bavel et al., 2020). Necessary trust is a two-way street in health emergencies, for both citizens and public authorities.

Moreover, this two-way street is often cyclically traveled: in fact, the citizens themselves become fully aware (perceive the request and expectation) of the need for public authorities to receive the right degree of trust from citizens as a tool for achieving the *common* goal, and this awareness becomes one of the reasons for citizens to trust public authorities themselves. In other words, in the best-case scenario, this becomes a trust-based "alliance" toward a supreme common purpose. This civic alliance, or social pact, is grounded in a specific dynamic of trust: the trustor deliberately bestows trust on the trustee, even if partially skeptical of the trustee's qualities, in an attempt of motivating the trustee to "rise to the occasion" and *become* trustworthy. This is the sense in which trust breeds trust, as noted both by trust theorists (e.g., Falcone and Castelfranchi, 2001b) and by political economists (e.g., Feld and Frey, 2002). In the context of the early stages of the COVID-19 pandemic in Italy, we suggest that Italian citizens put their trust in public authorities in charge of facing the crisis as a way of opening up a "trust credit line" and thus putting pressure on such authorities to prove themselves worthy of that credit. Similarly, public authorities frequently manifested full trust in citizens' compliance with regulations (a topos often belabored on public occasions by all institutional actors, including the Prime Minister, the President of the Republic, and representatives of the Civil Protection), precisely for the same reason: by declaring their trust in the common sense and civic responsibility of Italian citizens, they were putting pressure on citizens to actually demonstrate such qualities.

Clearly, the objective need for trust created by a pandemic does not automatically evolve in greater trust toward public institutions. That need may find different outlets, so that other, bleaker outcomes may be equally possible: for instance, an already vulnerable trust relationship between citizens and public authorities may be shattered completely by a sudden crisis, especially if such crisis (or its poor management) are blamed on those authorities, possibly leading to a severe governmental crisis, and maybe even a takeover by authoritarian forces, or, in another scenario, public trust toward central authorities may dissolve, with citizens taking a turn toward tribalism and trying to face the crisis at the local level.[5] While these options are certainly viable in general, our results suggest that neither of these paths was being seriously considered by most Italian citizens in early March 2020: our survey revealed a sudden increase of trust toward public institutions, rather than its collapse or further erosion, and that trust was directed toward national authorities, not toward specific charismatic leaders or local powers. According to our findings, faced with an unexpected need for public trust, the Italian people in early March 2020 opted for putting their trust (at long last) in their elected representatives at the national level, rather than turning to authoritarian figures or local authorities for solutions. Beyond the evidence of our data, how the management of the pandemic unfolded over those weeks provides further support to this interpretation. The Italian Government consistently acted as a mediator between all the social forces affected by the crisis, repeatedly demonstrating high reliance on the indications of the experts in crafting every containment measure: in short, the national authorities acted as the very antithesis of an authoritarian leader. At the same time, local authorities at all levels were relying on the guidance of the National Government for facing the pandemic and, in some cases, were actively asking for its direct intervention to solve a crisis that

[5]We are grateful to one of the reviewers for pointing out the importance of considering also these alternative scenarios.

they were not equipped to deal with; more generally, there was widespread consensus, both in political debate and in the media, on the need for a national response to the COVID-19 emergency (a need well understood by our participants, as seen in the section "Results"). Again, an attitude that stands in sharp contrast with any shift toward tribalism.

Thus, assuming that the need for public trust prompted the high levels of institutional trust manifested by participants, we propose to interpret their other responses within the broad framework of motivated reasoning (Kunda, 1990) and cognitive dissonance theory (Festinger, 1957): as the chosen path to pursue the paramount goal of personal and public safety, trusting public authorities became in turn a necessary instrumental goal, thus coloring all other attitudes expressed by the respondents; more precisely, it prompted them to *actively look for reasons to justify their (unavoidable) trust in public authorities*, in order to minimize cognitive dissonance. Indeed, the need for trust experienced by Italian citizens during the COVID-19 emergency was at odds with their widespread attitude of distrust toward the very same public authorities they now needed to rely upon in the face of the outbreak: this, we argue, produced a massive and sudden shift in their perception of those public authorities, to better accommodate the new reality they had to deal with. In this interpretation, the trust boom observed in the survey was not produced by any collective epiphany on the actual qualities of the public institutions involved, but rather by a cognitive realignment of individual attributions to the current needs citizens were experiencing. All of a sudden, Italian citizens found themselves pressured to rely on some key public authorities in ways and to a degree never experienced before, at least since the worst days of World War II. Regardless of how well these authorities behaved in the first stages of the COVID-19 crisis, Italians opted to re-frame their attributional states in a way that made this novel institutional trust justified, thus flipping the usual causal connection involved in acts of trust: it is not a case of detecting the appropriate qualities in public authorities and therefore deciding to trust them, but rather an instance of having first the need to trust those authorities and then justify such trust by *assuming* that these authorities would manifest the qualities required to warrant that trust. This is also justified and supported by the implicit pact with which public authorities communicated the need for this responsible and trusted attitude toward them as decisive for the achievement of the common purpose.

It is worth noting that our reliance on motivated reasoning to explain some of these survey data is very different from the most common use of this notion in recent studies on public opinion: although originally conceived in much broader terms (Kunda, 1990), motivated reasoning in recent decades has become more and more associated with political ideology, with several studies investigating how partisan affiliations affect and filter our beliefs on matters of public interest (e.g., Redlawsk, 2002; Slothuus and de Vreese, 2010; Kahan, 2013; Bolsen et al., 2014). In fact, the same approach has been applied, with mixed results, to the public reaction to the COVID-19 pandemic, e.g., looking at how political partisanship affected people's ability to discriminate between reliable information and fake news (Pennycook et al., 2020), timeliness in the adoption of restriction measures (Rosenfeld, 2020), health behaviors (Kushner Gadarian et al., 2020), and compliance with social distancing guidelines (Rothgerber et al., 2020) and stay-at-home regulations (Goldstein and Wiedemann, 2020). While the relevance of politically grounded motivated reasoning provides an interesting perspective on public opinion dynamics, other predictors have been found to be more relevant in explaining some of the target phenomena (e.g., fake news vulnerability, see Pennycook and Rand, 2019); more to the point, this is not the type of motivated reasoning we are discussing here. On the contrary, our data show no effect of political partisanship on trust attributions toward Italian public authorities in charge of coordinating the COVID-19 response, including those that did have a clear political connotation, e.g., the National Government. Instead, we appeal to the notion of motivated reasoning in relation to *a manifestly non-partisan goal*, i.e., public safety, and the related need to trust public authorities to be able to ensure such goal: this is the kind of motivated reasoning we argue influenced responses in our sample, independently from the political affiliation of either the survey participants or the relevant public authorities.

Alongside the preservation of consistency in citizens' beliefs toward public authorities, there is also another, more emotional path through which a need for trust may generate broader shifts in public perception. As noted by many trust theorists (Luhmann, 1979; Gambetta, 1988; Batson, 1991; Hardin, 2002) and also described in the socio-cognitive model adopted here (Falcone and Castelfranchi, 2001a; Castelfranchi and Falcone, 2010), a fundamental function of trust is to allow both individuals and groups to face uncertainty, to moderate it and deal with it. Trusting someone or something immediately reduces the perception of risk; in this sense, trust offers the advantage of a subjective sense of safety, before and without being able to reach that safety objectively. It allows us to face the risk and take it, partially by giving us control over part of that risk, since trusting implies actively choosing to expose ourselves to a risk, i.e., the risk of having our trust betrayed (Mayer et al., 1995). This is why Koller (1988) individuated risk as a key determinant of trust, in the sense that a risky situation may bias people toward trustworthiness when assessing potential allies in facing such risk: "To the degree that the individual fears the occurrence of an event of negative valence (...) he exaggerates the subjective probability of an event of positive valence, which implies that he expects the interaction partner to behave promotively" (Koller, 1988, p. 275). This is very much in line with the higher levels of trust we observed in the most vulnerable age groups and in the Italian regions most affected by the COVID-19 outbreak (see Section "Gender Effects"). In the context of a health emergency such as the COVID-19 pandemic, this subjective dimension of trust becomes particularly apparent: consider how physicians and nurses in Italy turned overnight from marginalized workers in a distrusted field to the most revered national heroes. The individual and collective gain of this sudden change of perception is obvious: faced with the danger of contracting a deadly virus, the belief that your life will be in the hands of trusted professionals is incredibly valuable, not only for the unlucky few that will actually have to rely on those professionals, but for everybody,

since it greatly helps in calming down their fear and anxiety. In this perspective, the trust boom recorded in our survey should be considered not only as a merely intellectualistic attitude but also as a response with deep emotional undertones: this is the type of trust that is not only cognitively justified, but also *felt*, insofar as it provides us with the calmness needed to remain productive under the extreme stress of a pandemic.

It is worth noting that emphasizing the motivated nature of institutional trust during a pandemic is not the same as treating this newfound trust in Italian public authorities as a fiction, just a desperate figment of the imagination of a population looking for solace from a terrible crisis. Nothing could be farther from the truth: precisely because this institutional trust was experienced as a matter of necessity by the Italian people, it is also genuinely (and dramatically) authentic. Italian citizens, during those terrible days in early March 2020, truly believed that public authorities would prove themselves worthy of their trust—possibly for the first time after many decades of increasing institutional distrust. Yet, it is a very fragile belief, because it is massively based on assumptions: should the public authorities subsequently fail to prove themselves equal to the task at hand, this huge "trust credit" would come due, producing an even bigger backlash in terms of the gap between citizens and institutions. This would indicate the clear failure of an "alliance" in which citizens have invested their trust in public authorities. On the other hand, an actual demonstration of trustworthiness by the public authorities during the COVID-19 emergency may engender a more durable and long overdue step change in institutional trust in Italy. As the Nobel prize Joseph Stiglitz put it in a recent interview to the Italian newspaper *La Repubblica*[6] (30 April 2020), we should "not waste this crisis," since it opens up genuinely new opportunities for rethinking the fabric of our societies. What is more, respondents in our sample were fairly optimistic on the future of trust relationships with their institutions, with scientists, and among themselves, while expressing reservations on the adequacy of the current economic model (see Section "Descriptive Statistics"). However, optimism is, by its very nature, a delicate thing, so the danger of experiencing a "trust crack" right after the initial trust boom is as real as ever.

Indeed, other ongoing research on the relationship between institutional trust and public response to the COVID-19 emergency may invite a bleaker outlook on how things will unfold: in their comparison of data from 25 European countries, Oksanen et al. (2020) highlighted a negative correlation between institutional trust prior to the crisis and the delay in introducing restrictions to curtail contagion—the less trust was manifested in public authorities before the COVID-19 outbreak, the more time passed after the first confirmed virus-related death and the introduction of containment measures. While we do not dispute the role of institutional trust as a protective factor against virus outbreaks (already well documented with Ebola, see Blair et al., 2017; Vinck et al., 2019), we are skeptical of the particular correlation observed by Oksanen et al. (2020), since it does not take into account the fact that different European countries were affected by the COVID-19 outbreak at different times: in particular, Italy, France, and Spain [all "late intervention countries," according to Oksanen et al. (2020)] were among the first countries to record severe outbreaks, and much of the measures later adopted by other countries were largely based on the evidence coming in from these first, unwilling testbeds for the public response to the virus. This is confirmed by the same data used by Oksanen et al. (2020): in terms of absolute dates, Italy was among the first countries to endorse all the five types of interventions considered in their study, much earlier than many others that are instead regarded as "early adopters." Moreover, the alleged correlation considers only the adoption of some form of interventions, without discriminating between countries that adopted all of them (like Italy) or just a few, sometimes even only one (as in the case of Sweden). This is probably why subsequent data do not seem to support the proposed correlation: for instance, Sweden, one of the countries with one of the highest levels of institutional trust before COVID-19, as of May 11, 2020 has a very high ratio to the number of deaths per million inhabitants (among the top six nations in the world); similarly, Belgium, where containment measures were adopted much more promptly than in Italy according to Oksanen et al. (2020), in early May 2020 had the world's highest number of COVID-19 confirmed deaths per million inhabitants. For all these reasons, we are not persuaded that prior institutional trust was the main factor determining timely adoption of containment measures by public authorities: while early intervention remains critical in facing virus outbreak, in the case of COVID-19, we believe that this was determined mostly by other factors, e.g., where the outbreak manifested sooner in Europe.

Looking at the main predictors of trust highlighted by our regression analyses, respondents exhibited a matter-of-fact, evidence-based attributional strategy toward public authorities: consistently with the socio-cognitive model of Castelfranchi and Falcone (2010), competence, intentionality, trustworthiness as information sources, and the perceived adequacy of the proposed interventions were the most relevant factors in justifying trust in public authorities. The relevance given to the role of public authorities as information sources is also consistent with the significant weight that information has in shaping participants' institutional trust, based both on their own self-report and on regression analysis (see Sections "Descriptive Statistics" and "Regression Analyses"): this highlights the importance of feedback and control for trust. Even when trust on public authorities is perceived as a necessity by citizens, they try to retain a measure of control over it, by monitoring the quality of institutional information channels. Equally suggestive are some of the factors that failed to impact institutional trust in our sample: most notably, the amount of personal sacrifice imposed upon participants by the restrictions introduced by the Government. Significantly, this dimension did not affect citizens' trust in public authorities, contrary to what would be reasonable to expect under different circumstances: this, in turn, provides further support to our interpretation of the observed trust boom as a matter of necessity—insofar as public safety is the paramount goal, the severity of the necessary costs are immaterial

[6]Carofiglio, G. (2020, April 30). *Joseph Stiglitz: "Non sprecate questa crisi."* La Repubblica, Retrieved from https://rep.repubblica.it/pwa/robinson/2020/04/30/news/joseph_stiglitz_non_sprecate_questa_crisi_-255286208/

in modulating institutional trust. This provides a nice illustration of the complex and context-dependent nature of feedback mechanisms on trust attributions: whether or not a certain observable feature of the situation (in this case, personal costs) will affect trust depends on its role within a broader attributional process, which cannot be oversimplified as a single feedback loop (for discussion, see Falcone and Castelfranchi, 2004).

Finally, it is worth stressing that the main predictors of trust remained stable both geographically and temporally: nonetheless, controlling for region of residence allowed us to notice a more focused mindset for trust attribution in the most affected regions, whereas comparing responses before and after the new restrictions introduced in Italy on March 11 highlighted a leveling effect of these measures, which made us realize the national character of the COVID-19 crisis to everybody, including citizens living in areas with only minor outbreaks.

This last point underscores a common pattern to many of our main results: *a shift from the particular to the general* in how institutional trust is granted and justified by citizens, apparently caused by the unique circumstances of the COVID-19 pandemic. As we discussed in section "Results," the responsibility of dealing with this emergency was clearly assigned to the National Government, whereas regional and local authorities were perceived as marginal; moreover, high confidence was granted to public institutions, largely ignoring their political affiliation, unlike what happened in other countries, e.g., the United States (Goldstein and Wiedemann, 2020; Kushner Gadarian et al., 2020), and without concern for any further agenda they might serve (in fact, trust in public authorities was paralleled by distrust in the various political parties, including those currently in power); consistently with this mindset, collectivistic reasons for institutional trust trumped individualistic concerns, and the perception of a common effort toward shared goals overshadowed any personal sacrifice that may be required to individuals and groups (this also relates to the fact that personal health itself obliges to look and reflect primarily on collective health, on which the former strictly depends); finally, confidence in each other's compliance with general rules was high, and the future outlook on trust was positive for public institutions, science, and civic society, not so much for the overall model of development. In short, participants responded to this survey not as individuals calculating trust based on likelihood of personal gains or losses (the standard economic view of trust), but rather as members of a collective subject, jointly engaged in facing a problematic situation.

This tendency to make common cause against a shared concern is one of the most valuable assets any society can leverage to fight a public crisis, so in this sense, our data paint a positive picture of how Italian citizens responded to the COVID-19 emergency, as far as trust in public authorities is concerned. However, as repeatedly stressed above, this asset is also incredibly delicate, especially in a country with a complex and thorny history of institutional distrust, like Italy. Hence, a crucial research priority for future research, both in the short run and in the long term, is to keep monitoring how trust dynamics between citizens and public authorities will be affected by the next stages of the COVID-19 pandemic: in fact, while our data suggest a generally positive reaction in the early phases of the emergency, they provide no guarantee of the fact that such trend will continue in the same direction. On the contrary, as mentioned, things could either turn for the best, as our respondents chose to believe, or turn for the worst, should public authorities fail to live up to their citizens' high expectations.

DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article/**Supplementary Material**.

ETHICS STATEMENT

This study complied with all the ethical guidelines and standards for online surveys with human participants, in accordance with the local legislation and institutional requirements. The participants provided their written informed consent to participate in this study and were free to quit the survey at any time.

AUTHOR CONTRIBUTIONS

RF led the design of the survey. EC, AS, and SF performed data analysis. RF and FP wrote most of the manuscript. All authors listed have made a substantial, direct and intellectual contribution to the work, and approved it for publication.

Rethinking the Role of Affect in Risk Judgment: What We Have Learned From COVID-19 During the First Week of Quarantine in Italy

Due to COVID-19 spreading in Italy, on March 11 the Prime Minister of Italy declared a lockdown and imposed severe restrictive measures impacting citizens' freedom at several levels. People were required to stay at home and go out only to satisfy basic needs. Several risk models have postulated a link among online searching behavior, affect, anxiety, and complaints by individuals toward government restrictions (GR), which emerged as also related to an increased perception of knowledge toward risk. However, to date, no study has addressed how these key risk-related aspects (i.e., affect, anxiety, perceived knowledge on risk, and risk dimensions) can act jointly to orient online health information-seeking behavior, and people's complaints toward GR imposed during the lockdown. This study investigated the mechanisms underlying online health information-seeking behavior and people's complaints toward the government's restrictions during a COVID-19 emergency in the Italian population. Drawing from the health belief model (HBM), which postulates a link between sociodemographic variables, risk, and affect dimensions in emergency, we assumed risk factors as predictors of affect and anxiety, which, in turn, were posited as mediators between risk dimensions, online health information-seeking behavior, and complaints toward GR. Participants (1,031) were involved during the first week of the quarantine (March 11–18) and completed an online survey composed of (i) an adapted version of the Italian Risk Perception Questionnaire; (ii) the Italian Positive (PA) and Negative Affect (NA) Schedule (PANAS-10); (iii) the State Anxiety Scale (STAI-Y1); (iv) *ad hoc* personal knowledge measure about novel coronavirus; (v) *ad hoc* item measuring information search behavior regarding the novel coronavirus; (vi) *ad hoc* measure of the complains regarding GR; and (vii) sociodemographic questions. General linear models and structural equation modeling (SEM) were carried out to test the model. Sociodemographic and cognitive factors predicted the participants' affect and anxiety, which, in turn, motivated and fully mediated both information search behavior and complaint toward GR. This research can offer useful suggestions for policy-makers during the COVID-19 emergency, and it advanced the knowledge on the risk–emotion link in emergency situations.

Keywords: emotions, anxiety, quarantine, behavior, SARS-CoV-2

GENERAL INTRODUCTION

In December 2019, a cluster of pneumonia cases of unknown etiology was detected in the city of Wuhan, Hubei Province, central-eastern China. This initial phenomenon turned into a novel coronavirus (Zhu et al., 2020), which is named SARS-CoV-2 (i.e., Severe Acute Respiratory Syndrome), and which caused a disease named COVID-19 (Qu et al., 2020). Even though symptomatology has been defined clearly, it is still hard to define how long it will last and if a cure is possible (Porcheddu et al., 2020; Wangping et al., 2020). Recently, the infection has caused enough deaths to be considered as a pandemic by the World Health Organization (WHO) (Onder et al., 2020; Sohrabi et al., 2020).

In Italy, the outbreak spread on February 20, and after an *ad hoc* decree of the President of the Council of Ministers (DPCM), a lockdown was imposed on Italians (i.e., 20 days after the first recognized patient). All Italians were required to stay home if they were not involved in jobs or tasks involved in other people's survival. Since March 11 in Italy, restrictive and severe measures have been gradually implemented (from March 11 to 18) (De Giorgio, 2020a,b).

According to the health belief model (HBM) (Janz and Becker, 1984; Carpenter, 2010)—well-established theoretical frameworks in health-related behavior research—often, the psychological counterpart of disease-related emergencies can entail an increased risk perception (Bults et al., 2011) modulated also by sociodemographic variables (e.g., Vaughan, 2011; Clifton et al., 2016). This cognitive perception of risk can have significant implications on individuals' emotional states on the short and on the long-term (Cafagna and Barattucci, 2019). Moreover, it would be closely related to the intention to adopt protective behaviors (Leppin and Aro, 2009; Goodwin et al., 2011) as well as to personal susceptibility (Lin et al., 2020).

However, HBM has never been used to investigate the mechanisms underlying all these variables in a pandemic situation. Moreover, no data on the Italian population's risk perception have been reported yet. Crucially, no studies have investigated the impact of risk cognition and emotional response on research behavior and compliance with government actions.

This last aspect can be far more relevant if considering that cognitive perception of risk is sensitive to peculiar emergency-related environmental factors. For instance, Italians were forced to stay home, thus changing their normal habits related to work and leisure activities. Confined at home, Italians tended to rely more on the Internet to remain up-to-date on pandemic progress in a safe way. Crucially, online information searching regarding health issues is not a neutral task since it can influence people's affective states, especially anxiety (Jutel, 2017).

To investigate the joint impact of cognitive risk dimensions, affect, and anxiety on online searching behavior and compliance toward government restrictions (GR), in the peculiar context of the Italian pandemic emergency, we drew from the HBM to formulate and test a novel explicative model. First, we posed the first day of lockdown (March 11, 2020) as the *trigger* event and the online health information on COVID-19 searching behaviors as the main *outcome*. Then, we built and tested a novel model including sociodemographical factors, risk cognitions, behaviors, and affect as mediators between the trigger event and the main outcome of the online health information searching behaviors (**Figure 1**).

Elucidating this mechanism can be crucial also because information-seeking behaviors can influence the population' general compliance with government decisions (Clifton et al., 2016). Therefore, these data can provide the government with useful indications regarding which online communication strategies would be the most effective in an emergency situation (Liao et al., 2020).

Conceptualization of a New Model of Risk Perception

The term "risk" represents the possibility of suffering damage connected to foreseeable circumstances. In essence, it is consequently a variable connected to the frequency (or probability) of the occurrence of the damage and the magnitude that the latter can cause in the individual (Slovic, 2000). This universally recognized definition may look as reducible to a mere mathematical formula. However, its subjective dimension suggests a deeper complexity. Indeed, a plethora of approaches have been developed to capture all the key aspects related to risk perceptions, as well as its main consequences on people' behavior.

Among the main subjective dimensions of risk, cognitive factors emerged as playing a key role (Slovic, 2000; Leppin and Aro, 2009). Risk perception would be determined by a complex series of cognitive factors: (i) the perceived possibility of having damage to health; (ii) the subjective importance that the damage is more or less possible; (iii) by personal uncertainty associated with the exposure to a specific risk factor (Slovic et al., 2004). In the case of general risk or infection or disease, personal knowledge negatively affects the perception of risk danger (Shook et al., 2019). In turn, risk perception impacts behaviors (Sjöberg, 2000), specifically between different risk dimensions regarding infection, perceived fatality, severity, vulnerability, and uncontrollability, and are proven to have effects on protective conduct (de Zwart et al., 2009). In regard to pandemic-related risk perceptions, two main factors emerged as relevant, that is, vulnerability (a person's subjective perception of the risk of acquiring an illness or disease) and severity (a person's feelings on the seriousness of contracting an illness or disease) of harm (Carpenter, 2010). However, despite that it has been repeatedly shown that risk perception can affect behavior (Brewer et al., 2007; Vaughan, 2011; Shook et al., 2019), the underlying mechanism still needs to be elucidated.

Specifically, antecedents of cognitive dimensions of risk should be still clarified. With this regard, demographic factors/variables emerged as playing a key role in shaping pandemic risk perception and subsequent behaviors (see e.g., Vaughan, 2011). For instance, women resulted as more avoidant, fearful, and vulnerable in terms of pandemic risk perception, with lower risk acceptance scores when compared to men (see e.g., de Zwart et al., 2009). Conversely, age often leads to an increased perception of control on infection risk, lower susceptibility, avoidance, and higher acceptance of risk (see e.g., Clifton et al.,

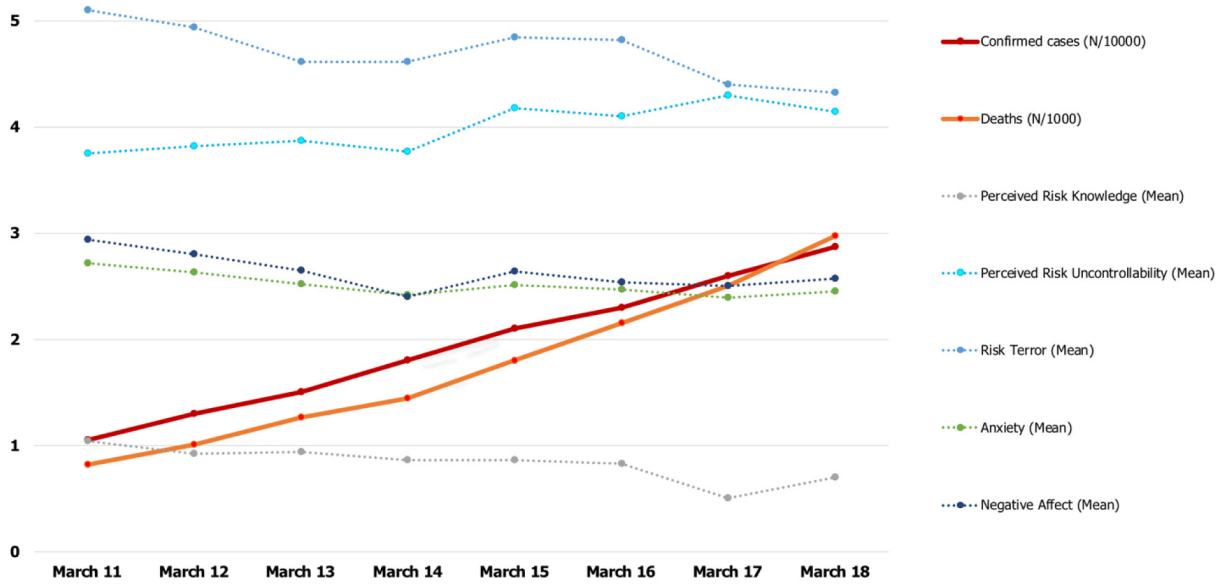

FIGURE 1 | The first week of lockdown in Italy: epidemiological and variable trends. All variables have been standardized. Due to the numerical difference of epidemiological data between Northern and Southern Italy, we divided the real values by 1,000 and have thus reported them in the *y*-axis.

2016). Conversely, the level of education was negatively related to the risk of infection and contagion (i.e., vulnerability) (Gidengil et al., 2012). Lower income and urbanization positively affected vulnerability and perceived infection risk (Brewer et al., 2007; De Zwart et al., 2007; Gidengil et al., 2012).

Another factor, which would act as a mediator, should be included between risk perception and behavior, that is, affect. Affect, such as fear, is related to a general amplification of the perception of the danger of risky events, while anger would be significantly associated with underestimation of dangers (Slovic, 2000; Brown, 2014). Moreover, the degree of emotional involvement in the perceived consequences of different risks, or specific personality dimensions that determine emotional attitudes, is associated with different aspects of risk perception (among all, vulnerability, and severity) (Slovic, 2000; Brown, 2014).

Crucially, among the stimuli triggering emotional states, also online searching information should be included, which could also lead to a phenomenon of large-scale emotional contagion (Hatfield et al., 1993). Emotions expressed via the Internet, and mainly through social media, can lead to a long-term psychological impact (Arapakis et al., 2008; Fowler and Christakis, 2008; Coviello et al., 2014; Kramer et al., 2014; Ferrara and Yang, 2015; Mui et al., 2018) including also a simple health information search (Gadahad et al., 2013). Specifically, both general and specific discrete emotional states can orient people's online search for information on health issues (Wissow, 2007; Myrick and Willoughby, 2019). Emotions and affect act as motivators of specific survival behaviors (Frijda et al., 1989), and this definition could hardly be more appropriate than in this worldwide emergency. In this case, one key survival behavior motivated by affect could consist of online health information seeking or avoidance (Savolainen, 2014). While positive affect (PA) resulted in determining people's attitudes toward information avoidance, negative affect (NA) predicted individuals' attitudes toward information seeking (Yang and Kahlor, 2013).

On the other hand, searching for information about symptoms or specific illnesses can increase people's distress and anxiety about their health (Graffigna et al., 2017). Crucially, NA and anxiety have often resulted in closely positively intertwined affective states (Crawford and Henry, 2004), even though they can be considered as clear, distinguishable constructs (Watson and Kendall, 1989; Clark and Watson, 1991). According to the Tripartite model of anxiety and depression, high levels of NA underlie both anxiety and depression, while NA would act as a central risk factor of anxiety (Clark and Watson, 1991). NA has also often been considered an early predictor of anxiety in several domains (Crawford and Henry, 2004; Cisler et al., 2010). During the lockdown, the Internet became one of the most important sources of health-related information; thus, it would be crucial to analyze antecedents of this behavior as well as its potential impact on compliance with GR.

To date, the literature regarding risk perception and behavior on worldwide pandemics has focused mainly on general population's or on healthcare workers' punctual psychological responses immediately after the end of isolation (Wilder-Smith and Freedman, 2020). Acute stress/posttraumatic disorders, as well as higher propensity to live state anxiety, emerged as serious issues (Leppin and Aro, 2009). Crucially, no data on the Italian population's risk perception have been reported yet. Moreover, no studies have investigated the role of risk cognition and emotional response to research behavior and compliance with government actions.

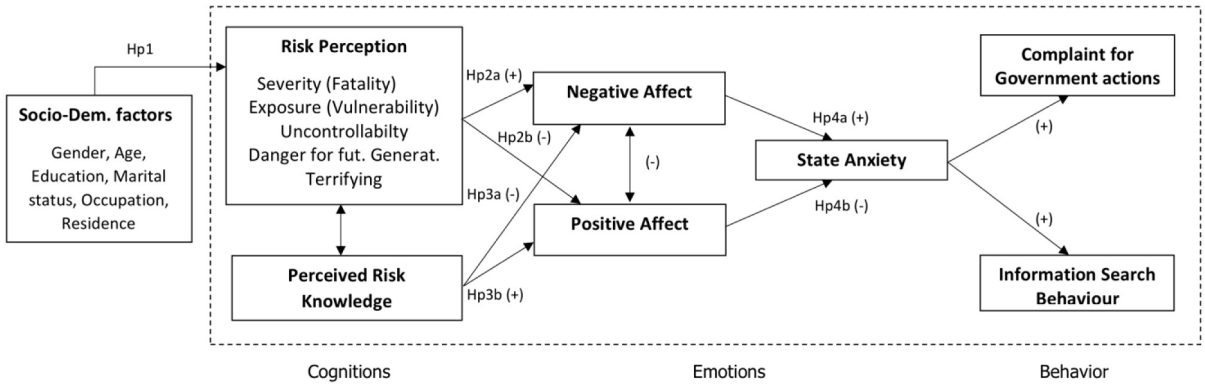

FIGURE 2 | Research model and hypotheses.

In this study, we aimed to advance previous studies on COVID-19 at two levels. First, we elucidated the link between cognitive and emotional risk dimensions in a pandemic, then, we built and tested a novel model linking cognitive, emotional, and sociodemographic factors to a peculiar behavior enacted in this emergency, which would be probably increasingly adopted in the future, that is, online searching behavior of health-related information. Moreover, we also used the HBM, for the first time, as a general explicative framework in a pandemic situation.

Health belief model posits a cognitive appraisal framework, in which perception of the risk for individual health affects emotions and protective behavior (Roseman, 1996). More specifically, when referring to the HBM framework (Janz and Becker, 1984) and adapting recent theoretical models (Watson and Spence, 2007; Keller et al., 2012; Lemée et al., 2019), the present research model considers sociodemographics as antecedents of risk cognition and emotion as a buffering factor between risk perception and behavior (**Figure 2**).

This novel model proposes that two different risk cognition aspects have independent effects on PA and NA. Perceptions regarding specific pandemic and perceived knowledge of risk (Champion and Skinner, 2008; Carpenter, 2010) can act differently on contingent affect, which can have an impact on both information search behavior and complaints regarding government action. In a situation of physical and social constraint, i.e., quarantine, the sudden perceptions of the risk would depend mainly on mass media, social media, and word of mouth information (Jung et al., 2015). This growing information impacting the emotional state can, in turn, act as both a search trigger for further infection information and a facilitator of compliance with the government's restrictions (Goodwin et al., 2011; Rolison and Hanoch, 2015).

In line with HBM and literature, major evidence linking cognitive risk dimensions and affect (de Zwart et al., 2009; Keller et al., 2012), this study aimed to explore the following hypotheses: sociodemographic factors have an impact on risk perception and perceived risk knowledge (Hp1); more precisely, the research expects that age (Hp1a) and education (Hp1b) will negatively affect risk perception and positively risk knowledge; thus, it is hypothesized that women will have a worse perception of pandemics and less perceived knowledge compared to men (Hp1c). The research assumed that risk perception would positively impact on NA (Hp2a) and negatively on PA (Hp2b); on the contrary, it expected that risk knowledge would negatively impact on NA (Hp3a) and positively on PA (Hp3b). Moreover, the research intends to elucidate whether the differential effect of NA (Hp4a) and PA (Hp4b) on search behavior and a complaint is mediated by state anxiety (Hp4). In order to test all the mentioned hypotheses thoroughly, we tested this novel model by means of structural equation modeling (SEM) (**Figure 2**).

MATERIALS AND METHODS

Participants

One thousand thirty-one participants from Italy voluntarily took part to this study (mean age = 38.34; SD = 13.02, range = 18–82). After removing the data of the participants who did not answer all the survey questions, we analyzed 998 participants, of which 739 were females (mean age = 37.01; SD = 12.39) and 259 were males (mean age = 42.15; SD = 14). Their marital status was as follows: 37.68% were engaged in a relationship, 32.57% were married, 23.75% were single, 5.42% were divorced, 0.6% were widowed; 23.75% reported living in central big city areas, 20.4% were living in the suburb of a big city, 36.07% reported living in a small town (i.e., less than 50,000 inhabitants), and 20.14% reported living in the countryside; 57.52% resided in Northern Italy, 17.33% resided in central Italy, 17.64% resided in South Italy, and 7.52% resided in the Islands; 20.44% were students, 2.51% were retired, 25.35% were freelance, 11.72% were temporary workers, and 30.96% were full-time employees with a permanent position; and 52.93% reported having no children, 17.13% reported having two children, 16.43% reported having one child, and 0.6% reported having more than three children.

Regarding schooling, 3.71% reported having a middle school diploma, 31.16% declared having a high school degree, 18.84% reported having a bachelor's degree, 24.15% reported having a master's degree, and 21.64% reported having a Ph.D.

This study was conducted in accordance with APA ethical standards and with the Declaration of Helsinki. Participants:

(i) were fully informed in regard to institutional affiliations of the researchers and research scope; (ii) continued the survey only if they were adult (>18 years old); (iii) gave information that could not allow their identification; (iv) had the right to refuse to participate in the study and withdraw at any time; (v) filled an anonymous questionnaire and confirmed the understanding of instructions and voluntary participation.

Procedures and Materials

Participants completed an online survey between March 11, the first day of quarantine and national lockdown, and March 18. The research design relied on snowball sampling (chain referral process). Participants were recruited through flyers, social networks, and by word of mouth. The questionnaire answering began in the evening (March 11) when the DPCM decree was issued. First, participants completed the part of the questionnaire created to gather sociodemographic information. Second, the following questionnaires were then completed:

1. *Italian Risk Perception Questionnaire* (Cafagna and Barattucci, 2019): originally developed by Savadori et al. (1998). Based on literature indications (Keller et al., 2012), the study deduced that the pandemic risk could generally be identified as terrifying, uncontrollable, fatal, and dangerous for future generations, and widespread in terms of exposure. Hereupon, the researchers built a tool that measures five single-item dimensions of risk infection, on a seven-point scale ranging from 1 to 7: severity, vulnerability, uncontrollability, terror, and danger for future generation (item examples: "Considering the scale below (1 'not fatal' to 7 'fatal'): in your opinion, when the virus infects a subject, how likely are the consequences of being fatal?" "Considering the scale below (1 'not exposed' to 7 'totally exposed'), in your opinion, to what extent do you think you are exposed to the coronavirus risk?"
2. *Italian short version of the Positive and Negative Affect Schedule* (Terraciano et al., 2003): a 10-item self-report scale on a five-point Likert scale, which captures the two main clusters of the current affective experience, i.e., positive (five adjectives; Cronbach's alpha = 0.790) and negative affect (five adjectives; Cronbach's alpha = 0.940).
3. *State Anxiety Scale (STAI-Y1)*: a 20-item self-report questionnaire on a four-point Likert scale (from 1 "not at all" to 4 "very much so"; original Cronbach's alpha = 0.954) to assess participants' current state of anxiety.
4. *Ad hoc* measure about *Novel coronavirus personal knowledge*, which tests how people know the disease: "Do you know exactly the difference between COVID-19 and SARS-CoV-2?" This measurement tool consists of a three-level ordinal scale: (i) Yes, I know it perfectly. (ii) Yes, I know generally. (iii) No.
5. *Ad hoc Information search behavior* item regarding novel coronavirus: "Thinking about the last week, how many times did you search on the Internet (Google, news, articles on social networks, etc.) for information on COVID-19, SARS-CoV-2, or Coronavirus?" This measurement tool consists of a four-level ordinal scale: (i) never, (ii) sometimes, (iii) several times, (iv) often, and (v) everyday.
6. *Ad hoc Complaint regarding government actions* item: "The Government has acted late to contain the spread of the virus." This measurement tool consists of a four-level ordinal scale of accordance with the phrase: (i) I totally disagree. (ii) I disagree a little. (iii) I mostly agree. (iv) I totally agree.

Data Analysis

A Kolmogorov–Smirnov test for each of the variables involved in this study was carried out to test their distribution. We found that all target variables (i.e., anxiety, NA, risk dimensions, online health information searching behavior, and the complaint about government measures) were normally distributed. To test the causal relationship between all demographical variables (i.e., marital status, job position, age, gender, residence area, and residence area in Italy) and each target variable, a generalized linear model (GLM) for categorical and ordinal data was carried out with SPSS Ver. 21.0 (IBM Co., Armonk, NY, United States) statistical program. The GML is robust to the violation of sphericity as it does not necessarily assume a normal distribution of variables (Agresti and Kateri, 2011). Moreover, regarding the residence area, we operationalized the "residence area" into two different variables. The former "residence area" refers to how far from the city center a person lives: (i) city center; (ii) suburb of a city; (iii) town; (vi) countryside, and (v) the latter, "residence area in Italy" refers to a zone of residence from the north to the south of Italy and islands, which also coincides with the distance from the first epidemic center of diffusion (i.e., Codogno) in Northern Italy. A comprehensive structural equation model with AMOS22 was used to test the proposed theoretical model and the main hypotheses. Commonly reported fit statistics were: comparative fit index (CFI), Tucker–Lewis index (TLI), normed fit index (NFI), goodness of fit index (GFI), incremental fit index (IFI), root mean square error of approximation (RMSEA), plus standardized root mean square residual (SRM) for measurement model fit. Research has sought to reduce response bias and common-method variance problems utilizing suggested methods (Podsakoff et al., 2012): scales were visually divided, and different formats and endpoints were used for each different measure.

RESULTS

Sociodemographic Variables and Psychological Impact on Anxiety, Negative Affect, Risk Dimensions, and Search Behavior

All factors are reported in **Table 1** with significant regression coefficients and Wald statistics. All Omnibus models were

TABLE 1 | Generalized linear model multiple regressions with gender, marital status, education, number of children, residency, residency in Italy and age as predictors and anxiety, positive affect, negative affect, search behavior, knowledge of COVID-19, vulnerability, control, severity, risk as terrifying, risk as damage for future generations, and complaint to Government's measures as predicted variables.

Note. "male" as category of "gender"; "single" as a category of "status"; "Ph.d./MS" as a level of "Education"; "three or more children" as "Number of children"; "city center" as a level of "Residency"; "Islands" as a level of "Residency in Italy" were not reported since they are a redundant levels. Marital status was transformed into a dummy variable (engaged vs. single). [a]The predictor was significant, but the omnibus model was not. CI95, conventional 95% confidence interval; PA, positive affect; NA, negative affect; SB, search behavior; KNW, knowledge; VUL, vulnerability; CON, control; SEV, severity; TER, terrifying; DFG, damage for future generations; COM, compliance.

significant except for the model with "Knowledge," i.e., a risk dimension, as the predicted variable.

We reported results for each of the dependant variables (anxiety, PA, NA, SB, KNW, VUL, CON, SEV, TER, DFG, COM) in relation to all predictors taken together (gender, marital status, education, number of children, residency, residency in Italy). Only B values useful for explaining results were reported in order to avoid redundancies.

Younger females (Age: B = −0.104) with lower education (high school: B = 4.59) are related with highest levels of anxiety. Regarding PA, being male (gender: B = −1.367), with lower number of children (number of children: beta decreased from one to no children but with a negative value: B = −1.369 to −1.287) and older (B = 0.024) significantly increased PA. Indeed, NA was significantly positively predicted by being a woman, not engaged (engaged marital status: B = −0.963) with lower education (from bachelor = 1.183 to high school: B = 1.672) and younger (B = −0.062). Younger (B = −0.26) and single people (gender did not result as a significant predictor) positively predicted the frequency of online health information searching behavior. Being female (B = 12.75), with a lower level of education (B = 2.163–0.776) and senior (B = 0.015), led to significantly higher perception of risk knowledge. Only being single (B = −0.21), i.e., not engaged, significantly positively predicted the perception of being vulnerable against risk. A lower education (beta decreased positively from high school to elementary school) and being older (B = 0.016) significantly positively predicted the perception of control over the risk associated with the pandemic. Being female, with a lower level of education, and with no to one child and older led to a significantly higher perception of risk severity. Being less educated and younger led to a significantly higher perception of risk as terrifying. Being female, with lower education, and an increasing number of children (from no to two children) led to a significantly higher perception of risk damage associated with new generations. Females with lower education and younger tended to report more compliance toward the government's measures.

Path Analysis

Descriptive statistics for all the measures and zero-order correlations between them are described in **Table 2**. With the aim of exploring a measurement model and construct validity, a confirmatory factor analysis (CFA) was conducted comparing four nested models from one factor to a final model composed of the four principal latent factors (risk perception, NA, PA, and anxiety). **Table 3** represents Chi-square and goodness of fit indices for the four measurement models developed. Considering that risk perceptions were all measured with single items, and despite the final CFA indexes not being optimal, there was an evident amelioration of all indices from the first to the final model. Therefore, the measurement model can be profitably used in further testing of the proposed structural model.

Thus, we tested through SEM the proposed structural model (**Figure 2**): the five risk perception dimensions (fatality, vulnerability, uncontrollability, terrifying) and risk knowledge as (correlated) antecedents, with direct relationships with both NA and PA as intermediate variables, which themselves have direct

TABLE 2 | Descriptive statistics and zero-order correlations among the variables of the study.

TABLE 3 | Goodness of fit indices of the alternative measurement models on measured variables.

	Chi-square	df	RMSEA	CFI	IFI	SRMR
Model 1 – one factor	7205.047	560	0.154	0.734	0.724	0.113
Model 2 – two factors	6488.564	559	0.134	0.792	0.793	0.096
Model 3 – three factors	5720.552	557	0.101	0.853	0.843	0.089
Model 4 – four factors	5438.563	554	0.089	0.904	0.898	0.081

df, degrees of freedom; RMSEA, root mean square error of approximation; CFI, comparative fit index; IFI, incremental fit index; SRMR, standardized root mean square residual.

links with state anxiety that fully mediates information search behavior. The proposed model exhibited optimal goodness of fit: Chi-square = 112.812 (df = 23; $p < 0.000$), RMSEA = 0.063, CFI = 0.966, IFI = 0.967, NFI = 0.958, GFI = 0.980, TLI = 0.919. Consequently, we tested the same model deleting nonsignificant relationships (severity, vulnerability, and terrifying with PA; risk knowledge with NA) and some correlations between antecedents (vulnerability and danger for future generations, with terrifying risk, risk dimensions, and risk knowledge). Consistent with our hypothesized relationships, the model showed excellent goodness of fit: Chi-square = 129,737 (df = 33; $p < 0.000$), RMSEA = 0.054, CFI = 0.964, IFI = 0.964, NFI = 0.952, GFI = 0.977, TLI = 0.94, with all significant relationships ($p < 0.001$). Regression weights are presented in **Table 4**, while the path diagram of the final model is shown in **Figure 3**.

As hypothesized (Hp2a), each dimension of risk perception is positively related to NA. In contrast, only two dimensions (uncontrollability and danger for future generations) are significantly linked to PA, not confirming what was expected (Hp2b); conversely, confirming Hypotheses Hp3a but not Hp3b, risk knowledge is only positively related to PA. Results confirmed that the expected differential effect of NA (Hp4a) and PA (Hp4b) on search behavior and on a complaint is fully mediated by state anxiety (PA indirect effect on search behavior: $\beta = -0.051$, $p < 0.001$; NA indirect effect on search behavior: $\beta = 0.142$, $p < 0.001$). Overall, the relationships expressed in the model explained 17% of the variance for NA, 18% for PA, 82% for state anxiety, 10% for search behavior, and 7% for complaint in government actions.

DISCUSSION AND CONCLUSION

The present research carried forward the literature regarding the fact that cognitive factors predict population affect that, in turn, motivate and fully mediate information search behavior and complaints about government actions, overturning contributions that proposed that risk behavior is driven by affects (Kahan, 2008; Leppin and Aro, 2009; Wu et al., 2018).

Considering our sample of participants, results showed that being female and younger with a lower level of education led to more anxiety, NA, a higher risk perception as terrifying, and higher complaint regarding GR. Moreover, PA increased significantly in older males and those with a decreasing number

TABLE 4 | Standardized path coefficient (regression weights) of the final model.

			Estimate
Negative affect	←	Severity	0.110
Negative affect	←	Vulnerability	0.142
Negative affect	←	Uncontrollability	0.080
Negative affect	←	Danger for future generation	0.205
Negative affect	←	Terrifying	0.145
Positive affect	←	Knowledge	0.104
Positive affect	←	Damage for future generation	−0.090
Positive affect	←	Uncontrollability	−0.103

of children (less than two). Younger people or those who were not engaged or married tended to look for information online about the COVID-19 more frequently. Older females with a lower education level (from middle to elementary school) were more prone to perceive themselves as competent regarding their acquired knowledge on COVID-19. Being engaged or married acted as a protective factor regarding the perceived vulnerability against COVID-19. Older people with lower levels of education (from high school to elementary school degree) tended to feel more able to control the gravity of risks associated with this pandemic. Older females having from one to no children, and with high-school to elementary school degree, tended to perceive the COVID-19-associated risk as more severe. Females who have a higher number of children (from no child to two children) and with a lower level of education (this effect increased from bachelor to elementary school) tented to perceive an increased risk associated with COVID-19 for future generations. Younger females with lower education tended to report more compliance toward the government's measures.

Theoretical Implications

In this study, we elucidated two crucial phenomena in emergency: general NA and its link with anxiety. NA and anxiety have often resulted in closely positively intertwined affective states (Crawford and Henry, 2004) even though they can be considered as clear, distinguishable constructs (Watson and Kendall, 1989; Clark and Watson, 1991). The Tripartite model of anxiety and depression confirmed that high levels of NA underlie both anxiety and depression, while NA acts as a predictor of anxiety (Clark and Watson, 1991). Specifically, NA has been often considered as an early predictor of anxiety in several domains (Crawford and Henry, 2004; Cisler et al., 2010). The model tested in this study confirmed the direction of this link.

Emotions and affect also act as motivators of specific survival behaviors (Frijda et al., 1989), and this definition could hardly be more appropriate than in this worldwide emergency. In this case, affect can trigger behaviors such as online health information seeking or avoidance (Savolainen, 2014). While PA resulted in playing a pivotal role in determining people's attitudes toward information avoidance, the negative one predicted individuals' attitudes toward information seeking (Yang and Kahlor, 2013). On the other hand, searching for information about symptoms or specific illnesses can increase people distress and anxiety about their health following a reinforcing spiral to the extent that a new term has been coined to refer to this condition, i.e., "cyberchondria" (Te Poel et al., 2016). Indeed, people with high health anxiety (i.e., fears stemming when individuals exaggerate in interpreting their bodily symptoms as an indicating severe illnesses) (McMullan et al., 2019) trend to increase their negative responses related to the likelihood of suffering from a given disease now and in the future (Baumgartner and Hartmann, 2011).

The present result showed that anxiety triggered by NA acted as a strong predictor of people's searching behavior regarding health. In other words, Italians were motivated by anxiety stemming from NA and triggered by their risk perception on the controllability and vulnerability regarding SARS-CoV-2 spread and health searching behavior. Overall, results provided support for the cognitive appraisal framework in risk perception (Roseman et al., 1996; Keller et al., 2012) and the main hypotheses. Risk perception and knowledge acted with different mechanisms on emotions: risk perception mainly contributed to having an effect on negative affect, while knowledge influenced only positive affect. Furthermore, in line with our hypotheses, emotions fully mediated the relation among risk cognition, complaint, and information search behavior (Champion and Skinner, 2008; Carpenter, 2010; Jung et al., 2015).

Policy Implications

Risk perception and affective response to pandemics can be crucial factors for managing population behaviors, thus ensuring the best adherence to prescription and safety norms (Poletti et al., 2011; Merino, 2014; Shook et al., 2019). Moreover, the efficiency of prevention behaviors in pandemics by the Government is related to population cooperation, which is highly related to risk perception (Leppin and Aro, 2009; Goodwin et al., 2011). Exploring risk perception during pandemics is fundamental because misperceptions can often cause inadequate responses (Poletti et al., 2011; Merino, 2014). In particular, perceptions regarding infection can lead people to take safer actions, to reduce exposure, and to increase protective conducts (e.g., vaccination, social distancing, hygiene, search for information; Shook et al., 2019). These individual behaviors can significantly influence the disease progression at a system level (De Zwart et al., 2007; Jiang et al., 2009).

Since emotion and behavior are closely related (Loewenstein et al., 2001; Slovic and Peters, 2006; Brown, 2014), beliefs and perceptions regarding risk represent core predisposing factors to predict people reactions. Therefore, it would be crucial to promote public order and right risk communication and to prevent counterproductive behaviors linked to bad information and fake news (Brug et al., 2004; Voeten et al., 2009; Shook et al., 2019).

The risk controllability is one of the most important factors that need to be considered since PA can reduce anxiety and, consequently, affect complaint and informational search behavior. In Italy, especially during the first days of the epidemic (from the end of February), there was too much conflicting information (e.g., "This virus is very similar to normal flu."/"Please, pay attention, it is a very dangerous virus; it is not like normal flu.").

It is crucial to evidence that too much information, especially if conflicting (or worse, fake news), can cause confusion in the population, and this, in turn, can affect emotional states (Bawden and Robinson, 2009). Politicians should act on proper information dispersion procedures regarding specific risk, as perceived knowledge may act on search behavior and complaint. Our results can suggest more tailored strategies of communication for prevention to be implemented by the government, not just in pandemic emergency (Smith, 2006).

Research regarding the way the population appraised hazards acquired significant scientific attention, and different approaches and paradigms to the perception of risk have been discussed (Leppin and Aro, 2009; Keller et al., 2012). Recent contributions have conformed on the emotional appraisal of risk perception (Loewenstein et al., 2001; Wu et al., 2018). Thus, results from our study could offer evidence in favor of the hypothesis that the analytic system (i.e., risk judgment) would precede the emotional one, at least in a pandemic emergency.

Country-Level Implications

COVID-19 is having, and is predicted, to have a substantial impact on the world economy, both due to the effect on national health systems, and on the slowdown of business activities through lockdowns and measures of social distancing. The economic impact would be even more substantial in developing countries, due to both difficulties related to social distancing in the slums and in the suburbs, as well as for the absence of stable health systems, welfare measures, and smart-working policies, and for the access to the various forms of institutional communication and to the mass media. The literature concerning the other pandemics has clearly shown that the perception of risk has a strong cultural component; thus, communication strategies should be tailored according to the peculiarities of each country (Jiang et al., 2009). In this regard, the proposed model can indicate a priority of all the variables capable of influencing preventive behavior or adherence to restrictions directly, which must be taken into account when planning communication to the general public. For instance, accurate and clear communication should clarify the danger for future generations, the terror aroused, and the degree of exposure to the pandemic (Van Bortel et al., 2016). Furthermore, the proposed model evidenced also perceived knowledge of risk as another key variable to be considered in mass communication. Finally, communication in developing countries should consider that people living in precarious economic conditions could give less weight to the health consequences of COVID-19, in a cost-benefit assessment process that could overestimate economic costs to the detriment of those for health and economics (Leppin and Aro, 2009).

Limitations of the Study

Given the novelty and relevance of this study, some limitations should be discussed. First of all, the cross-sectional design of the research limits the generalizability of its findings.

Although results should be interpreted, especially concerning the specificity of both the contagion risk and the quarantine situation, useful indications on the mechanism that operates between cognitions, emotions, and behaviors in situations of high stress and forced captivity can be provided. Moreover, due to the recruitment type (i.e., online), and despite a large number of participants, this sample cannot be considered as fully representative of the Italian population (26% males, 57% in Northern Italy). Almost 50% of the participants filled out the survey in the first 2 days (maybe caused by people's reactions to the lockdown). Therefore, this distribution does not allow for longitudinal analysis.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

AD and MB conceived and designed the experiments. MB and AC done through questionnaires to target groups investigation. MB, AC, and GK analyzed the data. AD contributed the analysis tools. MB, AC, and AD wrote the manuscript. AD and GK critically reviewed the manuscript. All authors contributed to the article and approved the submitted version.

From Resilience to Burnout: Psychological Features of Italian General Practitioners During COVID-19 Emergency

Cinzia Di Monte, Silvia Monaco, Rachele Mariani and Michela Di Trani*

Department of Dynamic and Clinical Psychology, Sapienza University of Rome, Rome, Italy

During the COronaVIrus Disease 2019 (COVID-19) pandemic in Italy, general practitioners (GPs) are ensuring continued access to primary care for citizens while also absorbing more of the impact of the crisis than most professional groups. The aim of this study is to explore the relationships between dimensions of burnout and various psychological features among Italian GPs during the COVID-19 emergency. A group of 102 GPs completed self-administered questionnaires available online through Google Forms, including Maslach Burnout Inventory (MBI), Resilience Scale, Intolerance of Uncertainty Scale Short Form (IU), and Coping Inventory for Stressful Situations (CISS). Cluster analysis highlighted four distinct burnout risk profiles: Low Burnout, Medium Risk, High Risk, and High Burnout. The High Burnout group showed both lower Resilience and lower CISS Task-oriented coping strategy than the Medium Risk group and higher IU Prospective than the Low Burnout group. Results of a linear regression analysis confirmed that CISS Emotion-oriented style positively predicted MBI Emotional Exhaustion, CISS Task-oriented and Emotion-oriented emerged as significant predictors (negatively and positively, respectively) of MBI Depersonalization, and Resilience positively predicted MBI Personal Accomplishment. In conclusion, the results showed that the COVID-19 emergency had a significant impact on GPs' work management. Implementing task-oriented problem management, rather than emotional strategies, appears to protect against burnout in these circumstances. It is possible that the emotions related to the pandemic are too intense to be regulated and used productively to manage the professional issues that the COVID-19 pandemic presents.

INTRODUCTION

When a pandemic strikes, as COronaVIrus Disease 2019 (COVID-19) has over the last half year, the health system and the people working within it must adapt rapidly to cope with new challenges (Kaba and Kitaw, 2020). Healthcare professionals may be forced to put their lives at risk by serving as the first line of defense. This has certainly been the case in Italy, which, as of May 5, 2020, was the second highest in number of COVID-19 infections (211,938)

and highest in total number of deaths (29,079) in Europe (European Centre for Disease Prevention and Control, n.d.). Recently the "Federazione nazionale degli ordini dei medici chirurghi e degli odontoiatri FNOMCeO (2020)" website has created a section for all the physicians who have died fighting COVID-19. As of May 5, 2020, there are 154 reported victims, of which 52 are general practitioners (GPs), one of the most affected categories.

The pandemic has an impact on the mental health of the general population through rapid and abrupt changes, producing high levels of stress and depression, especially in those most at risk to contract the virus (Rodríguez-Rey et al., 2020). Under this tremendous existential threat, GPs continue to ensure access to primary care for citizens. In reporting infections, supporting regional assistance networks, treating patients with minor symptoms, and taking care of the worried well, they play a critical role in suppressing any pandemic (Opstelten et al., 2009) and in confronting disaster conditions (Redwood-Campbell and Abrahams, 2011). Ultimately, their primary care work prevents overcrowding in emergency departments (Levi et al., 2019) and consequently limits the spread of the disease.

In this context, GPs must cope with professional and personal challenges, highlighting big differences between countries (Burns et al., 2020). For example, in Italy, GPs have historically played an important and personal role in the lives of families, but in this pandemic situation, GPs modified their practice methods by using telephone calls and other digital approaches (Fiorino et al., 2020). With these changes, some typical functions of primary care, including physical examinations and immunizations, have been unavoidably neglected (Thornton, 2020) while GPs are tasked with new responsibilities, such as additional safety protocols, learning new technology, and daily e-mails for prescriptions.

Thus, now more than ever, Italian GPs are facing abnormal burdens of work, stressful clinical and organizational conditions, and emotional charges that are challenging their ability to resist stress.

Burnout is a psychological syndrome that occurs in response to chronic job-related stress, with features involving emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment (Maslach et al., 1986). It is common among healthcare professionals who are frequently exposed to high levels of occupational stress, especially due to overwhelming emotional and interpersonal interactions (Bria et al., 2012). Burnout among healthcare professionals has been the subject of a great deal of research because at its higher levels, it is associated with negative impacts on individual physicians, patients, and healthcare organizations and systems (West et al., 2018). All of the research on GPs and burnout has been conducted in the context of daily work; the appropriateness of applying conclusions from that work to pandemic situations is questionable.

The majority of Italian studies presented in the literature were focused on physicians working in a hospital setting. Bressi et al. (2008) reported that levels of burnout were high in hemato-oncology physicians with specific demographic profiles and for those experiencing physical exhaustion and working with demanding patients. Sanfilippo et al. (2018) highlighted that cardiac anesthesiologists are at high and moderately high risk of developing burnout syndrome. Mannocci et al. (2019) showed that 40% of 70 healthcare professionals in hematological units had a high level of emotional exhaustion. Another Italian study compared the burnout levels of GPs to those of hospital physicians: GPs had higher levels of emotional exhaustion than hospital physicians but there were no significant differences for other burnout dimensions explored (Grassi and Magnani, 2000). This study showed that GPs have a high risk of developing burnout syndrome. Recent studies examined the prevalence of burnout during the COVID-19 emergency in health professionals working in Northern Italy (Giusti et al., 2020), showing high levels of burnout especially in Emotional Exhaustion and reduced Personal Accomplishment. These burnout findings were significantly higher than those detected in other Italian samples before the COVID-19 outbreak, especially for Emotional Exhaustion (Barello et al., 2020).

Some individual psychological features can contribute to or prevent the development of burnout.

Psychological resilience, described as the ability to "bounce back" from negative emotional experiences and to adopt flexible solutions to the changing demands of stressful experiences (Tugade and Fredrickson, 2004), has emerged as the main protective factor of burnout among nurses (Guo et al., 2018). In a study of 566 surgical residents, Lebares et al. (2017) showed, with statistical significance, that higher levels of resilience were associated with a lower risk of burnout from emotional exhaustion, depersonalization, and low personal accomplishments. Little information is available about GPs' resilience. In a survey on Australian GPs, Cooke et al. (2013) found an association between high resilience and low burnout.

In addition, the literature has focused on the role of coping strategies in the development or prevention of burnout syndrome. When individuals experience stress, they can rely on coping mechanisms, which can be either problem-focused (actively changing the stressful environment) or emotion-focused (managing the emotional response to the stressor). Endler and Parker (1994) detected three coping styles: task-, emotion-, and avoidance-oriented coping. Other research has demonstrated that task-oriented coping predicts lower burnout among healthcare professionals while emotion-oriented coping predicts increased burnout (Jaracz et al., 2005; Howlett et al., 2015; Rodríguez-Rey et al., 2019).

Finally, another psychological feature related to the ability to regulate stress is the intolerance of uncertainty, defined as "an individual's dispositional incapacity to endure the aversive response triggered by the perceived absence of salient, key, or sufficient information, and sustained by the associated perception of uncertainty" (Carleton, 2016). In the Cooke et al. (2013) study mentioned above, GPs' ability to tolerate uncertainty was also explored with greater intolerance being associated high levels of burnout and low resilience.

The majority of the findings discussed in this *Introduction* have involved studies taking place outside of the context of states of emergency, so are not necessarily directly applicable in a pandemic. They are likely of value in establishing a baseline

understanding of burnout among medical professionals but clearly it would be useful to examine how the related phenomena function in a pandemic.

The first aim of this study is to explore the relationships between dimensions of burnout and some psychological features (resilience, intolerance of uncertainty, and coping styles) among Italian GPs during the COVID-19 emergency. Its second aim is to identify which psychological and/or demographic features predict higher levels of burnout.

MATERIALS AND METHODS

Participants

The study focused on Italian GPs currently in service in the time period between March 10, 2020, and May 18, 2020, excluding pensioners and other medical specializations. Individuals in training at GP offices and functioning essentially in the same role as GPs, but not yet certified, were included. A total of 102 individuals participated in the study.

Procedure

We conducted a study on Italian GPs using snowball sampling and self-administered questionnaires. In March 2020, questionnaires were made available online through Google Forms, and several GP Associations and the State Medical Board were involved in data collection that was stopped on May 18, 2020. GPs accepted the informed consent and the privacy policy before the beginning of the questionnaires.

The study was carried out in accordance with the code of ethics of the World Medical Association (Declaration of Helsinki) for experiments involving humans. Ethical approval was granted by the ethics committee of the Department of Dynamic and Clinical Psychology.

Measures

Sociodemographic Questionnaire

The self-administered questionnaire collected data on multiple variables, including years of work experience, age, number of children, etc.

Maslach Burnout Inventory

The questionnaire adopted in this study to measure burnout is the Italian validation of the Maslach Burnout Inventory (MBI; Maslach et al., 1986; Sirigatti and Stefanile, 1993), composed of 22 items with a Likert scale from 0 (never) to 6 (daily). It defines burnout in three dimensions: emotional exhaustion (EE), depersonalization (DP), and personal accomplishment (PA). The EE represents the depletion of one's emotional resources (example: "I feel used up at the end of workday"). The dimension of DP brings a view of coworkers and clients as dehumanized objects instead of people (example: "I feel I treat some patients as if they were impersonal objects"). Finally, the PA reflects feelings of competence, productivity, and successful achievement in one's work (example: "I feel I'm positively influencing other people's lives through my work"). For this dimension only, a high score indicates low burnout level. In this study, Cronbach's alpha was satisfactory for all subscales: EE (α: 0.92), DP (α: 0.80), PA (α: 0.79).

Coping Inventory for Stressful Situations

The Coping Inventory for Stressful Situations (CISS; Endler and Parker, 1994) is a questionnaire of 48 items measured on a Likert scale from 1 (not at all) to 5 (very much). It was administered in the Italian validation (Sirigatti and Stefanile, 2009). The questionnaire can bring up three basic dimensions: *task-*, *emotion-*, and *avoidance-oriented coping*. The scale of Task-oriented coping emphasizes an action oriented to the task and on attempts to solve the problem. The Emotion-oriented coping scale involves the use of emotional strategies to reduce stress, where there are emotional responses (get angry, become tense) and in some cases the reaction actually increases stress. The scale of Avoidance-oriented coping describes activities and cognitive changes aimed at avoiding the stressful situation. The range of possible scores of each subscale is 16–80 with higher scores indicating greater use of a given coping style. Cronbach's alpha coefficient was 0.88 for Task-oriented coping, 0.90 for Emotion-oriented coping, and 0.85 for Avoidance-oriented coping.

The 14-Item Resilience Scale

The 14-item Resilience Scale (RS-14) used in this study is a 14-item resilience assessment (Wagnild, 2009) derived from the original Resilience Scale of Wagnild and Young (1993). This questionnaire is largely used in literature. The respondents to RS-14 were asked to state the degree to which they agree or disagree with each item on a 7-point Likert-type scale from 1 (strongly disagree) to 7 (strongly agree). In this research, we adopted the Italian version (Callegari et al., 2016) of this questionnaire (Cronbach's alpha: 0.89).

Intolerance of Uncertainty Scale Short Form

The Italian validation of Intolerance of Uncertainty Scale Short Form (IUS; Lauriola et al., 2016) is composed of 12 items measured on a Likert scale from 1 (not at all agree) to 5 (totally agree). In this questionnaire, uncertainty is conceptualized as a psychological stressor that can threaten an individual's capacity to cope effectively with situations when there is little or no information. The IUS has two scales: prospective IU and inhibitory IU. The prospective scale measures both the desire for predictability and an individual's active engagement in seeking information to increase certainty. The inhibitory scale reflects avoidance of uncertainty and paralysis in the face of uncertainty. In this study, Cronbach's alpha was 0.86 for prospective IU and 0.91 for inhibitory IU.

Data Analysis

The statistical analyses were conducted using the Statistical Package for Social Science (SPSS) version 25 for Windows (IBM, Armonk, NY, USA). Data were reported as frequencies and percentages for discrete variables and as means and standard deviations for continuous variables. Regarding burnout dimensions, a description of the levels at the MBI scales was

reported based upon cutoff scores identified by Sirigatti and Stefanile (1993). Moreover, we conducted a Cluster Analysis, which enables the categorization of participants on the basis of their profiles of responses on a selected set of variables (here, dimensions on the MBI). This approach allows researchers to identify groups that may not emerge *via* classical categorizations (i.e., low, medium, and high) but that nevertheless occur and do have a meaning for participants. The groups identified by the Cluster Analysis were compared on coping styles, intolerance of uncertainty, and resilience through one-way ANOVAs.

In addition, Pearson correlations were performed to explore the association between burnout dimensions and psychological features (coping, resilience, and intolerance of uncertainity). Finally, a set of multiple regression analyses was performed to investigate possible predictors of the burnout dimensions; multiple regression analyses were done separately for each of the three components of burnout as a dependent variable and the variables that were significant from the correlation analysis as predictors.

In all performed analyses, a significance criterion equal to or less than 0.05 was used to determine statistical significance.

TABLE 1 | Sociodemographic variables of the sample and descriptive statistics.

Sociodemographic variables	Mean	Standard deviation
Age	55.13	11.40
	%	*N*
Gender		
Female	62.7	64
Male	36.3	37
Other	1	1
Years of work experience		
Less than 3	7.8	8
From 3 to 5	2	2
From 5 to 10	3.9	4
More than 10	86.3	88
Psychotherapy		
No	88.2	90
Yes	11.8	12
Psychological Variables	**Mean**	**Standard Deviation**
MBI Emotional Exhaustion	26.47	13.33
MBI Depersonalization	7.53	6.13
MBI Personal accomplishment	35.02	6.95
CISS Task-oriented coping	62.38	9.19
CISS Emotion-oriented coping	39.21	12.00
CISS avoidant-oriented coping	45.40	11.02
Resilience	75.85	12.27
IU Prospective	22.12	6.49
IU Inhibitory	10.62	4.91

CISS, coping inventory for stressful situations; IU, intolerance of uncertainty; MBI, Maslach burnout inventory.

RESULTS

Descriptive Analysis

The total sample consisted of 102 Italian GPs (64 female). The sociodemographic characteristics and the questionnaire mean scale scores of the participants are presented in **Table 1**.

Regarding burnout levels, the EE score appears to be the most concerning finding (**Table 2**); 46.1% of the sample had a high level of EE based on the MBI cutoff (Maslach et al., 1986).

TABLE 2 | Levels of burnout in the sample.

	Low burnout Cutoff <17	Moderate burnout Cutoff 18–29	High burnout Cutoff >30
MBI Emotional Exhaustion	30.4%	23.5%	46.1%
	Low burnout Cutoff <5	**Moderate burnout Cutoff 6–12**	**High burnout Cutoff >12**
MBI Depersonalization	47.1%	35.3%	17.6%
	Low burnout Cutoff >40	**Moderate burnout Cutoff 36–39**	**High burnout Cutoff <36**
MBI Personal accomplishment	28.4%	29.4%	42.2%

MBI, Maslach burnout inventory.

Hierarchical Cluster Analysis and One-Way ANOVAs

As a first step, a hierarchical Cluster Analysis using Ward's method was run. We then adopted the squared Euclidean distance to determine profiles of participants according to their *z* scores on each subscale of the MBI (Hair et al., 2009; Berjot et al., 2017). The hierarchical Cluster Analysis suggested a four-cluster solution as shown by an examination of the dendrogram. The Bayesian Index Criterion (Schwarz, 1978) confirmed the four-cluster solution, as the lowest value was observed for this solution. In a second step, to validate the four-cluster solution, a k-mean Cluster Analysis on the numbers of clusters emerging in the hierarchical Cluster Analysis was run (Blashfield and Aldenderfer, 1988; Ransom and Fisher, 1995).

As shown in **Figure 1**, Cluster 1 (labeled "Medium Risk Burnout" profile, $N = 30$) included GPs who had relatively high levels of emotional exhaustion but medium depersonalization and personal accomplishment. Cluster 2 ("High Burnout" profile, $N = 6$) included GPs who had concomitantly high levels of emotional exhaustion and depersonalization and medium levels of personal accomplishment. Cluster 3 ("High Risk Burnout" profile, $N = 25$) was characterized by moderate levels of emotional exhaustion and depersonalization but also very low levels of personal accomplishment. Finally, Cluster 4 ("Low Burnout" profile, $N = 41$) was characterized by low levels of emotional exhaustion and depersonalization and a moderate level of personal accomplishment.

Means and SD for each dimension of the MBI scale according to the clusters were reported in **Table 3**.

Finally, we ran a series of one-way ANOVAs with clusters as an independent variable and each dimension – CISS, IU, and Resilience – as a dependent variable. As shown in **Table 4**, significant differences emerged on CISS Task-oriented ($F = 9.49$, $p = 0.00$) and Emotion-Oriented ($F = 16.78$, $p = 0.00$). Specifically, Bonferroni *post hoc* analysis showed lower levels of CISS Task-oriented coping in High Risk GPs compared to both

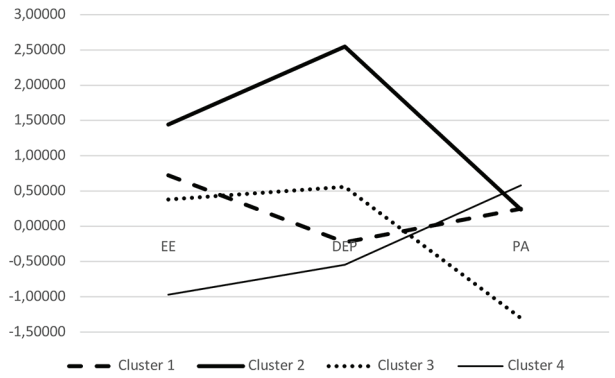

FIGURE 1 | Plot of means for each variable according to clusters. Cluster 1, medium risk burnout; Cluster 2, high burnout; Cluster 3, high risk burnout; Cluster 4, low burnout.

TABLE 3 | Mean scores and standard deviations for each dimension of the MBI scale according to clusters.

	N	Mean	SD
Emotional exhaustion			
Medium Risk Burnout	30	0.72	0.57
High Burnout	6	1.44	0.60
High Risk of Burnout	25	0.38	0.62
Low Burnout	41	−0.97	0.51
Depersonalization			
Medium Risk Burnout	30	−0.23	0.62
High Burnout	6	2.55	0.78
High Risk of Burnout	25	0.56	0.71
Low Burnout	41	−0.55	0.60
Personal accomplishment			
Medium Risk Burnout	30	0.25	0.62
High Burnout	6	0.24	0.92
High Risk of Burnout	25	−1.30	0.48
Low Burnout	41	0.58	0.73

Medium Risk (p = 0.05) and Low Burnout GPs (p = 0.05); higher levels of CISS Emotion-Oriented in High Burnout GPs compared to all the other groups (always p = 0.05). Regarding Resilience, higher levels emerged in Medium Risk GPs than in High Risk GPs (p = 0.05) and in Low Burnout than in High Risk (p = 0.05). Finally, higher levels of IU Prospective emerged in High Risk GPs than in Low Burnout (p = 0.05), and higher levels of IU Inhibitory were found in High Burnout GPs compared to both Medium Risk and Low Burnout GPs (always p = 0.05).

Correlational Analysis

Pearson correlational analyses were carried out to explore relationships between burnout subscales and sociodemographic characteristics. A correlation between MBI Depersonalization and age (r = −0.300, p = 0.002) and years of work experience (r = −0.283, p = 0.004) emerged, whereas no significant relationships were found for the gender and burnout dimensions.

Regarding the relationships between burnout and coping dimensions (**Table 5**), Pearson correlation analysis showed that MBI Emotional Exhaustion scale was positively correlated with CISS Emotion-oriented (r = 0.495, p = 0.001) and negatively with CISS Task-oriented (r = −0.247, p = 0.012); MBI Depersonalization scale correlated positively with CISS Emotion-Oriented (r = 0.522, p = 0.001) and Avoidance-oriented (r = 0.233, p = 0.019) and negatively with CISS Task-oriented (r = −0.221, p = 0.025); MBI Personal Accomplishment scale was correlated negatively with CISS Emotion-oriented (r = −0.312, p = 0.001) and positively with CISS Task-oriented (r = 0.590, p = 0.001).

Regarding the Resilience scale (**Table 5**), the analysis highlighted a significant positive correlation with the MBI Personal Accomplishment score (r = 0.686, p = 0.001) and a negative correlation with MBI Emotional Exhaustion (r = −0.247, p = 0.012) and Depersonalization (r = −0.200, p = 0.044).

Finally, the relationships between Burnout dimensions and Intolerance of Uncertainty (IU) subscales were explored (**Table 5**). MBI Emotional Exhaustion was correlated with IU Prospective and Inhibitory (respectively, r = 0.279, p = 0.005; r = 0.305, p = 0.002); MBI Depersonalization was positively correlated with IU Prospective (r = 0.232, p = 0.019); MBI Personal Accomplishment, on the other hand, was negatively correlated with IU Prospective and IU Inhibitory (respectively, r = −0.267, p = 0.007; r = −0.265, p = 0.007).

Regression Analysis

Since significant correlations between each dimension of burnout and participants' psychological and sociodemographic features emerged, three multiple linear regression models were performed to investigate possible predictors of MBI Emotional Exhaustion, Depersonalization, and Personal Accomplishment measures.

The first model of linear regression with MBI Emotional Exhaustion as the dependent variable and Resilience, CISS Emotion-oriented and Task-oriented, and IU Prospective as predictors was significant. The model predicted 27% of BMI Emotional exhaustion (R^2 = 0.274; adjusted R^2 = 0.244; p < 0.001) with only CISS Emotion-oriented scores found to be a significant predictor (beta = 0.461; p < 0.001).

A linear regression analysis having MBI Depersonalization as the dependent variable and age, resilience, all dimensions of CISS (Task-oriented, Emotion-oriented, and Avoidance-oriented), and IU Prospective as predictors was run. This model was significant and predicted 36% of MBI Depersonalization scores (R^2 = 0.365; adjusted R^2 = 0.318; p < 0.001); age and CISS Task-oriented and Emotion-oriented emerged as significant predictors (respectively, beta = 0.183, p = 0.034; beta = −0.298, p = 0.023; beta = 0.496, p < 0.001).

The last model of linear regression with MBI Personal Accomplishment as a dependent variable and Resilience, IU Inhibitory, and CISS Task-oriented and Emotion-oriented as predictors was run. This model was significant and predicted 51% of MBI Personal Accomplishment

*MBI, Maslach burnout inventory; CISS, coping inventory for stressful situations; Task, task-oriented coping; Emotional, emotion-oriented coping; Avoidance, avoidance-oriented coping; IU, intolerance of uncertainty. *$p < 0.05$; **$p < 0.001$.*

(R^2 = 0.512; adjusted R^2 = 0.486; $p < 0.001$) and showed that only Resilience was a predictor of MBI Personal Accomplishment (beta = 0.500; $p < 0.001$).

DISCUSSION

This research explored the relationships among psychological phenomena (coping, resilience, and perception of uncertainty) and Burnout among GPs in Italy. The extraordinary impact of the COVID-19 emergency on GPs, as frontline medical providers, was in part produced by the uncertainty of the procedures and treatments required and the immediate saturation of hospitals for critical case management. GPs had to respond directly to a huge number of requests without clear prevention or screening instruments. All these aspects affected the GPs, who, according to the MBI cutoff, simultaneously showed high perception of competence and productivity (the 28.4% of the sample had a high level of Personal Accomplishment at the MBI) and a reduction in emotional resources (the 46.1% had a high level of Emotional Exhaustion). In addition to a classification of participants according to existing cutoff scores, we utilized an alternative technique, cluster analysis, which provides criteria specific to the population under study. This choice allowed us to rise above "all or nothing" conceptualizations (i.e., people suffer from burnout or they do not) and to identify subgroups of burnout according to the individual experience of work (Berjot et al., 2017). It also allowed for the identification of specific groups or at-risk groups, which may enable the selection and the deployment of specific prevention and intervention programs (Clatworthy et al., 2005). The cluster analysis showed four different profiles, labeled "Low Burnout," "High Burnout," "Medium Risk Burnout," and "High Risk Burnout."

Results partially confirmed the cutoff categorization, showing 40% of the sample in the Low Burnout profile and only about 5% in the High Burnout profile.

Cluster analysis allows for a more qualitative reading using burnout scales. It highlighted two risk profiles: a "Medium Risk Burnout" cluster (30% of the sample) and a "High Risk of Burnout" cluster (25% of the sample). Those two groups cannot be classified as suffering burnout, but they emerged by cluster analysis as groups that can be described as being "at risk of burnout," composed of professionals who may 1 day suffer burnout if environmental demands and threats remain high while resources remain low. Specifically, the "Medium Risk Burnout" profile included GPs who had relatively high levels of emotional exhaustion but medium depersonalization and personal accomplishment while the "High Risk Burnout" profile was characterized by moderate levels of emotional exhaustion and depersonalization but very low levels of personal accomplishment. In this last case, the gratification that work

can offer cannot act as a personal resource, protecting against the risk of depersonalization and emotional exhaustion. Comparing all four groups strengthens this observation, highlighting that the high risk group showed lower resilience and did less task-oriented coping than the medium risk group and demonstrated more need for control than the low burnout group. These specific characteristics can be used as indications for differentiated interventions in support of GPs, focusing and intervening on specific pandemic reaction patterns. Moreover, the group with high burnout was characterized by higher use of emotional strategies to reduce stress than the other three groups and higher avoidance of uncertainty, as well as paralysis in the face of it.

Starting from these first analyses, and from the correlations' results, the regressions were performed in order to examine which psychological features predicted burnout levels. Results showed, according to the previous comparison between burnout profiles, that depletion of the emotional resources was related to emotion-oriented coping, so the activation of emotional strategies was associated with a less functional response to the emergency. These data are probably affected by the fact that GPs' activities were limited by lockdown rules and the impossibility of using concrete clinical findings to manage patients' symptoms and disease progression, relying instead on patient reports of their subjective experiences. Emotion-oriented coping is strictly related to a higher sense of responsibility to solve other problems (i.e., I blame myself for not knowing what to do) and take care of the situation, so the missing doctor-patient relationship and the absence of medical protocols generated a higher sense of inefficacy and frustration in the immediate reactions to the pandemic. Moreover, it is possible that GPs did not have the resources to experience and process the intense emotional reactivity linked to the pandemic, and to the perception of the risk of being infected, at least in the immediate emergency. This may have left many of them with intense, unregulated emotions, which could interfere with professional response.

This hypothesis is supported by the results related to the Depersonalization scale of the MBI that was predicted by high levels of Emotion-oriented coping and low levels of Task-oriented coping. The primary resource to avoid the tendency of viewing coworkers and clients as dehumanized objects seemed to be the task-oriented coping that, consistent with previous research, represented a proactive and concrete response to stress (Chang and Chan, 2015; Lall et al., 2019). In a highly stressful situation like the COVID-19 emergency, emphasizing a task-oriented action, planning, and problem-solving, rather than an emotion-oriented strategy, appears to be a more effective way to provide care without depersonalization. It is also important to note that depersonalization was the only variable related to age and years of work experience; this finding is supported by the literature (Lim et al., 2010), where a longer period of exposure to suffering tends to generate more depersonalization. The years of work variable was found to have the most significant positive correlations to Burnout (Iglesias et al., 2010). This finding is important to take into consideration in understanding any GP turnover that may follow this traumatic situation, as well as in simply understanding the impact of the pandemic on GPs. On the basis of these results, it would be appropriate for medical systems in Italy and beyond to develop programs for preventing and treating burnout syndromes in GPs.

The findings in this paper contribute to our field's understanding of the benefits and drawbacks of coping strategies focused on emotions or on problem-solving, which appear to be dependent on context. Understanding that in the context of a crisis like a pandemic, problem-solving strategies may do more to prevent burnout and depersonalization among medical professionals and can help to tailor training and preparation for these frontline providers in the future.

Furthermore, it is clear from these results that Resilience has an important role: it is a significant predictor of burnout Personal Accomplishment, according to the literature (Taku, 2014; Kutluturkan et al., 2016). Resilience is a person's ability to manage his or her sense of responsibility in an unfamiliar and chaotic situation like the COVID-19 pandemic and can have a meaningful impact on his or her capacity to work effectively. In fact, resilience – defined as a person's capacity for or produced outcome of successful adaptation despite challenging or threatening circumstances (Masten et al., 1990) – is positively correlated with feelings of competence, productivity, and success. Moreover, our findings showed that the High Risk Burnout group had lower scores in Resilience than all other groups, suggesting that this feature is important to prevent burnout. The fact that GPs' capacity for resilience in the present pandemic situation is connected in this research with their sense of work efficacy suggests that resilience may be an important part of professional identity in the medical field, as may be the case for a general belief in medical practice, even when immediate solutions and pharmacological cures fall short.

Finally, the perception of the COVID-19 pandemic as an unpredictable situation was analyzed using an assessment scale (Intolerance of Uncertainty Scale) that revealed two factors as principal reactions to uncertainty: the desire for predictability and uncertainty paralysis (Hong and Lee, 2015). Although the scales were not significant predictors of burnout in the regression analyses, they were positively correlated with emotional exhaustion and negatively correlated with personal accomplishment. The unpredictable situation and unfamiliar scenarios had a strong impact on emotional distress and raised psychological defenses. We can speculate that chaotic situations and constantly changing protocols affected self-efficacy and made a direct impact on GPs' personal and emotional lives.

There are several limitations inherent in the present study. First, since the COVID-19 pandemic affected regions of Italy in different ways, it would be interesting to have a larger sample to be able to verify whether the relationships between burnout and psychological characteristics are different depending on the severity of the health emergency in any given region. A second limitation involves the absence of a control group, which would be useful in future investigations for performing comparative analysis. Hospital staff, rather

than other emergency management personnel (such as the army force), could represent a comparison group. This would allow for the identification of specific stress reaction patterns in the different groups. In addition, long-term follow-up to collect further data on GPs' health status would help to verify the predictive role of burnout on the long-term psycho-physical health of participants.

In conclusion, the results of this study showed an impact on GPs' work management during the COVID-19 emergency. Implementing task-oriented problem management, rather than emotional strategies, appears to protect against burnout. It is possible that the emotions related to the pandemic are too intense to be regulated and used in order to manage the professional issues that the COVID-19 pandemic involves. Moreover, these results support the need to organize both training and psychological interventions for GPs, with the aim of providing them with greater skills in emotional regulation in general and, over the course of an emergency, supporting their capacity to process intense emotional experiences, which can impact the quality of medical work.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Ethics Committee of Department of Dynamic and Clinical Psychology, University of Rome, Sapienza. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

CDM contributed to all the phases of the study. SM participated in research design development, in results interpretation, and in writing and editing the manuscript. Introduction: Health emergencies, such as epidemics, have detrimental and long-lasting consequences on people's mental health, which are higher during the implementation of strict lockdown measures. Despite several recent psychological researches on the coronavirus disease 2019 (COVID-19) pandemic highlighting that young adults represent a high risk category, no studies specifically focused on young adults' mental health status have been carried out yet. This study aimed to assess and monitor Italian young adults' mental health status during the first 4 weeks of lockdown through the use of a longitudinal panel design.

Methods: Participants (n = 97) provided self-reports in four time intervals (1-week intervals) in 1 month. The Syndromic Scales of Adult Self-Report 18-59 were used to assess the internalizing problems (anxiety/depression, withdrawn, and somatic complaints), externalizing problems (aggressive, rule-breaking, and intrusive behavior), and personal strengths. To determine the time-varying effects of prolonged quarantine, a growth curve modeling will be performed.

Results: The results showed an increase in anxiety/depression, withdrawal, somatic complaints, aggressive behavior, rule-breaking behavior, and internalizing and externalizing problems and a decrease in intrusive behavior and personal strengths from T1 to T4.

Conclusions: The results contributed to the ongoing debate concerning the psychological impact of the COVID-19 emergency, helping to plan and develop efficient intervention projects able to take care of young adults' mental health in the long term.

Keywords: coronavirus disease 2019, quarantine, young adult, mental health, Achenbach adult self-report, internalizing/externalizing problems, growth model

INTRODUCTION

The novel coronavirus disease 2019 (COVID-19) is a highly infectious disease that began as a viral pneumonia in late December 2019. In March 2020, the World Health Organization (WHO) declared the state of pandemic.

As rapidly pointed out (Fiorillo and Gorwood, 2020; Jakovljevi et al., 2020), the COVID-19 global pandemic has affected—and is still affecting—not only physical health but also individual, family, and collective mental health. In line with recent studies (Horesh and Brown, 2020; Masiero et al., 2020), the COVID-19 pandemic should be classified as a critical event with a potential traumatic nature, which may be overwhelming and could lead to complex emotional responses that can negatively affect individuals and collective psychological systems.

Starting with China and followed by other states, extraordinary measures and containment efforts (e.g., lockdown) aimed to prevent the high risk of contagion and limit the COVID-19 outbreak have been adopted. In Europe, Italy was the first country that had to face the pandemic. Here, on March 09, 2020, strict lockdown measures were imposed by the government. A series of decrees imposed restrictions on the movements of individuals in the entire national territory from March 10 until May 3. During the lockdown, people were allowed to leave their homes only for limited and documented purposes. Schools, universities, theaters, and cinemas, as well as any shops selling non-essential goods were, therefore, temporarily closed.

As previous studies demonstrated (Tucci et al., 2017), health emergencies, such as epidemics, have detrimental and long-lasting consequences on people's mental health. Concerning the COVID-19 pandemic, initial studies carried out in China reported high levels of anxiety, depression, and trauma-related symptoms (Qiu et al., 2020), both during the epidemic peak and 1 month later (Wang et al., 2020). Moreover, the detrimental effect of epidemics on mental health seems to be higher during the implementation of strict lockdown measures. Specifically, previous studies have associated quarantine with higher levels of trauma-related disorders (Wu et al., 2009), depression (Hawryluck et al., 2004), irritability and insomnia (Lee et al., 2005), acute stress (Bai et al., 2004), and avoidance behaviors and anger (Marjanovic et al., 2007). In a recent review, Brooks et al. (2020) individuated major stress factors as being the long duration of quarantine, the fear of infection, the inadequate supplies and information, boredom, and frustration. In a recent Italian study carried out during the third week of lockdown, Cellini et al. (2020) have highlighted that Italians reported high levels of depression, anxiety, and sleep disturbances. Similarly, Rossi A. et al. (2020) have found that high rates of negative mental health outcomes were seen in the general population 3 weeks into the COVID-19 lockdown.

Within the stream of research investigating the impact of quarantine during epidemics on individual's mental health, there have been very few longitudinal investigations aimed at understanding and monitoring the changes in the mental health status during quarantine (Brooks et al., 2020). Where longitudinal research designs were carried out, they were limited to investigating people's mental health during and after quarantine (Jeong et al., 2016; Wang et al., 2020).

Recent psychological research on COVID-19 has also highlighted that specific target groups are more at risk than others to develop a wide variety of psychological problems, such as medical workers, marginalized people (i.e., homeless and migrants), and young adults. Regarding young adults (18–30 years old), recent researches have highlighted that they present higher levels of anxiety, distress, and depression than do other adult groups (Cao et al., 2020; Huang and Zhao, 2020; Qiu et al., 2020). These findings have also been confirmed in Italy (Rossi R. et al., 2020). According to Cheng et al. (2014), one of the possible reasons can be found in young adults' tendency to obtain information from social media, which can represent a high stress factor for mental health. These initial findings strongly suggest the need to assess and monitor young adults' psychological situation during the epidemic and the weight of their mental health outcomes. To the best of the authors' knowledge, there are no previous studies specifically aimed at evaluating the impact of lockdown measures on Italian young adults' mental health and monitor the changes in their mental health status.

To fill this gap, the current study presents a longitudinal panel design aimed to assess the Italian young adults' mental health status and monitor their mental health trends during the firsts 4 weeks of lockdown imposed from the Italian government during the COVID-19 outbreak. On the basis of recent literature on the general population, an increase in mental health problems among young adults during quarantine was hypothesized.

MATERIALS AND METHODS

Participants

Participants were enrolled online and provided self-reports over 1 month (1-week intervals, T1–T2–T3–T4). Participants were considered eligible for participation if they met the following inclusion criteria: (a) were between 19 and 29 years and (b) were in a lockdown condition. Exclusion criteria were as follows: (a) diagnosis of psychiatric disorder and/or psychopharmacological treatment (assessed with filter questions in the survey) and (b) not "absolute" lockdown condition (workers who were allowed to work outside their home during the lockdown measures).

From the initial sample size of T1 (N = 120), nine participants did not participate at T2 (N = 111); four other participants did not participate at T3 (N = 107); and 10 other participants did not participate at T4. These participants were, therefore, excluded from the data analysis. The final simple-size was composed of 97 participants.

Procedure

Approval from the University Research Ethics Committee was obtained for collecting data. Data collection took place during the Italian lockdown from mid-March 2020 to mid-April 2020. The administration took place in four time intervals (1-week intervals) in 1 month. The first survey (T1) was made at the end of the first week of lockdown. The second survey (T2) coincided with the end of the second week of the lockdown. The third

survey (T3) coincided with the end of the third week of the lockdown. The fourth survey (T4) coincided with the end of the fourth week of the lockdown.

Participants were informed about a complete guarantee of confidentiality and the voluntary nature of participation and their right to discontinue at any point. The enrollment procedure was carried out through an online advertising on social platforms. Participants voluntarily accessed the online platform used for data collection once a week for the 4 weeks of administration. To ensure anonymity, a request was made to create a personal identification code to be used for the four administrations.

Measures

Adult Self-Report (ASR/18-59)

The Syndromic Scales of Adult Self-Report 18-59 (Achenbach and Rescorla, 2003) were used to assess the internalizing and externalizing problems.

The ASR is especially valuable when used routinely, as in this study design. The ASR norms provide a standardized benchmark with which to compare what is reported by each individual. Standardized reassessments over a regular interval enable to identify reported stabilities and changes in a group who have particular kinds of problems. In this case, the ASR instrument was administered at regular intervals of 1 week for 4 weeks in the period of the Italian lockdown. The ASR was developed both to document specific problems and to identify syndromes of co-occurring problems. In this study, six specific Syndromic Scales, Anxious/Depressed, Withdrawn, Somatic Complaints, Aggressive Behavior, Rule-Breaking Behavior, and Intrusive were used. Anxious/Depressed (18 items) refers to anxiety and depressive symptoms (e.g., "I feel lonely" and "I am too fearful or anxious"). Withdrawn (8 items) mainly refers to attitudes of isolation and lack of contact with others (e.g., "I don't get along with other people" and "I keep from getting involved with others"). Somatic Complaints (12 items) include physical illness, without a known medical cause (e.g., "I feel dizzy or lightheaded" and "Physical problems without a known medical cause: stomachaches"). Aggressive Behavior (15 items) includes behaviors and attitudes characterized by poor control of one's aggression (e.g., "I blame others for my problems" and "I scream or yell a lot"). Rule-Breaking Behavior (14 items) refers to transgressive behavior and violation of social norms (e.g., "I am impulsive or act without thinking" and "I lie or cheat"). Intrusive (6 items) refers to the difficulty faced in the interpersonal relationships and to the prevalence of intrusive behavior (e.g., "I damage or destroy my things" and "I drink too much alcohol or get drunk"). In addition, the broadband scales, Internalizing and Externalizing, were computed. Internalizing problems reflect internal distress, while externalizing problems reflect conflicts with other people. The Internalizing scale consists of the syndrome scales Anxious/Depressed, Withdrawn, and Somatic Complaints, whereas the Externalizing scale consists of Aggressive Behavior and Rule-Breaking Behavior. Moreover, the scale of Personal Strengths (11 items) was used to assess the adaptive functioning of the individuals (e.g., "I try to get a lot of attention" and "I am louder than others").

The items are scored on a three-point rating scale: 0 (*not true*), 1 (*somewhat or sometimes true*), and 2 (*very true or often true*); and a total score may be calculated. Higher raw scores indicate more problematic behaviors on each scale. Then, a normalized *T* score—weighted for sex and age—was assigned for the Syndromic Scales and to each Internalizing and Externalizing Problem scales. Raw scores of the both types of scales have been quantitatively converted in terms of gender- and age-specific *T* scores. Clinical significant threshold is indicated by *T*-scores $\geq$ 70. Borderline range is from 65 to 69.

The ASR is a reliable and valid measure for the 18–59 general population (Achenbach and Rescorla, 2003). Cronbach's alpha (α) and McDonald's omega (ω) are reported in **Table 1**.

Data Analysis

Statistical analyses were performed with R software (v. 3.5.3; R Core Team, 2014, 2015) and the following packages: psych (v. 1.8.12; Revelle, 2018), irr (v. 0.84.1; Gamer et al., 2019), lme4 (v.1.1-21; Bates et al., 2015), lmerTest (v. 3.1-2; Kuznetsova et al., 2017), esvis (v. 0.3.1; Anderson, 2020), AICcmodavg (v2.3-0; Mazerolle, 2020), and ggplot2 (v. 3.1.0; Wickham, 2016).

No data were missing for any of the participants on any of the ASR scales at any of the measurement points. Reliability was evaluated by internal consistency analysis, using Cronbach's alpha (α) and McDonald's omega for categorical data (ω).

First, the mean differences between the four time intervals (T1, T2, T3, and T4) were performed. The unbiased sample estimate of standardized mean difference effect sizes (Hedges' *g*; Hedges, 1981) was performed, evaluating the magnitude of these differences. The following established ranges guide interpreting standardized mean difference magnitude: from 0.20 to 0.49 = small; from 0.50 to 0.79 = medium; and 0.80 = large (Cohen, 1988).

Growth curve analysis (GCA) models were used to estimate the growth trajectories (i.e., slopes) of the Syndromic Scales of the ASR—both Internalizing and Externalizing scales—and the personal strength scale. Models also estimated subject variability in change across time, as represented in random-intercepts coefficients. Parameters in each GCA model were computed with maximum likelihood (ML) estimation.

Several models were estimated for each of the outcome variables, separately. Specifically, it was hypothesized that the time (the week of quarantine) could have had an effect on the ASR Syndromic Scales. In addition, it was also hypothesized that covariates, such as sex and the experience of COVID-19 (EXP-CVD19), intended as the experience of direct proximity with relatives and/or friends affected by COVID-19, could have had an effect on the shape of the growth curve across time. Models were sequentially specified according to the guidelines (Long, 2012; Grimm et al., 2017). *First*, a null model was estimated to provide a baseline comparison and to calculate the intraclass correlation coefficient (Model 0—Intercept only). *Second*, a null model with covariates was specified (Model 1—Intercept model with covariates). *Third*, a linear model with time as predictor and covariate interactions was estimated (Model 2—Linear model with covariates). *Fourth*, a quadratic model was specified with linear interaction effects of the covariates (Model 3—Quadratic

model with linear covariates interactions). *Fifth*, a quadratic model was specified with all possible interactions of the covariates (Model 4—full quadratic model with covariates). Equations of each model are reported in **Table 2**.

The best model fit was assessed with several indices. First of all, the likelihood ratio test (LRT) was performed between one model and the following one in a step-up approach analysis: Model 0 vs. Model 1; Model 1 vs. Model 2; Model 2 vs. Model 3; and Model 3 vs. Model 4—the most parsimonious model will be preferred (Long, 2012). In addition, also "information criteria" indices were computed by comparing the abovementioned models. First, the Schwarz Bayesian information criterion (BIC; Schwarz, 1978; Burnham and Anderson, 2002) was calculated: the model with the lower BIC indicated the best model—and it is recommended when model parsimony is overriding (Kadane and Lazar, 2004; Long, 2012). Moreover, considering that the BIC tends to favor simpler model (Long, 2012), the corrected Akaike information criterion (AICc; Akaike, 1973; Azari et al., 2006) was also computed: even in this case, the model with the lower AICc indicated the best model. In addition, considering that—on a theoretical level—the BIC is less desirable for model evaluation than the AICc (Long, 2012), several effect sizes based on the AICc were carried out: (I) the difference of AICc (ΔAICc); (II) the weight of evidence (W_h): given a set of competing models and the unknowable true model, the W_h indicates the probability that a model *h* is the best approximate model (the model with the large W_h is the best-fitting model) (the more probable the model is, the best approximating the model will be to the true model); (III) the evidence ratio (E_h) that expresses the difference—in odds—between the best-fitting model and the first worst-fitting model: the higher the E_h, the more plausible is the best-fitting model.

RESULTS

Preliminary Analysis

Of 97 participants, 48 were male (49.5%) and 49 were female (50.5%). The mean age of the sample was 24.62 (*SD* = 2.88; range = 19–29). A total of 29 participants (29.9%) had experienced proximity with a COVID-19-infected relative or friend. Most of the participants lived with their parents during the quarantine (80.4%). All participants came from the Campania region, in Southern Italy, and attended the university.

Means and standard deviations between the four time intervals (T1, T2, T3, and T4) and the effect size of means difference (Hedges' *g*) are displayed in **Table 1**. The preliminary analysis showed that the increments tended to be small from T1 to T2 for each syndromic scale and breadboard scale (0.45 was the highest value). From T2 to T3, the results highlighted a medium increase for the Anxious/Depressed, Withdrawn, and Internalizing scales. From T3 to T4, the increase was null. For Somatic Complaints, Aggressive Behaviors, Rule-Breaking Behavior, and Externalizing scales, the magnitude of the effect size was medium only considering the increments from T1 to T4. Across the weeks of quarantine, the Somatic Complaints scale increased with an almost null effect. Finally, the Personal Strengths showed a small increase only from T1 to T3 and from T1 to T4.

Scatterplot (**Figure 1**) showing the change of the Syndromic Scales and broadband scales score over time. **Figures 2–5** graphically show means and standard error of the Syndromic

TABLE 2 | Equations of each estimated model.

	Model	Equation
M.0	Intercept only	$y_{ij} = (\beta_0 + b_{0i}) + \varepsilon_{ij}$
M.1	Intercept model with covariates	$y_{ij} = (\beta_0 + b_{0i}) + \beta_1\,(sex_i) + \beta_2\,(experience\ with\ COVID19_i) + \varepsilon_{ij}$
M.2	Linear model with covariates	$y_{ij} = (\beta_0 + b_{0i}) + \beta_1\,(week\ of\ quarantine_{ij}) + \beta_2(sex_i) + \beta_3\,(experience\ with\ COVID19_i) + \beta_4(week\ of\ quarantine_{ij} * sex_i) + \beta_5(week\ of\ quarantine_{ij} * experience\ with\ COVID19_i) + \varepsilon_{ij}$
M.3	Quadratic model with linear covariates interactions	$y_{ij} = (\beta_0 + b_{0i}) + \beta_1\,(week\ of\ quarantine_{ij}) + \beta_2(week\ of\ quarantine_{ij}^2) + \beta_3\,(sex_i) + \beta_4\,(experience\ with\ COVID19_i) + \beta_5\,(week\ of\ quarantine_{ij} * sex_i) + \beta_6\,(week\ of\ quarantine_{ij} * experience\ with\ COVID19_i) + \varepsilon_{ij}$
M4	Quadratic model with all covariates interactions	$y_{ij} = (\beta_0 + b_{0i}) + \beta_1\,(week\ of\ quarantine_{ij}) + \beta_2(week\ of\ quarantine_{ij}^2) + \beta_3\,(sex_i) + \beta_4\,(experience\ with\ COVID19_i) + \beta_5\,(week\ of\ quarantine_{ij} * sex_i) + \beta_6\,(week\ of\ quarantine_{ij} * experience\ with\ COVID19_i) + \beta_7(week\ of\ quarantine_{ij}^2 * sex_i) + \beta_8\,(week\ of\ quarantine_{ij}^2 * experience\ with\ COVID19_i) + \varepsilon_{ij}$

Scales, as well as the related broadband scales, across the weeks of quarantine. Specifically, **Figure 3** was split by sex (males vs. females), and **Figure 4** was split by the experience of COVID-19 (yes vs. no). Finally, **Figure 5** shows the interaction between sex and experience of COVID-19. The broken lines demarcate a borderline clinical range from the 93rd to 97th percentiles for the Syndromic scales and from the 84th to 90th percentiles for the Internalizing and Externalizing broadband scales. Scores above the top broken line, i.e., above the 97th percentile for the Syndromic scales and above the 90th for the Internalizing and Externalizing broadband, indicate that the individual reported enough problems to be of clinical concern. Scores below the bottom broken line is in the normal range. As show in **Figure 2**, the Anxious/Depressed scale is above the clinical threshold in T3, and the Withdrawn scale is above the normal threshold in T3 with an increase in T4.

Anxious/Depressed

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 24.41.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 ($b = -0.961$, $SE = 3.460$, $t = 0.077$, $p = 0.782$) or their main effects (sex: $b = -0.081$, $SE = 1.891$, $t = -0.043$, $p = 0.966$; EXP-CVD19: $b = 0.191$, $SE = 2.476$, $t = 0.077$, $p = 0.939$).

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.310$, $SE = 1.065$, $t = 0.291$, $p = 0.771$) or the two simple main effects (sex: $b = 4.797$, $SE = 2.908$, $t = 1.649$, $p = 0.099$; EXP-CVD19: $b = -1.076$, $SE = 3.176$, $t = -0.339$, $p = 0.735$). However, the model revealed a statistically significant interaction effect between time and sex ($b = -2.066$, $SE = 0.975$, $t = -2.118$, $p = 0.035$) as well as the principal effect of time ($b = 5.114$, $SE = 0.760$, $t = 6.732$, $p < 0.001$). **Figure 3** shows a greater increase in males from T1 to T2 and from T2 to T3 than in females.

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.310$, $SE = 1.057$, $t = 0.293$, $p = 0.769$) or the two simple main effects (sex: $b = 4.797$, $SE = 2.892$, $t = 1.659$, $p = 0.098$; EXP-CVD19: $b = -1.076$, $SE = 3.156$, $t = -0.341$, $p = 0.734$). However, the model revealed a statistically significant linear interaction effect between time and sex ($b = -2.066$, $SE = 0.967$, $t = -2.125$, $p = 0.033$) as well as the principal effect of time: both linear ($b = 11.016$, $SE = 2.807$, $t = 3.925$, $p < 0.001$) and quadratic ($b = -1.180$, $SE = 0.541$, $t = -2.183$, $p = 0.030$).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 5.1607$, $SE = 5.991$, $t = 0.861$, $p = 0.340$) nor quadratic ($b = -0.970$, $SE = 1.179$, $t = -0.823$, $p = 0.411$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = -4.990$, $SE = 5.485$, $t = -0.910$, $p = 0.364$) nor quadratic ($b = 0.585$, $SE = 1.080$, $t = 0.542$, $p = 0.589$). Furthermore, also the simple main effects of sex ($b = -7.721$, $SE = 6.123$, $t = 1.261$, $p = 0.208$), EXP-CVD ($b = -5.926$, $SE = 6.688$, $t = -0.886$, $p = 0.376$), and time (quadratic term: $b = -1.186$, $SE = 0.841$, $t = -1.410$, $p = 0.160$) revealed a non-statistically significant effect. Only the main effect of time (linear term: $b = 11.043$, $SE = 4.272$, $t = 2.585$, $p = 0.010$) became statistically significant.

The comparison of the different multilevel growth curve models provided ambiguous results. Indeed, M.2 showed the lower BIC, but M.3 showed the lower AICc. The LRT suggested a statistical significant difference between M.3 and M.2 [$\chi^2(1) = 4.726$; $p = 0.030$]. In addition, the ΔAICc suggested a small difference M.3 and M.2 (2.63); the W_h of M.3 suggested that this model had 68% probability of being the best approximate model; and the E_h suggested that M.3 had a weight of evidence almost four times (3.72) greater than that of M.2 of being the best approximate model (**Table 3**).

Withdrawn

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 38.95.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 ($b = -2.474$, $SE = 3.768$, $t = -0.657$, $p = 0.513$) or their main effects (sex: $b = -0.059$, $SE = 2.059$, $t = -0.029$, $p = 0.977$; EXP-CVD19: $b = -1.441$, $SE = 2.696$, $t = -0.534$, $p = 0.594$).

BM, best model; ASR, adult self-report; LRT, likelihood ratio test; BIC, Bayesian information criterion; AICc, corrected Akaike information criterion; Wh, weight of evidence.

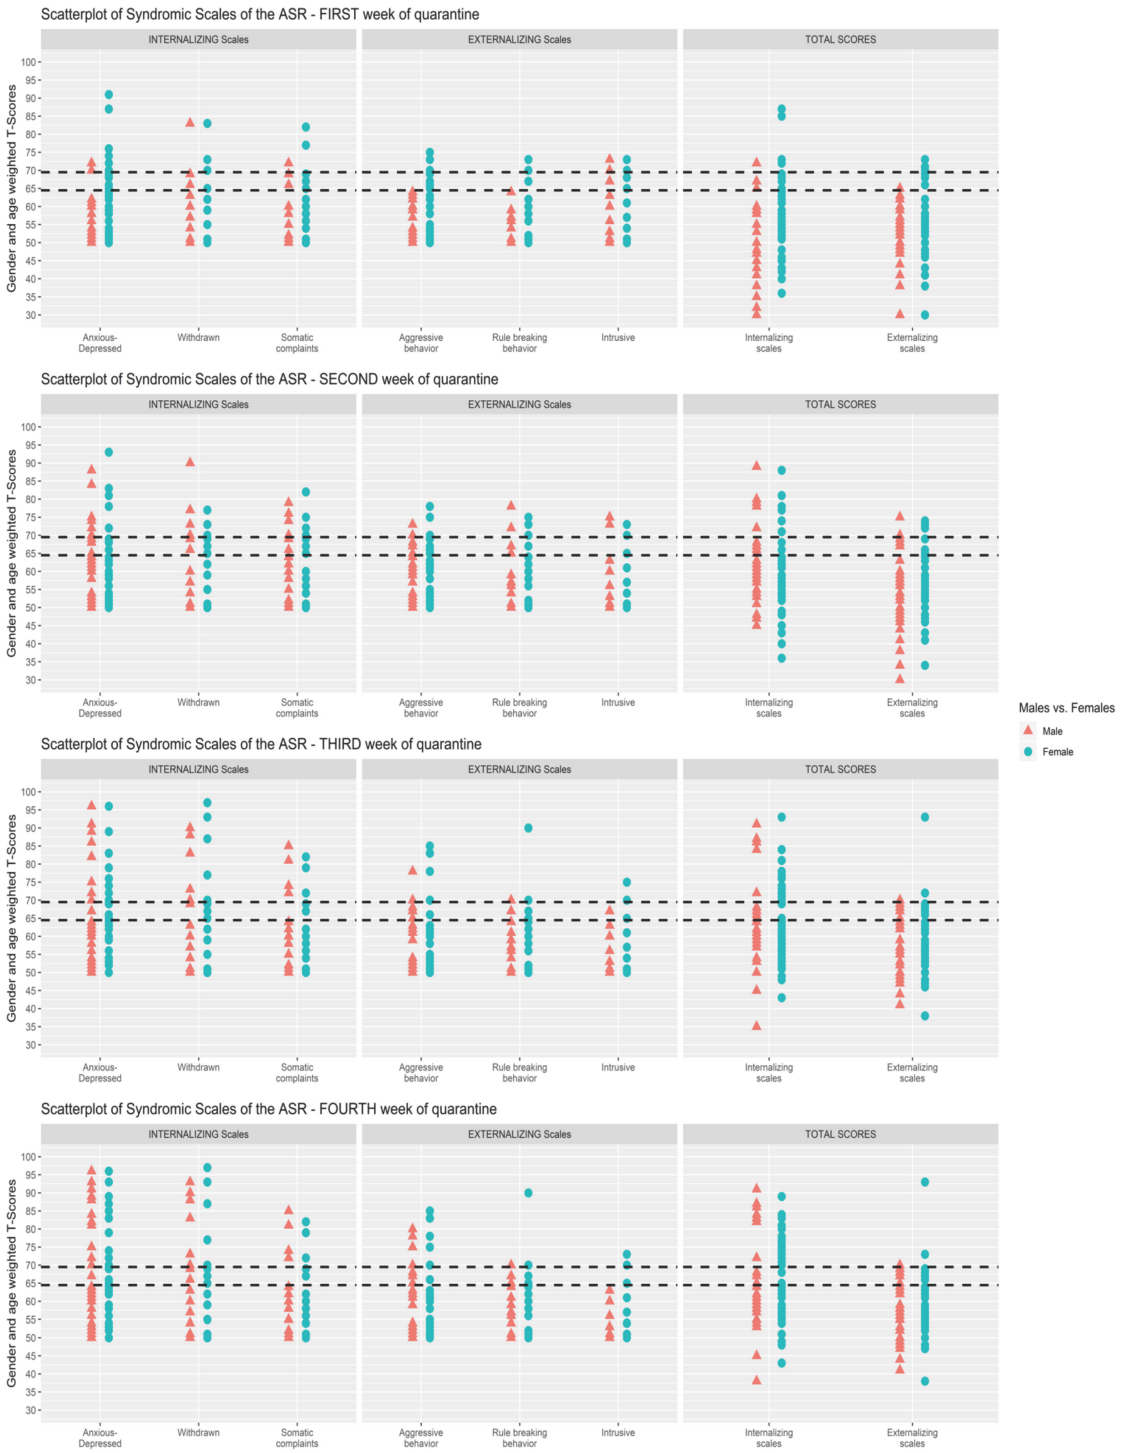

FIGURE 1 | Scatterplot of Syndromic Scales of the Adult Self-Report (ASR) for each week of quarantine.

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 (b = 0.925, SE = 1.079, t = 0.858, p = 0.392) or the two simple main effects (sex: b = −3.817, SE = 3.015, t = −1.266, p = 0.206; EXP-CVD19: b = −5.022, SE = 3.292, t = −1.525, p = 0.128). Moreover, the model revealed a non-statistically significant interaction effect between time and sex (b = 1.205, SE = 0.988, t = 1.222, p = 0.222). Only the main effect of time (b = 2.705, SE = 0.769, t = 3.515, p < 0.001) became statistically significant.

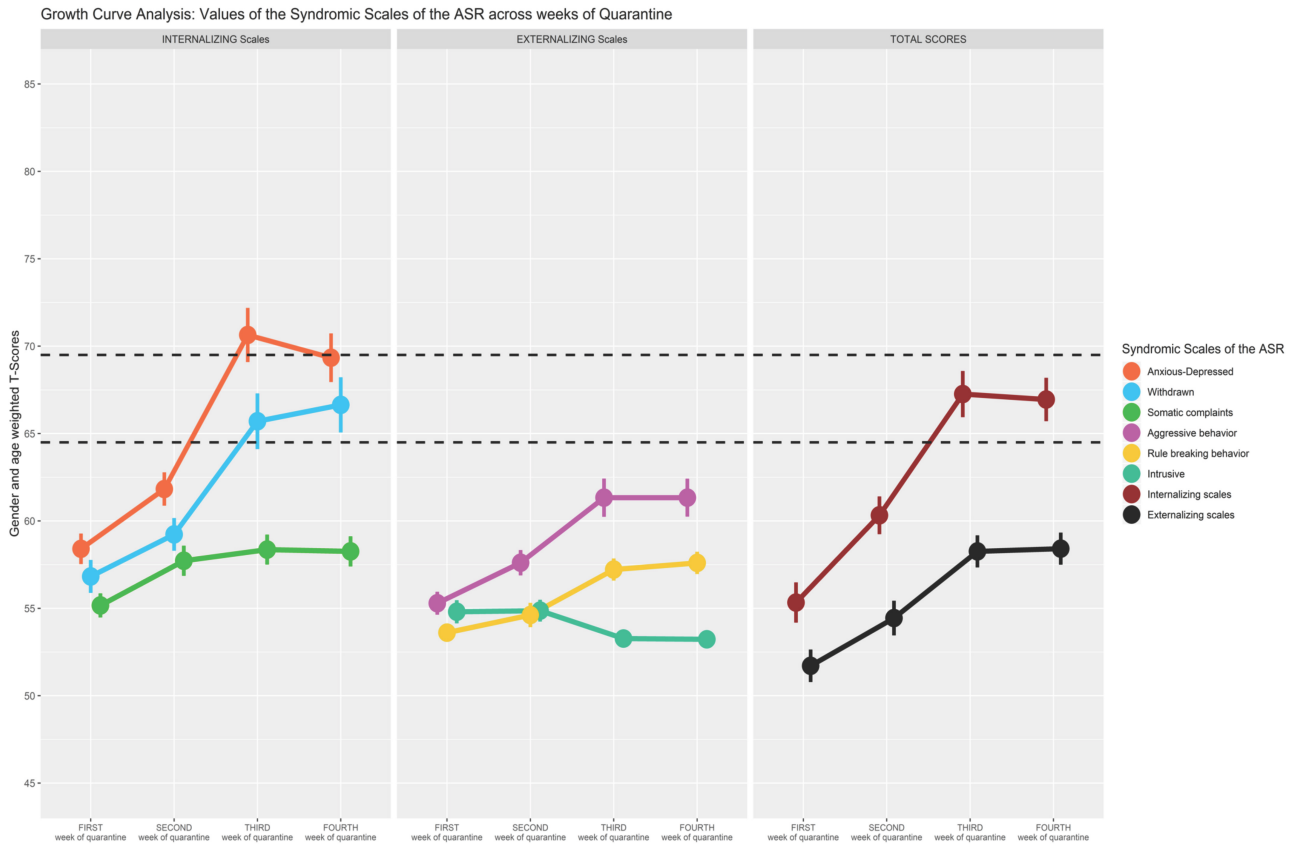

FIGURE 2 | Growth curve analysis: means and standard error of the Syndromic Scale across weeks of quarantine.

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.925$, $SE = 1.078$, $t = 0.858$, $p = 0.391$) or the two simple main effects (sex: $b = 3.817$, $SE = 3.013$, $t = -1.267$, $p = 0.206$; EXP-CVD19: $b = -5.022$, $SE = 3.291$, $t = -1.526$, $p = 0.128$). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex ($b = 1.207$, $SE = 0.987$, $t = 1.223$, $p = 0.222$) as well as the principal effect of time: both linear ($b = 4.535$, $SE = 2.864$, $t = 1.583$, $p = 0.114$) and quadratic ($b = -0.366$, $SE = 0.552$, $t = -0.663$, $p = 0.508$).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 5.035$, $SE = 6.116$, $t = 0.823$, $p = 0.411$) nor quadratic ($b = -0.822$, $SE = 1.204$, $t = -0.683$, $p = 0.495$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = 3.739$, $SE = 5.600$, $t = -0.669$, $p = 0.505$) nor quadratic ($b = 0.506$, $SE = 1.102$, $t = -0.459$, $p = 0.646$). Furthermore, also the simple main effects of sex ($b = -6.349$, $SE = 6.281$, $t = -1.011$, $p = 0.313$), EXP-CVD ($b = -9.132$, $SE = 6.859$, $t = -1.331$, $p = 0.184$), and time (linear term: $b = 2.027$, $SE = 4.361$, $t = 0.465$, $p = 0.642$, and quadratic term: $b = -0.136$, $SE = 0.859$, $t = 0.158$, $p = 0.875$) revealed a non-statistically significant effect.

The comparison of the different multilevel growth curve models suggested that the linear model with covariates (M.2) showed the lower BIC and the lower AICc. The LRT showed that M.2 was statistically significantly different from M.1 (intercept model with covariates). However, despite that M.2 was not statistically significantly different from M.3, it was the most parsimonious, and thus, it was chosen as the best model. Indeed, the ΔAICc suggested a small difference M.2 and M.3 (1.66), the W_h of M.2 indicates that this model had 66% probability of being the best approximate model, and the E_h suggested that M.2 had a weight of evidence more than two times (2.29) greater than M.3 of being the best approximate model (**Table 3**).

Somatic Complaints

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 6.25.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 ($b = -0.557$, $SE = 2.019$, $t = -0.276$, $p = 0.783$) or their main effects (sex: $b = 0.169$, $SE = 1.103$, $t = 0.153$, $p = 0.878$; EXP-CVD19: $b = 1.704$, $SE = 1.445$, $t = 1.179$, $p = 0.241$).

The linear model with covariates (M.2) revealed a statistically significant effect of the interaction between time and EXP-CVD19 ($b = 2.714$, $SE = 0.734$, $t = 3.698$, $p < 0.001$), and of the simple main effect of EXP-CVD19 ($b = -5.365$, $SE = 2.094$,

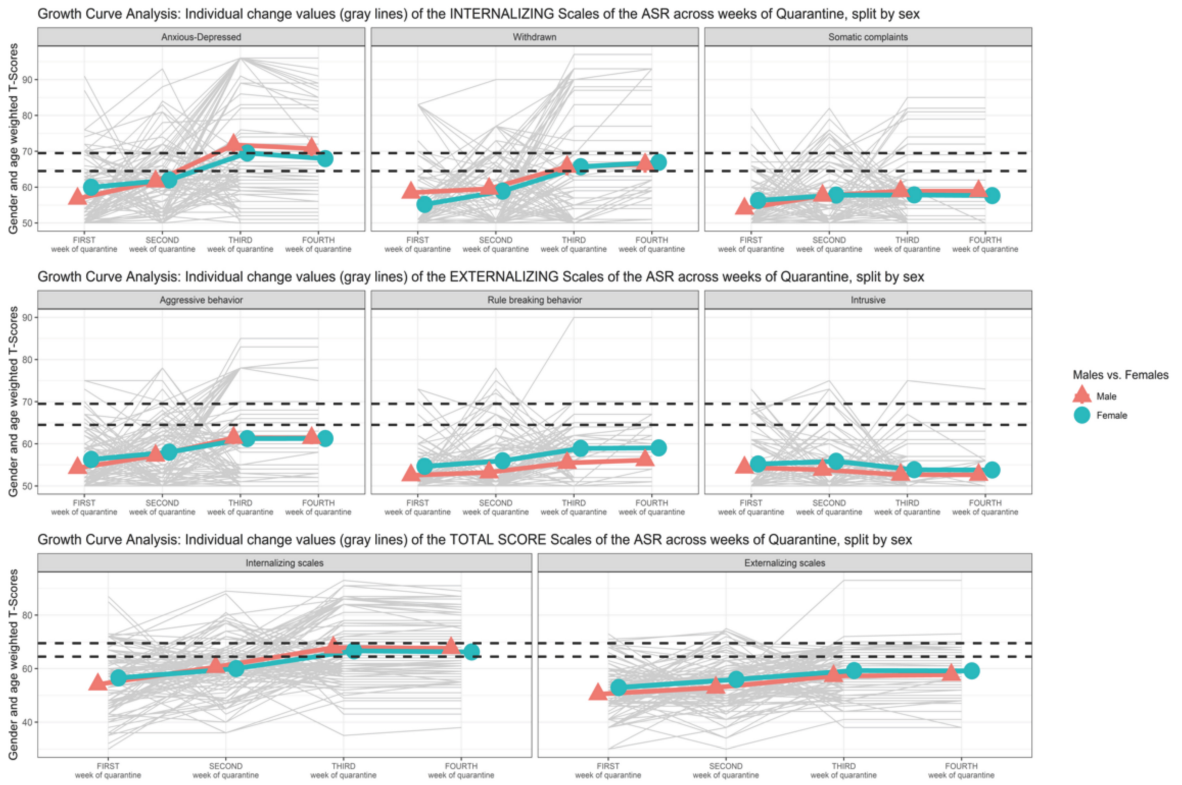

FIGURE 3 | Growth curve analysis (GCA): means and standard error of the Syndromic Scale across weeks of quarantine split by sex.

$t = -2.562$, $p = 0.011$). However, the model revealed a non-statistically significant main effect of sex ($b = 3.049$, $SE = 1.912$, $t = 1.590$, $p = 0.113$). Moreover, the model revealed a non-statistically significant interaction effect between time and sex ($b = -1.219$, $SE = 0.762$, $t = 1.183$, $p = 0.070$) as well as the principal effect of time ($b = 0.796$, $SE = 0.523$, $t = 1.521$, $p = 0.129$). **Figure 4** shows a greater increase from T3 to T4 of the participants with EXP-CVD19.

The quadratic model with linear interaction (M.3) showed a statistically significant effect of the interaction between time and EXP-CVD19 ($b = 2.714$, $SE = 0.729$, $t = 3.718$, $p < 0.001$), and of the simple main effect of EXP-CVD19 ($b = -5.365$, $SE = 2.085$, $t = -2.573$, $p = 0.010$). However, the model revealed a non-statistically significant main effect of sex ($b = 3.049$, $SE = 1.901$, $t = 1.597$, $p = 0.111$). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex ($b = -1.219$, $SE = 0.668$, $t = 1.823$, $p = 0.069$). The model showed a statistically significant effect of time as linear ($b = 4.121$, $SE = 1.938$, $t = 2.125$, $p = 0.034$) but not as a quadratic term ($b = -0.665$, $SE = 0.373$, $t = 1.780$, $p = 0.076$).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 6.929$, $SE = 4.134$, $t = 1.676$, $p = 0.094$) nor quadratic ($b = -0.843$, $SE = 0.814$, $t = -1.036$, $p = 0.301$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = -3.668$, $SE = 3.786$, $t = -0.969$, $p = 0.333$) nor quadratic ($b = 0.490$, $SE = 0.745$, $t = 0.657$, $p = 0.511$). Furthermore, also the simple main effects of sex ($b = 5.498$, $SE = 4.186$, $t = 1.314$, $p = 0.190$) and time (linear term: $b = 4.098$, $SE = 2.948$, $t = 1.390$, $p = 0.166$, and a quadratic term: $b = -0.660$, $SE = 0.580$, $t = 1.138$, $p = 0.256$) revealed a non-statistically significant effect. However, the model showed a statistically significant effect of EXP-CVD19 ($b = -9.580$, $SE = 4.571$, $t = -2.096$, $p = 0.037$).

The comparison of the different multilevel growth curve models provided unclear results. Indeed, the linear model (M.2) showed the lower BIC, but the quadratic model (M.3) showed the lower AICc. The LRT showed that M.2 was not statistically significantly different from M.3. However, M.2 was the most parsimonious and thus was chosen as best model. Also the effect size indices suggested a negligible preference for M.3 instead of M.2. Indeed, the ΔAICc suggested a very small difference M.2 and M.3 (1.66), the W_h of M.3 suggested that this model had 54% probability of being the best approximate model (W_h of M.2 was 32%), and the Eh suggested that M.3 had a weight of evidence almost two times (1.7) greater than M.2 of being the best approximate model (**Table 3**).

Aggressive Behavior

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 14.70.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and

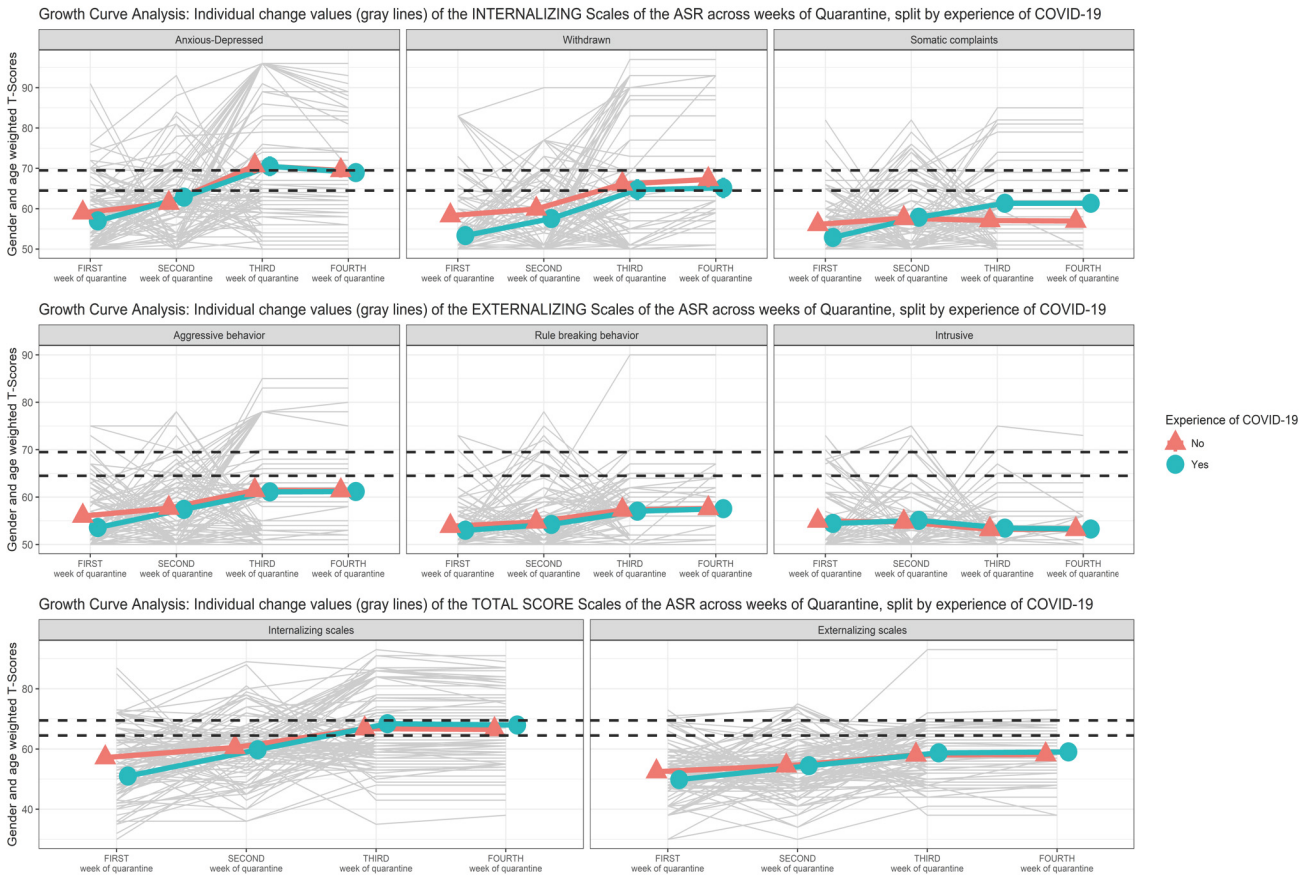

FIGURE 4 | Growth curve analysis (GCA): means and standard error of the Syndromic Scale across weeks of quarantine split by "experience of COVID-19".

EXP-CVD19 ($b = 1.333$, $SE = 2.518$, $t = 0.529$, $p = 0.598$) or their main effects (sex: $b = 0.250$, $SE = 1.376$, $t = 0.182$, $p = 0.856$; EXP-CVD19: $b = -1.507$, $SE = 1.802$, $t = -0.836$, $p = 0.405$).

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.670$, $SE = 0.788$, $t = 0.850$, $p = 0.396$) or the two simple main effects (sex: $b = 2.533$, $SE = 2.141$, $t = 1.183$, $p = 0.238$; EXP-CVD19: $b = -2.498$, $SE = 2.338$, $t = -1.069$, $p = 0.286$). Moreover, the model revealed a non-statistically significant interaction effect between time and sex ($b = -0.754$, $SE = 0.721$, $t = -1.045$, $p = 0.297$) but only a statistically significant principal effect of time ($b = 2.365$, $SE = 0.562$, $t = 4.221$, $p < 0.001$).

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.670$, $SE = 0.785$, $t = 0.853$, $p = 0.394$) or the two simple main effects (sex: $b = 2.533$, $SE = 2.135$, $t = 1.186$, $p = 0.236$; EXP-CVD19: $b = -2.499$, $SE = 2.332$, $t = -1.071$, $p = 0.285$). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex ($b = -0.754$, $SE = 0.719$, $t = -1.049$, $p = 0.295$) and the principal effect of time as a quadratic term ($b = -0.580$, $SE = 0.402$, $t = -1.444$, $p = 0.150$). Conversely, the model showed a statistically significant principal effect of time as a linear term ($b = 5.265$, $SE = 2.085$, $t = 2.525$, $p = 0.012$).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 3.262$, $SE = 4.453$, $t = 0.733$, $p = 0.464$) or quadratic ($b = -0.519$, $SE = 0.877$, $t = -0.592$, $p = 0.555$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = -2.320$, $SE = 4.077$, $t = -0.569$, $p = 0.570$) nor quadratic ($b = 0.313$, $SE = 0.830$, $t = 0.390$, $p = 0.670$). Furthermore, also the simple main effects of sex ($b = 4.099$, $SE = 4.546$, $t = 0.902$, $p = 0.368$), EXP-CVD19 ($b = -5.091$, $SE = 4.964$, $t = -1.026$, $p = 0.306$), and the time both linear ($b = 5.281$, $SE = 3.175$, $t = 1.663$, $p = 0.097$) and quadratic ($b = -0.583$, $SE = 0.625$, $t = -0.933$, $p = 0.352$) revealed a non-statistically significant effect.

The comparison of the different multilevel growth curve models suggested that the linear model with covariates (M.2) showed the lower BIC and the lower AICc. The LRT showed that M.2 was statistically significantly different from M.1 (intercept model with covariates). However, although M.2 was not statistically significantly different from M.3, it was the most parsimonious—and thus, it was chosen as the best model. However, the effect size indices suggested a negligible preference

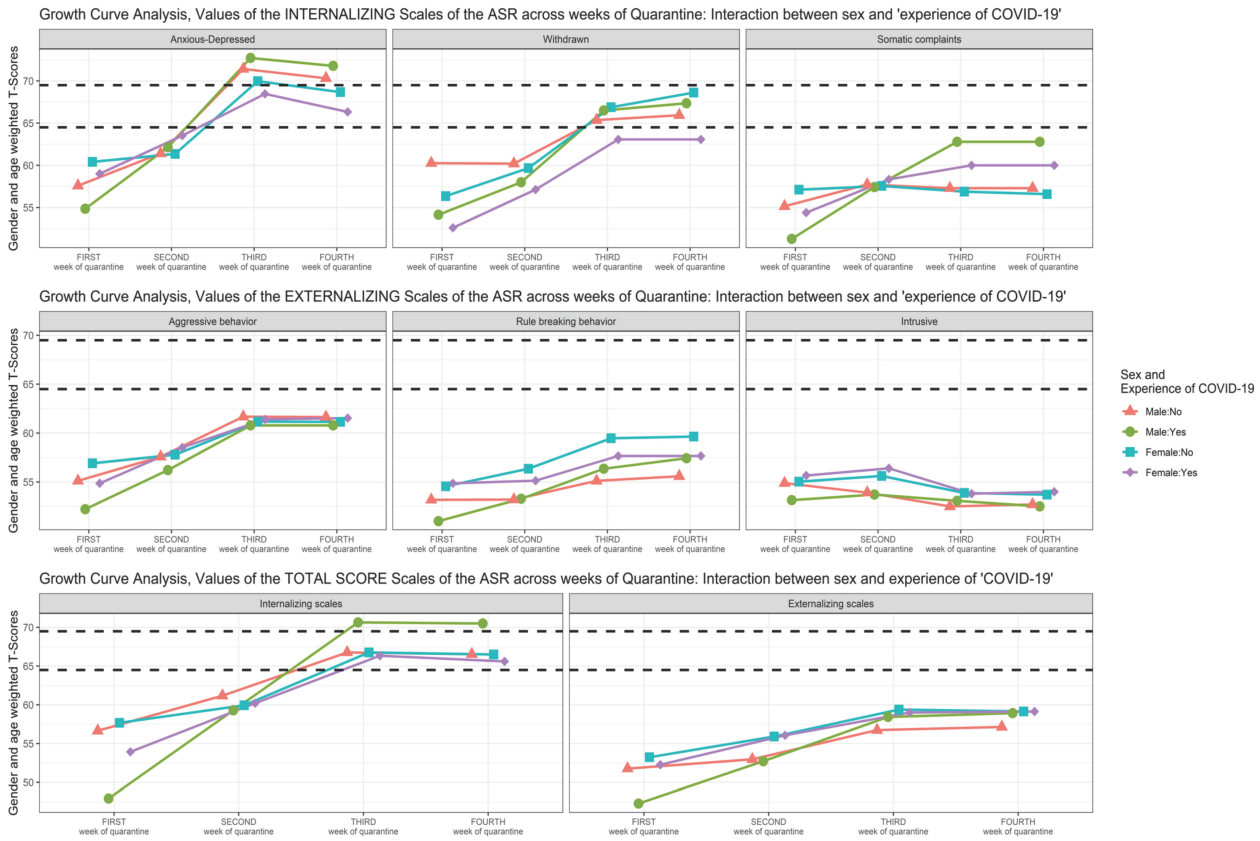

FIGURE 5 | Growth curve analysis (GCA): means of the Syndromic Scale across weeks of quarantine—interaction between "sex" and "experience of COVID-19".

for M.2. Indeed, the ΔAICc suggested a very small difference M.2 and M.3 (0.02), the W_h of M.2 suggested that this model had 47% probability of being the best approximate model (W_h of M.3 was 46%), and the E_h suggested that M.2 had a weight of evidence of 1.01 greater than M.3 of being the best approximate model (**Table 3**).

Rule-Breaking Behavior

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 5.53.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 ($b = -1.419$, $SE = 1.540$, $t = -0.922$, $p = 0.359$) or the main effect of EXP-CVD19 ($b = 0.246$, $SE = 1.102$, $t = 0.223$, $p = 0.824$). Instead, the model shows a significant effect of sex ($b = 3.235$, $SE = 0.842$, $t = 3.843$, $p < 0.001$).

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.263$, $SE = 0.548$, $t = 0.480$, $p = 0.632$) or the two simple main effects (sex: $b = 2.045$, $SE = 1.441$, $t = 1.419$, $p = 0.157$; EXP-CVD19: $b = -1.139$, $SE = 1.573$, $t = -0.724$, $p = 0.469$). Moreover, the model revealed a non-statistically significant interaction effect between time and sex ($b = 0.306$, $SE = 0.502$, $t = 0.610$, $p = 0.542$) but a statistically significant principal effect of time ($b = 1.223$, $SE = 0.391$, $t = 3.129$, $p = 0.002$).

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.263$, $SE = 0.548$, $t = 0.480$, $p = 0.631$) or the two simple main effects (sex: $b = 2.045$, $SE = 1.440$, $t = 1.420$, $p = 0.156$; EXP-CVD19: $b = -1.139$, $SE = 1.573$, $t = -0.724$, $p = 0.469$). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex ($b = 0.306$, $SE = 0.502$, $t = 0.611$, $p = 0.542$) as well as the principal effect of time: both linear ($b = 2.009$, $SE = 1.455$, $t = 1.381$, $p = 0.168$) and quadratic ($b = -0.157$, $SE = 0.280$, $t = -0.561$, $p = 0.575$).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 0.408$, $SE = 3.110$, $t = 0.131$, $p = 0.896$) nor quadratic ($b = -0.029$, $SE = 10.612$, $t = -0.047$, $p = 0.962$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = 1.757$, $SE = 2.847$, $t = 0.617$, $p = 0.538$) nor quadratic ($b = -0.290$, $SE = 0.560$, $t = -0.518$, $p = 0.605$). Furthermore, also the simple main effects of sex ($b = 0.594$, $SE = 3.151$, $t = 0.189$, $p = 0.851$), EXP-CVD19 ($b = -1.284$, $SE = 3.441$, $t = -0.373$, $p = 0.709$), and time (linear term: $b = 1.233$, $SE = 2.218$, $t = 0.556$, $p = 0.579$; quadratic term: $b = -0.001$, $SE = 0.436$, $t = 0.005$, $p = 0.996$) revealed a non-statistically significant effect.

The comparison of the different multilevel growth curve models suggested that the linear model with covariates (M.2) showed the lower BIC and the lower AICc. The LRT showed that M.2 was statistically significantly different from M.1 (intercept model with covariates). However, despite that M.2 was not statistically significantly different from M.3, it was the most parsimonious—and thus, it was chosen as the best model. However, the effect size indices suggested a small preference for M.2. Indeed, the ΔAICc suggested a small difference M.2 and M.3 (1.78), the W_h of M.2 indicates that this model had 68% probability of being the best approximate model, and the E_h recommend that M.2 had a weight of evidence more than two times (2.24) greater than M.3 of being the best approximate model (**Table 3**).

Intrusive Behavior

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 2.81.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 ($b = 0.801$, $SE = 1.339$, $t = 0.598$, $p = 0.551$) or their main effects (sex: $b = 1.059$, $SE = 0.732$, $t = 1.446$, $p = 0.151$; EXP-CVD19: $b = -0.393$, $SE = 0.958$, $t = -0.410$, $p = 0.683$).

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.165$, $SE = 0.509$, $t = 0.324$, $p = 0.746$) or the two simple main effects (sex: $b = 1.282$, $SE = 1.317$, $t = 0.973$, $p = 0.331$; EXP-CVD19: $b = -0.395$, $SE = 1.439$, $t = -0.275$, $p = 0.784$). Moreover, the model revealed a non-statistically significant interaction effect between time and sex ($b = 0.006$, $SE = 0.466$, $t = 0.014$, $p = 0.989$) as well as the principal effect of time ($b = -0.685$, $SE = 0.363$, $t = -1.88$, $p = 0.060$).

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 ($b = 0.165$, $SE = 0.509$, $t = 0.324$, $p = 0.746$) or the two simple main effects (sex: $b = 1.281$, $SE = 1.317$, $t = 0.973$, $p = 0.331$; EXP-CVD19: $b = -0.395$, $SE = 1.438$, $t = -0.275$, $p = 0.784$). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex ($b = 0.006$, $SE = 0.466$, $t = 0.014$, $p = 0.989$) as well as the principal effect of time: both linear ($b = -0.557$, $SE = 1.352$, $t = -0.412$, $p = 0.681$) and quadratic ($b = -0.025$, $SE = 0.260$, $t = -0.099$, $p = 0.921$).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 1.431$, $SE = 2.889$, $t = 0.495$, $p = 0.621$) nor quadratic ($b = -0.253$, $SE = 0.568$, $t = -0.445$, $p = 0.656$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = 1.481$, $SE = 2.645$, $t = 0.560$, $p = 0.576$) nor quadratic ($b = -0.295$, $SE = 0.521$, $t = -0.566$, $p = 0.572$). Furthermore, also the simple main effects of sex ($b = -0.192$, $SE = 2.918$, $t = -0.066$, $p = 0.947$), EXP-CVD19 ($b = -1.662$, $SE = 3.187$, $t = -0.521$, $p = 0.602$), and time (linear term: $b = -1.680$, $SE = 2.060$, $t = -0.815$, $p = 0.415$; quadratic term: $b = 0.199$, $SE = 0.406$, $t = 0.490$, $p = 0.624$) revealed a non-statistically significant effect.

The comparison of the different multilevel growth curve models provided unclear results. Indeed, the intercept-only model (without covariates—M.0) showed the lower BIC, but the linear model (M.2) showed the lower AICc. The LRT showed that M.0 was not statistically significantly different from M.1 (intercept model with covariates) but M.2 was statistically significantly different from M.1. In addition, the effect size indices suggested a negligible preference for M.2. Indeed, the ΔAICc suggested a very small difference M.2 and M.0 (1.44), the W_h of M.2 suggested that this model had 47% probability of being the best approximate model (W_h of M.0 was 23%), and the E_h suggested that M.2 had a weight of evidence two times (2.05) greater than M.0 of being the best approximate model (**Table 3**).

Internalizing Broadband Scale

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 16.37.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 ($b = 0.514$, $SE = 3.224$, $t = -0.159$, $p = 0.874$) or their main effects (sex: $b = -0.059$, $SE = 1.762$, $t = -0.033$, $p = 0.973$; EXP-CVD19: $b = -0.690$, $SE = 0.307$, $t = -0.299$, $p = 0.766$).

The linear model with covariates (M.2) revealed a statistically significant effect of the interaction between time and EXP-CVD19 ($b = 2.540$, $SE = 1.062$, $t = 2.392$, $p = 0.017$) and the EXP-CVD19 simple main effect ($b = -7.304$, $SE = 3.106$, $t = -2.351$, $p = 0.019$). Moreover, the model revealed a non-statistically significant interaction effect between time and sex ($b = -1.269$, $SE = 0.972$, $t = -1.305$, $p = 0.193$) and the sex simple main effect ($b = 2.961$, $SE = 2.844$, $t = 1.041$, $p = 0.298$). Only the main effect of time ($b = 4.061$, $SE = 0.757$, $t = 5.636$, $p < 0.001$) became statistically significant.

The quadratic model with linear interaction (M.3) showed a statistically significant effect of the interaction between time and EXP-CVD19 ($b = 2.540$, $SE = 1.051$, $t = 2.417$, $p = 0.016$) and the simple main effects of EXP-CVD19 ($b = -7.304$, $SE = 3.083$, $t = -2.369$, $p = 0.018$). However, the model revealed a non-statistically significant linear interaction effect between time and sex ($b = -1.269$, $SE = 0.962$, $t = -1.319$, $p = 0.188$) and the sex simple main effect ($b = 2.961$, $SE = 2.822$, $t = 3.827$, $p < 0.001$). The effects of time both linear ($b = 10.685$, $SE = 2.792$, $t = 3.827$, $p < 0.001$) and quadratic ($b = -1.325$, $SE = 0.538$, $t = -2.463$, $p = 0.014$) became statistically significant.

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear ($b = 9.509$, $SE = 5.950$, $t = 1.598$, $p = 0.111$) nor quadratic ($b = -1.394$, $SE = 1.171$, $t = -1.190$, $p = 0.325$). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear ($b = -4.910$, $SE = 5.448$, $t = -0.901$, $p = 0.368$) nor quadratic ($b = 0.728$, $SE = 1.073$, $t = 0.679$, $p = 0.498$). Furthermore, also the simple main effects of sex ($b = -6.601$, $SE = 6.058$, $t = 1.090$, $p = 0.277$) and time (quadratic term: $b = -1.275$, $SE = 0.835$, $t = -1.527$, $p = 0.128$) revealed a non-statistically significant effect. The main effects of EXP-CVD19 ($b = -14273$, $SE = 6.616$, $t = -2.157$, $p = 0.031$)

and the time as a linear term (b = 10.439, SE = 4.243, t = 2.460, p = 0.014) became statistically significant.

The comparison of the different multilevel growth curve models suggested that the quadratic model with linear covariates interaction (M.3) showed the lower BIC and the lower AICc. The LRT showed that M.3 was statistically significantly different from M.2 (linear model with covariates). However, the LRT suggested that M.3 was not statistically significantly different from M.4, but it was more parsimonious—and thus, M.3 was chosen as the best model. However, the effect size indices suggested a small preference for M.3. Indeed, the ΔAICc suggested a small difference M.3 and M.4 (2.38), the W_h of M.3 suggested that this model had 69% probability of being the best approximate model, and the E_h suggested that M.3 had a weight of evidence more than three times (3.29) greater than M.4 of being the best approximate model (**Table 3**).

Externalizing Broadband Scale

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 5.82.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 (b = 0.013, SE = 2.269, t = 0.006, p = 0.996) or their main effects (sex: b = 2.264, SE = 1.240, t = 1.826, p = 0.071; EXP-CVD19: b = −0.315, SE = 1.624, t = −0.194, p = 0.847).

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 (b = 1.131, SE = 0.867, t = 1.303, p = 0.193) or the two simple main effects (sex: b = 3.319, SE = 2.241, t = 1.481, p = 0.139; EXP-CVD19: b = −3.135, SE = 2.448, t = −1.281, p = 0.201). Moreover, the model revealed a non-statistically significant interaction effect between time and sex (b = −0.420, SE = 0.794, t = −0.529, p = 0.597). Only the main effect of time (b = 2.266, SE = 0.619, t = 3.662, p < 0.001) became statistically significant.

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 (b = 1.130, SE = 0.864, t = 1.308, p = 0.192) or the two simple main effects (sex: b = 3.319, SE = 2.235, t = 1.485, p = 0.138; EXP-CVD19: b = −3.135, SE = 2.441, t = −1.284, p = 0.199). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex (b = −0.420, SE = 0.792, t = −0.531, p = 0.596) as well as the principal effect of time as a quadratic term (b = −0.644, SE = 0.442, t = −1.456, p = 0.146). Only the main effect of time as a linear term (b = −5.487, SE = 2.296, t = 2.389, p = 0.017) became statistically significant.

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear (b = 4.135, SE = 4.905, t = 0.943, p = 0.400) nor quadratic (b = −0.601, SE = 0.966, t = −0.622, p = 0.534). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear (b = 0.965, SE = 4.492, t = 0.215, p = 0.830) nor quadratic (b = −0.277, SE = 0.884, t = −0.313, p = 0.754). Furthermore, also the simple main effects of sex (b = 1.934, SE = 4.953, t = 0.390, p = 0.696), EXP-CVD19 (b = −6.140, SE = 5.410, t = −1.135, p = 0.258), and time (linear term: b = 3.889, SE = 3.498, t = 1.112, p = 0.267, and quadratic term: b = −0.325, SE = 0.689, t = −0.472, p = 0.638) revealed a non-statistically significant effect.

The comparison of the different multilevel growth curve models provided unclear results. Indeed, the linear model (M.2) showed the lower BIC, but the quadratic model (M.3) showed the lower AICc. The LRT showed that M.3 was not statistically significantly different from M.2. However, despite that M.2 was not statistically significantly different from M.3, it was the most parsimonious—and thus, it was chosen as the best model. However, the effect size indices suggested a negligible preference for M.3. Indeed, the ΔAICc suggested a very small difference M.3 and M.2 (0.02), the W_h of M.3 suggested that this model had 47% probability of being the best approximate model (W_h of M.2 was 46%), and the E_h suggested that M.3 had a weight of evidence of 1.01 greater than M.2 of being the best approximate model (**Table 3**).

Personal Strengths

Preliminary analyses (M.0) revealed that the variance related to the random intercept of the participants was equal to 1.18.

The null model with covariates (M.1) revealed a non-statistically significant effect of the interaction between sex and EXP-CVD19 (b = −0.248, SE = 0.792, t = −0.313, p = 0.755) or their main effects (sex: b = −0.154, SE = 0.433, t = −0.357, p = 0.722; EXP-CVD19: b = 0.499, SE = 0.567, t = 0.880, p = 0.381).

The linear model with covariates (M.2) revealed a non-statistically significant effect of the interaction between time and EXP-CVD19 (b = 0.066, SE = 0.274, t = 0.242, p = 0.809) or the two simple main effects (sex: b = 0.228, SE = 0.724, t = 0.315, p = 0.752; EXP-CVD19: b = 0.206, SE = 0.791, t = 0.261, p = 0.794). Moreover, the model revealed a non-statistically significant interaction effect between time and sex (b = −0.182, SE = 0.250, t = −0.729, p = 0.466). Only the main effect of time (b = −0.513, SE = 0.195, t = −2.629, p = 0.009) became statistically significant.

The quadratic model with linear interaction (M.3) showed a non-statistically significant effect of the interaction between time and EXP-CVD19 (b = 0.066, SE = 0.273, t = 0.242, p = 0.809) or the two simple main effects (sex: b = 0.228, SE = 0.723, t = 0.316, p = 0.752; EXP-CVD19: b = 0.206, SE = 0.789, t = −0.261, p = 0.794). Moreover, the model revealed a non-statistically significant linear interaction effect between time and sex (b = −0.182, SE = 0.250, t = −0.730, p = 0.466) as well as the principal effect of time: both linear (b = −1.157, SE = 0.726, t = −1.594, p = 0.112) and quadratic (b = 0.128, SE = 0.139, t = 0.921, p = 0.358).

Finally, the quadratic model with all covariates interactions (M.4) showed a non-statistically significant effect of the interaction between time and EXP-CVD19, neither linear (b = 0.820, SE = 1.549, t = 0.529, p = 0.597) nor quadratic (b = −0.150, SE = 0.305, t = −0.494, p = 0.621). In addition, M.4 showed also a non-statistically significant effect of the interaction between time and sex, neither linear (b = −1.314, SE = 1.418, t = −0.926, p = 0.355) nor quadratic (b = 0.226, SE = 0.279, t = 0.810, p = 0.418). Moreover, also the simple main effects of

sex (b = 1.360, SE = 1.572, t = 0.865, p = 0.388), EXP-CVD19 (b = −0.547, SE = 1.717, t = −0.319, p = 0.750), and time (linear term: b = −0.811, SE = 1.104, t = −0.734, p = 0.463; quadratic term: b = 0.059, SE = 0.217, t = 0.274, p = 0.784) revealed a non-statistically significant effect.

The comparison of the different multilevel growth curve models suggested that the linear model with covariates (M.2) showed the lower BIC and the lower AICc. The LRT showed that M.2 was statistically significantly different from M.1 (null model with covariates). However, the LRT suggested M.2 was not statistically significantly different from M.3, but it was more parsimonious—and thus, M.3 was chosen as the best model. However, the effect size indices suggested a small preference for M.2. Indeed, the ΔAICc suggests a small difference M.2 and M.3 (1.25), the W_h of M.2 indicates that this model had 61% probability of being the best approximate model (W_h of M.3 was 33%), and the E_h suggested that M.2 had a weight of evidence almost two times (1.87) greater than M.3 of being the best approximate model (**Table 3**).

DISCUSSION

As stated above, in addition to being a public physical health emergency, the COVID-19 pandemic also implies a global mental health emergency that may have a potential traumatic nature and provoke complex emotional responses that could negatively affect individual and collective mental health (Jakovljevi et al., 2020; Masiero et al., 2020). Therefore, this global pandemic constantly requires researchers and professionals to monitor and assess the current mental health situation, in order to plan and develop efficiency-driven strategies aimed to reduce its negative psychological impacts.

This study assessed and monitored Italian young adults' mental health status during the firsts 4 weeks of lockdown imposed by the government during the COVID-19 outbreak, from March 16 to April 16. To the authors' knowledge, this is the first study specifically focused on young adults' mental health status during COVID-19 quarantine, both in Italy and worldwide. A longitudinal panel design was carried out in order to assess *Internalizing* and *Externalizing problems* on 97 Italian young adults living in the Campania region, Southern Italy. A GCA (Jackson et al., 2018) was performed to monitor the changes during the first 4 weeks of quarantine.

First of all, in line with the global trend reported by previous studies carried out on the general population (Cao et al., 2020; Huang and Zhao, 2020; Qiu et al., 2020; Rossi R. et al., 2020), this study confirmed the negative behavioral and emotional responses provoked by COVID-19 quarantine and also highlighted the high vulnerability of young adults in developing psychological distress.

Comparing the *Internalizing* and *Externalizing domains*, the results showed an analogous increase for both areas from T1 to T4, even though higher rates of internalizing manifestations were registered. Specifically, the growth curve modeling highlighted that, within the Internalizing problems area, the levels of *Anxiety/Depression*, *Withdrawal*, and *Somatic Complaints* overall increased from T1 to T4, showing an increase while the lockdown measures were in place. In this context, in line with results obtained on medical health workers (Zhang et al., 2020), having experienced a closeness with a COVID-19-infected relative or friend resulted in an increase of somatic complaints. Similarly, within the Externalizing problems area, the levels of *Aggressive Behavior* and *Rule Breaking Behavior* increased from T1 to T4. Among the *Internalizing domains*, youth reported clinical-level symptoms of anxiety and depression. According to the recent review on the psychological impact of quarantine (Rajkumar, 2020), anxiety as well as depressive symptomatology was the most common. Furthermore, the results showed that *Withdrawal* level was above the normal threshold. This finding could be related to the specific situation of quarantine and the impossibility to engage in social behaviors due to the lockdown. Indeed, the physical distance can intensify feelings of loneliness that in turn trigger intense anxiety (Boffo et al., 2012; Banerjee and Rai, 2020; Rossi A. et al., 2020).

If, broadly, the results obtained confirmed the general detrimental effects of social isolation due to epidemics on young adults' mental health (Hawryluck et al., 2004; Tucci et al., 2017; Qiu et al., 2020; Wang et al., 2020), some brief reflections need to be outlined about the specificities of young adults' condition. Indeed, young adults live a specific transition period in which their identity development process is based and founded on continuous affective investments on social and extra-familiar relationships (Sica et al., 2018). In this context, the lockdown measures may be interpreted as a forced regression that triggers negative mental health outcomes even more. Within the range from T1 to T4, higher levels of *Internalizing* and *Externalizing* problems were registered at T3, whereas a sort of stabilization from T3 to T4 emerged. The peak reported at T3 probably indicated a sort of gradual cognitive and emotional recognition experienced from young adults about the seriousness of the pandemic, which increased feelings of anxiety, depression and worry, and irritability and anger. Regarding the stabilization of both internalizing and externalizing problems between T3 and T4, these findings might need to be interpreted in relation to the specific historical context of the COVID-19 pandemic in Italy. Specifically, T4 corresponded to the week from April 16 to 12 in which a double attitude was observed in Italy. On the one hand, despite the lockdown, the Italian "Civil Protection" continued to alert the general population about the very high levels of contagions; on the other hand, in that period, Italians also started to receive the first information about the so-called "Phase 2," which followed the forced lockdown. It might be hypothesized that the high levels of viral load continued to worry participants, even though the closeness to Phase 2 assumed a sort of protective function regarding an eventual mental health worsening.

In correspondence to the increase of mental health distress, the results also showed a gradual decrease of participants' perception of their personal strengths, suggesting the need for researchers to strengthen individual's psychological resources in order to mediate the individual reaction to the COVID-19 pandemic (Di Giuseppe et al., 2020).

In conclusion, regarding gender differences, a significant increase of the levels of *Anxiety/Depression* from T1 to T2 and, to a lesser extent, from T2 to T3 in males than the females

emerged. These findings were in line with previous studies that pointed out higher symptoms of anxiety and depression in condition of social isolations in boys than girls (Troop-Gordon and Ladd, 2005; Derdikman-Eiron et al., 2011). The results reported no other statistically significant differences between sex. These findings seemed to be in opposition with the recent studies that have investigated the impact of COVID-19 on mental health and highlighted a higher vulnerability for women to develop negative mental health outcomes, as compared with men (Qiu et al., 2020; Rossi R. et al., 2020). In the context of gender studies, a wide range of recent literature tended to connect these results to the reinforced gender inequalities promoted by the lockdown measures. According to these studies (Adams-Prassl et al., 2020; Béland et al., 2020; Etheridge and Spantig, 2020), in fact, during the lockdown measures, the increase of unemployment rates as well as the commitment into the domestic work and in the management of children has represented a high risk factor for women, compared with men. Within the same interpretation field, the lack of significant gender differences as emerged by the results might be correlated to the same nature of the sample, which mostly involved university students who probably were involved in the same challenges and tasks and did not experienced greater or smaller efforts connected to specific gender roles, such as to outline differences.

The present study is not free from limitations. First of all, the number of participants should be increased in future studies, and the results need to be replicated in other geographical areas to determine their generalizability. Furthermore, the sample was only composed of university students who came from the Campania region in Southern Italy where the COVID-19 outbreak has been taken more under control. To assess the mental health of young people during the quarantine, only a self-report measure was used. Consequently, the data may be influenced by a reporting bias (e.g., social desirability). Moreover, despite the longitudinal panel, the study is an observational study. In this sense, experimental manipulations and a control group are lacking. Future researches need to extend the young adults' mental health assessment to other Italian regions, taking into consideration that in the South of Italy, where the study was carried out, the COVID-19 outbreak has been taken moderately and was under control, compared with the North. Higher levels of distress might be hypothesized in places where very high numbers of losses and deaths have been registered. Moreover, the present study investigated the internalizing and externalizing problems as individual responses to COVID-19 pandemic; further investigations to measure the traumatic symptomatology and the characteristics of post-traumatic effects caused by such stressful events are needed (Troisi, 2018; Margherita and Tessitore, 2019). Follow-up investigations are also needed. Considering the high levels of *Withdrawal* that emerged from the results, future investigations should explore the function and the role played by virtual environments and e-communities during pandemic in-depth, taking into account the roles played by the online environments and by the use of social media in terms of both risks and protective functions (Faccio et al., 2019; Gargiulo and Margherita, 2019; Margherita and Gargiulo, 2018; Procentese et al., 2019; Boursier et al., 2020). In this sense, future investigations might be also directed to investigate the changes in the dynamics of social and love relationships (Mannarini et al., 2013, 2017a; Balottin et al., 2017; Margherita et al., 2018) as well as the role of social support (Ratti et al., 2017) post-lockdown and post-pandemic. In conclusion, recognizing the fundamental value of qualitative investigations to shed light on the inner aspects and subjective meanings of personal experiences is also vital (Margherita et al., 2017; Tessitore and Margherita, 2019; Tessitore et al., 2019; Felaco and Parola, 2020; Parola, 2020; Parola and Felaco, 2020; Tessitore and Margherita, 2020). These are much needed actions in order to develop an in-depth understanding of the emotional and affective dimensions connected to the experience of the COVID-19 pandemic, as well as possible risk and protective factors for mental health.

In conclusion, the present study could contribute to the ongoing debate concerning the psychological impact of the COVID-19 emergency, helping to develop efficient and person-centered intervention projects able to take care of young adults' mental health in the medium and long terms, understanding their specific needs and susceptibilities (Benedetto et al., 2018; Parola and Donsì, 2018, Parola and Donsì, 2019; Fusco et al., 2019). This is even more urgent considering that despite the distressing and prolonged situation, a significant number of people avoid seeking psychological help (Rossi and Mannarini, 2019). On the one hand, some of these people may be reluctant to seek professional help due to the associated stigma (Mannarini et al., 2017b, 2018, 2020; Faccio et al., 2019; Mannarini and Rossi, 2019). On the other hand, some individuals may deny the problem, leading them to think that it will probably resolve itself naturally (Sareen et al., 2007; Rossi Ferrario et al., 2019; Rossi Ferrario and Panzeri, 2020), thus choosing to manage the psychological issue on their own (Wilson and Deane, 2012).

DATA AVAILABILITY STATEMENT

The datasets generated in this article are not readily available because to ensure the privacy of the participants. Requests to access the datasets should be directed to AP, anna.parola@unina.it.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethical Committee of Psychological Research of University of Naples Federico II and was carried out in accordance with the American Psychological Association rules. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

AP developed the theoretical framework of the present study, designed the study, and developed the methodological approach. AR performed all the analyses and designed tables and figures. FT and GT led the literature search and interpretation of data. SM critically revised the manuscript. All authors read and approved the final version of the work.

Correlates of Health-Protective Behavior During the Initial Days of the COVID-19 Outbreak in Norway

Janis H. Zickfeld[1,2†], Thomas W. Schubert[1†], Anders Kuvaas Herting[1], Jon Grahe[3] and Kate Faasse[4]*

[1] Department of Psychology, University of Oslo, Oslo, Norway, [2] Mannheimer Zentrum für Europäische Sozialforschung, University of Mannheim, Mannheim, Germany, [3] Department of Psychology, Pacific Lutheran University, Tacoma, WA, United States, [4] School of Psychology, University of New South Wales, Sydney, NSW, Australia

The coronavirus outbreak manifested in Norway in March 2020. It was met with a combination of mandatory changes (closing of public institutions) and recommended changes (hygiene behavior, physical distancing). It has been emphasized that health-protective behavior such as increased hygiene or physical distancing are able to slow the spread of infections and *flatten the curve*. Drawing on previous health-psychological studies during the outbreak of various pandemics, we investigated psychological and demographic factors predicting the adoption and engagement in health-protective behavior and changes in such behavior, attitudes, and emotions over time. We recruited a non-representative sample of Norwegians (n = 8676) during a 15-day period (March 12–26 2020) at the beginning of the COVID-19 outbreak in Norway. Employing both traditional methods and exploratory machine learning, we replicated earlier findings that engagement in health-protective behavior is associated with specific demographic characteristics. Further, we observed that increased media exposure, perceiving measures as effective, and perceiving the outbreak as serious was positively related to engagement in health-protective behavior. We also found indications that hygiene and physical distancing behaviors were related to somewhat different psychological and demographic factors. Over the sampling period, reported engagement in physical distancing increased, while experienced concern or fear declined. Contrary to previous studies, we found no or only small positive predictions by confidence in authorities, knowledge about the outbreak, and perceived individual risk, while all of those variables were rather high. These findings provide guidance for health communications or interventions targeting the adoption of health-protective behaviors in order to diminish the spread of COVID-19.

Keywords: COVID-19, coronavirus, health protective behavior, perceived risk, concern, Norway

INTRODUCTION

On the 30th of January 2020, the World Health Organization (WHO) declared the outbreak of a new coronavirus type (SARS-CoV-2) a Public Health Emergency of International Concern. While first cases of COVID-19, caused by this virus, were reported in the Chinese city of Wuhan at the end of December 2019, by the end of March 2020 the virus had spread to all populated

continents, resulting in exponential growth and more than 700.000 recorded infections and 30.000 fatalities worldwide. At that time, COVID-19 had already significantly impacted physical and psychological health in many countries, with consequences for many individuals' daily lives and economic situations.

Increasing evidence about COVID-19 suggests that adopting widespread public behavior change can have strong influences on controlling the virus' spread and limiting its harmful consequences on physical health and healthcare systems (Ferguson et al., 2020; Li et al., 2020). Some of these changes may be enforced by states (e.g., closure of schools), while others may be advised but not strictly enforced (e.g., reduction of group size in public), and others may be advised but outside of a state's control (e.g., hand washing in private). Experiences from previous disease outbreaks such as Ebola, SARS, and the swine flu suggests that psychological factors including attitudes and affective reactions have a significant impact on whether individuals adopt health protective behavior or not (e.g., Tang and Wong, 2003; Bish and Michie, 2010; Bults et al., 2011). Facilitating such behavior change during an outbreak is an important task of applied psychology during the COVID-19 outbreak (Lunn et al., 2020; Van Bavel et al., 2020).

In the current study, we explore what demographic and psychological variables predicted the adoption and engagement in health-protective behavior and how attitudes and self-reported behaviors changed over the course of a period of 15 days during the COVID-19 outbreak in Norway. Norway represents an interesting case as it featured the second highest rate of confirmed cases per capita (after Italy) at the beginning of data collection (12th March), while having Europe's third lowest population density. Four weeks after the closing of schools and beginning of our data collection, Norway had managed to reverse the growth of hospitalizations due to COVID-19. Our data are collected during this period. While our data are cross-sectional rather than longitudinal, they allow the description of a social change process, in addition to exploring correlates of individual behavior.

Protective behavior in a pandemic can be categorized broadly into three types: preventive, avoidant, and management behavior. Preventive behavior includes mainly increase in hygiene (e.g., handwashing), avoidant behavior refers mainly to physical distancing[1], and management includes taking medication and seeking help from health professionals and use of help lines. An important question to curb infections is, what individual factors predict this kind of behavior. Bish and Michie (2010) reviewed the literature on this following the SARS crisis. They particularly focused on reported associations between demographic factors, attitudes, and behavioral measures (reported, intended, or actual behavior). Most reviewed studies were carried out in the middle of actual outbreaks, mostly of influenza and the SARS coronavirus (SARS-CoV). The review found that preventive and avoidant behavior was predicted by a few demographic factors. These behaviors were more common among women, older people, and people indicating a higher education level (cf. Ibuka et al., 2010; Agüero et al., 2011; Tooher et al., 2013; Moran and Del Valle, 2016; Zettler et al., 2020). More recent evidence has also identified household size as a crucial variable. People living in larger households seem more likely to take precautions (Ibuka et al., 2010), presumably out of increased fear of getting infected or out of increased sense of responsibility for others, or both. The driving factor may be the presence of school-aged children (Agüero et al., 2011; for contradicting findings, see Bults et al., 2011).

Preventive and avoidant behavior were also related to psychological factors. In particular, they were found to increase with perceived susceptibility to the disease (i.e., perceived likelihood of contracting the virus) and perceived severity of symptoms increase (Tang and Wong, 2003; Agüero et al., 2011; Tooher et al., 2013; Gershon et al., 2018; Webster et al., 2020). In a Spanish sample, the adoption of preventive measures during an influenza outbreak was increased by perceived effectiveness of these behaviors in reducing the risk of infection (Agüero et al., 2011; see also Tang and Wong, 2003). These observations are in line with classic and modern versions of expectancy-value theories, where expectancy equals susceptibility and severity equals value. For instance, the Theory of Planned Behavior explains behavior as deriving from intentions that are influenced by attitudes, perceived social norms, and perceived behavioral control or effectiveness of the behavior (Ajzen, 1991). Risk and severity may mediate effects of demographic variables, especially for gender.

Pandemics highlight the interdependence among individuals, and citizens' relations to their government. Bish and Michie (2010, p. 817) conclude from their review "that having a high level of trust in authorities and satisfaction with the communications received about the disease is associated with compliance with preventive, avoidant, and management behaviors." Evidence from actual outbreaks confirms this (Liao et al., 2010; Bults et al., 2011).

It seems that little is known on how crucial psychological variables develop during the course of an epidemic. Information on behavioral change over time is important for modeling a pandemic's course, and providing appropriate health messaging over time (Poletti et al., 2012; Collinson et al., 2015). Over the course of the first wave of the 2009 influenza (H1N1) epidemic in Hong Kong, knowledge on modes of transmission did not improve, the adoption of avoidant behavior did not change, and, surprisingly, physical distancing declined, suggesting that changes might sometimes be counterintuitive (Cowling et al., 2010). This may be due to the ongoing nature of the threat, the requirement to consistently engage in sometimes complex and unpleasant behaviors over a long period of time, and information or media fatigue resulting in reduced behavioral engagement. During the H1N1 outbreak in the Netherlands, perceived severity and anxiety decreased over time in line with better estimates of fatality, but also in line with claims that citizens can be fatigued by media reports (Collinson et al., 2015). It thus seems important to observe the time course of the involved psychological variables.

Wise et al. (2020) surveyed 1591 US-American participants between 3/11/20 and 3/16/20, focusing on perceived risk from the virus and propensity to engage in protective behaviors.

[1]Similar to previous studies (e.g., Pfattheicher et al., 2020), we employ the term *physical distancing* instead of *social distancing* to highlight the fact that individuals are advised to keep a *physical* distance.

Their sample (recruited through Prolific.co) had roughly equal numbers of women and men and a median age of 30, skewing young. Participants saw a medium risk of getting infected themselves (43%), which rose during the time of the sampling. Participants reported that they washed their hands more and stayed at home more than usual, and this also increased during the sampling period. Notably, they were able to reassess a subsample of participants, once at the beginning and once at the end of the sampling period, and confirmed that these changes also occurred within participants.

Self-reported increased hand-washing and physical distancing were predicted by perceived likelihood of becoming infected, but not severity of illness. To a lesser extent, perceived impact from global consequences also predicted both behaviors. Wise et al. (2020) used multiple regressions with 10 different risk perceptions as simultaneous predictors for these analyses and controlled for age. The other predictors (e.g., likelihood of infecting somebody else) did not predict behavior above risk to self, and neither did age. Wise et al. (2020) also identified a subgroup in their sample that perceived low risk and disengaged from information seeking.

In a non-representative sample of 1210 respondents from 194 cities in China during the initial phase of the pandemic, about one third reported moderate to severe anxiety. Interestingly, precautionary measures (e.g., hand hygiene, wearing a mask) were associated with lower levels of stress and anxiety, suggesting successful coping and belief in the behavior's effectiveness (Wang et al., 2020).

In a small, mostly British, community sample (n = 324) collected between March 27th and 28th, experiencing fear was the only positive and stable predictor of health-protective behavior (Harper et al., 2020). Sampling 770 US adolescents from the 20th to the 22nd of March, health-protective behavior including physical distancing and hand washing was positively predicted by perceived severity of the outbreak and social responsibility, as well as negatively predicted by self-interest (Oosterhoff, 2020).

Finally, a nearly identical version of the questionnaire employed in the current project was distributed among Australian adults (n = 2174) between the 2nd and 9th of March (Faasse and Newby, 2020). As the number of cases was considerably low in Australia at that time (<100), the authors observed low prevalence of physical distancing behavior but rather high engagement with hygiene behavior. Further, in the study engagement in health-protective behavior was positively predicted by the amount of media exposure, concern or worry about the outbreak, perceived severity of the outbreak, confidence in scientists and health professionals, and accurate knowledge about COVID-19. Perceived likelihood of being infected was not a significant predictor of engagement with health behaviors.

The first infected case in Norway became known on February 26. The number of known infections grew at a relatively slow pace to 227 until March 9, without much action by authorities or concern in the population. The total population of Norway is 5.4 Million. Because authorities had been blindsided by an influx of infected people coming back from winter holidays in Italian and Austrian skiing locations, infections then suddenly increased to 804 until March 12, and community spread was assumed.

That day, on which we started data collection, was tumultuous: The first death was registered. Because Norway lacked testing capacity, a change in testing criteria was announced, prioritizing severely sick people and health personnel rather than travelers. Mildly and moderately ill people did not have access to testing throughout the sampling period. Also on March 12, the Norwegian Institute of Public Health (Folkehelseinstitutet, FHI) published a report predicting that between 20 and 80% of the Norwegian Population would be infected in the first wave, which was expected to take up to 1 year (Folkehelseinstiuttet, 2020). That report was widely publicized. Finally, on the same day the government announced comprehensive measures to fight the virus, most notably shutting down schools and kindergartens, training facilities, and all cultural events. Increased stocking up on food and supplies lead to empty shelves in some grocery shops, which was documented on social media.

On March 13, it was reported that many Norwegians left cities toward holiday homes in remote locations, which led to a rebuke by the authorities due to risk of spreading the virus. Travel by foreigners without residence permits to Norway via plane or boat was shut down March 15. The same day, in an extraordinary announcement, the Norwegian King asked people to stand together and follow the authorities' advice. On March 16, FHI published a general call for increased physical distancing, and rules about quarantine, assemblies, and visiting cabins started being enforced with fines and short prison sentences. On the 17th, the national TV channel NRK aired a debate in which a medical doctor argued that Norway should go into total isolation and that FHI was too lax. This was seen as controversial, praised by some, but criticized by many others. The number of hospitalizations passed 200 on March 24, with 10 people dead.

Three representative data sets are available with Norwegian samples that help to anchor our data. Sætrevik (2020) reported data from a representative sample of more than 4000 Norwegians between March 20 and March 29. Respondents thought the average Norwegian was likely to be infected by the coronavirus (46% of the panel said "Somewhat high" or "Very high"), while fewer thought that this would happen to themselves. Quite few (8%) believed that they were at risk of becoming seriously ill themselves.

Kantar.no (Gallup) conducted web interviews with representative samples N = 947 and N = 1538, on March 12–13 and March 19–20, respectively, thus at the beginning and end of our first week of data collection (Kantar, 2020a,b). On March 19/20, the vast majority (>85%) said that they had high or very high confidence that the health authorities would take the necessary measures to handle the situation in the best possible way, and that they provided accurate information on the situation. Both numbers had increased compared to the week before. Less than half, 42% (up from 37 a week earlier), expected that they would likely or very likely be infected (up by 5% during the last week), while 18% said that was unlikely or very unlikely. A large group, 37%, was unsure, saying it was neither likely nor unlikely. Answers judging infection as likely or very likely were more frequent than average among inhabitants of Oslo and people younger than 44, but less frequent among people older than 60 (only 20%). The same age effect was reported by

Sætrevik (2020). When asked about behavioral changes in the last 7 days, more than half and up to 88% reported increased hygiene behavior, reduced social contact, and increased purchasing of goods. From March 12–13 to March 19–20, the number of people who were worried or very worried about the consequences for themselves or their families (the question did not specify what kind of consequences) increased by 6–78%.

Opinion.no conducted a daily poll of Norwegians from March 13 to March 21 (Opinion, 2020). N varied between 313 and 819 (Gaute Aas Askheim, 2020, March 23, 2020, personal communication). On every day of that period, more than 60% of polled individuals expressed confidence in the measures taken by the authorities and trust in the information given by them to the public; confidence actually increased from 65% on March 13–75% on March 17, and then fell again slightly.

In the current project we investigated the influence of psychological and demographic variables in predicting health-protective behavior in a Norwegian sample. Simultaneously, we focused on exploring the trajectories and developments of reported behavior, attitudes, and affective reactions during a 15-day period during the outbreak of COVID-19. We focused mainly on two aspects of protective behavior: preventive and avoidance behavior (Bish and Michie, 2010). We did not focus on management behaviors, such as taking medicine or seeing health-professional, as no medication was available at the time of data collection and the main focus was on minimizing transmission and rapid dissemination by flattening the curve through hygiene practices and physical distancing (Ferguson et al., 2020).

Note that our sampling strategy primarily reached participants who were already engaged in discussing topics related to COVID-19, and are presumably more concerned than average. We were thus less likely to sample a lot of participants who viewed the risk as low and were disengaged from seeking information on COVID-19. Our data are thus by no means representative. Absolute means should be interpreted as being at the upper end of the real distribution. Our analyses focus on relations between variables, which we assume to be generalizable to the larger population. Also note that our data are not longitudinal, and we cannot draw causal conclusions. We nevertheless use the term prediction to describe the results of regression analyses for ease of phrasing.

Our analysis strategy in identifying important variables predicting engagement in health-protective behavior was twofold. First, we focused on a theory-driven strategy based on reviews and previous studies relating to health epidemics. Second, we employed an exploratory data-driven machine learning approach in order to classify important variables. Based on reviews concerning factors predicting behavior during pandemics and recent research (e.g., Wise et al., 2020), we derived the following hypotheses for the first strategy:

(I) Engagement in health-protective behavior was expected to be predicted by gender, education level, age, and household size. Women, individuals with higher education level, older individuals, as well as those from larger households were expected to have more engagement in health-protective behavior.

(II) We expected that effects in I were mediated by own perceived risk (likelihood and severity; for gender, education level, and age) or by perceived risk of close others (likelihood and severity; for household size). Females, individuals with higher education or older age should show increased perceived risk, which in turn should be associated with higher reports in health-protective behavior. Similarly, larger household size should be associated with higher perceived risk for close others, which in turn should positively predict health-protective behavior.

(III) Increased confidence and trust in authorities should positively predict engagement in health-protective behavior.

Note that these hypotheses were generated while performing data collection and not completely *a priori*. This was mostly due to time constraints as we wanted to ensure data collection during early periods of COVID-19 outbreak in Norway.

The current project was ethically approved by the Internal Review Board of the University of Oslo. All materials, raw data, and syntaxes are available at our project page: https://osf.io/crs2n/.

MATERIALS AND METHODS

Participants

We recruited a total of 9537 participants residing in Norway through social media (e.g., Facebook, Twitter) and email lists. Data collection took place for 15 days from the 12th of March to the 26th of March 2020. Between March 13 and March 17, we ran a paid ad on Facebook, selecting Norwegian users older than 18 as the target group. The ad reached 33.655 viewers (71% female according to Facebook), of which 1990 clicked through to the survey. The post was shared 165 times and reached over 70.000 Facebook users. The researchers did not themselves share the study in their own networks. After the ad campaign on Facebook ended, the survey was shared on the website of the Department of Psychology (PSI) of the University of Oslo (UiO) and in the Facebook feeds of both PSI and UiO.

After excluding participants who failed an attention check or spent less than 1 min taking the questionnaire, we arrived at a final sample size of 8676 (6292 females, 1811 males, 59 non-binary or different identity, 28 preferred not to say, 486 missing). The majority of participants were between 20 and 59 years of age. Median age for both male and female participants was between 35 and 39. The majority of participants reported residing in Oslo county (n = 3302, 38.1%), while the fewest participants were from Nordland (n = 183, 2.1%). Similarly, the majority indicated residing in a large city (n = 4299, 49.5%), while the lowest amount came from a rural area (n = 938, 10.8%). The majority of the sample indicated a high degree of school education, having earned a college degree (41.8%), whereas a smaller proportion indicated their highest education as less than high school or high school graduate (16.6%). An

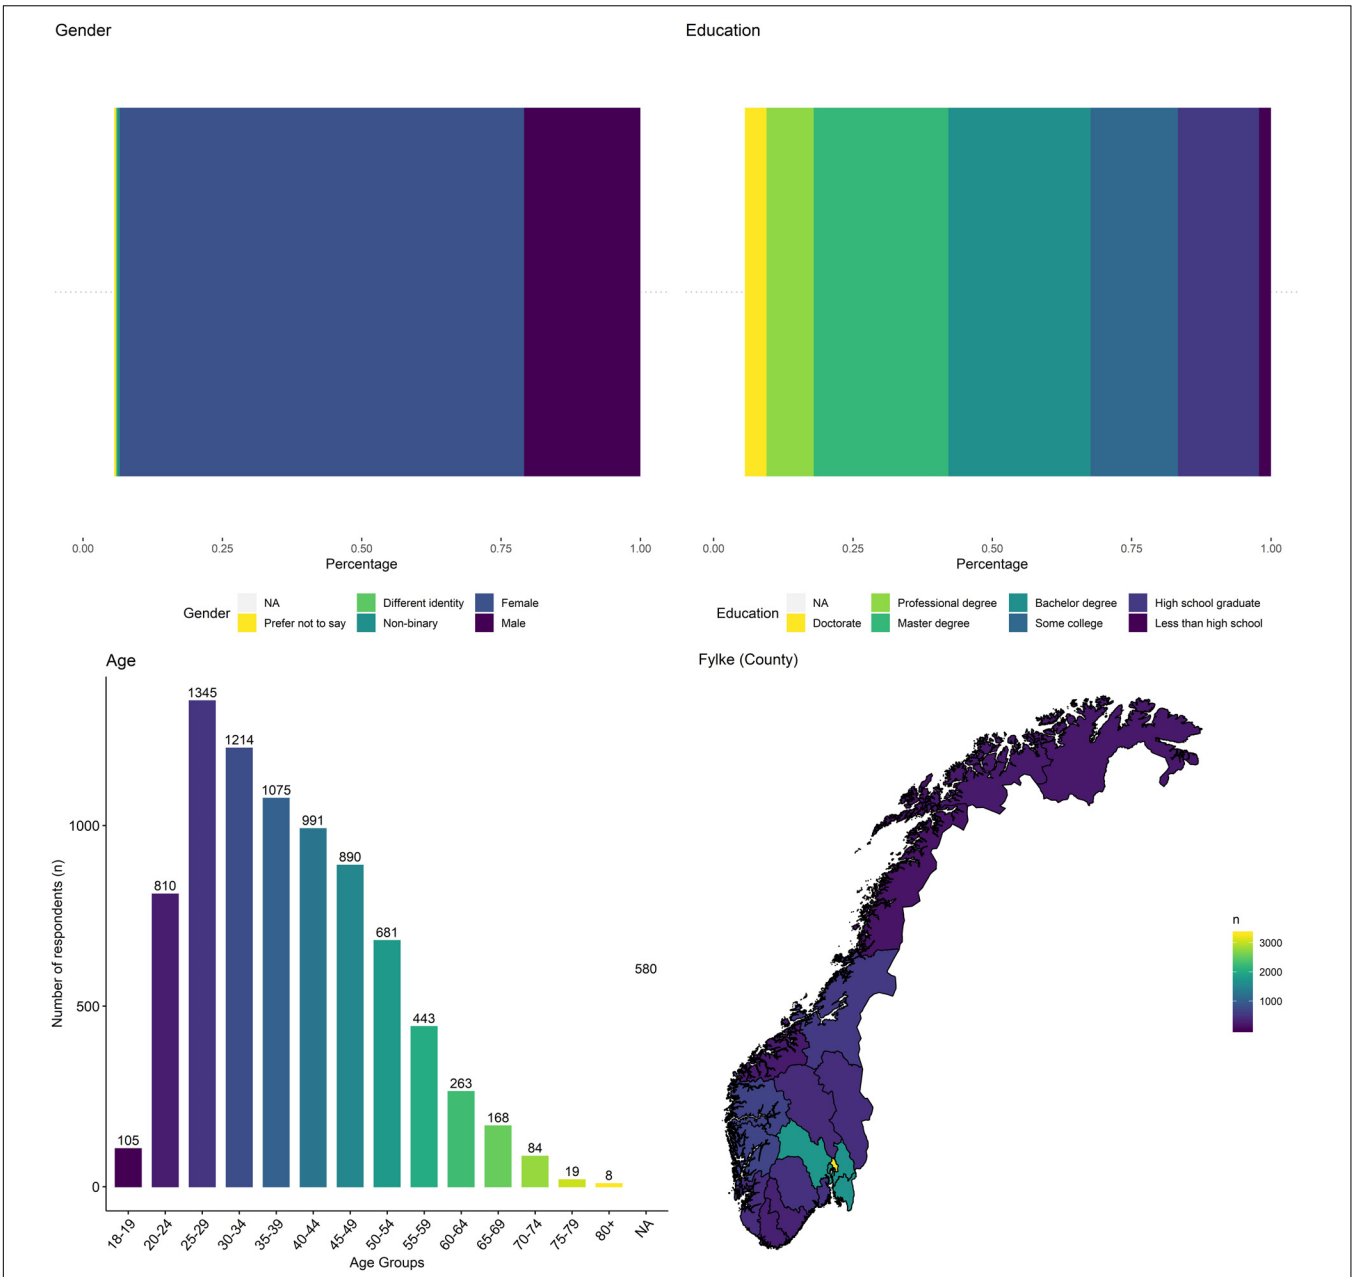

FIGURE 1 | Overview of sample characteristics based on gender, education, age, and residence.

overview of sample characteristics is provided in **Figure 1** or in the **Supplementary Materials**[2].

Participants were able to take part in a raffle getting the chance of winning one out of 20 vouchers at a value of 200 NOK. This served mainly to jumpstart the participation; we did not anticipate the large sample ultimately achieved. To participate in the voucher draw, participants were invited to enter their email in a separate follow-up survey that was not linked to the main dataset.

[2]https://osf.io/crs2n/

Materials and Procedure

The main procedure was based on a similar survey conducted in Australia and the US (Faasse and Newby, 2020).

Geographical Information

After providing informed consent, we checked whether potential respondents were residing in Norway. Those who did not were thanked and the survey was terminated. We then collected information on participants' postcodes and the county they resided in. Based on the postcode data, we identified the municipality participants resided in. Using these data, we added

the amount of COVID-19 cases for that given municipality on the day the respondent completed the survey based on numbers provided by the Norwegian institute of health [Folkehelseinstitutt (FHI)] and made accessible by the newspaper VG[3]. Similarly, we added information on population density per municipality level based on data from the Statistisk Sentralbyrå.

Information Sources

In order to assess the variety and amount of media exposure, we asked participants how much they had seen, read, or heard about COVID-19 [from nothing at all (1) to a lot (4)], how much they think they know about COVID-19 [nothing at all (1) to a lot (4)], and how closely they had been following news about the recent outbreak [from not at all (0) to very closely (10)]. These three items were combined into a mean media exposure score ($\alpha = 0.68$).

Afterward, we instructed respondents to check all possible sources through which they had been getting information about the COVID-19 outbreak [including news media, social media, official government websites, family member(s), colleague(s) or friend(s), none of the above, and other]. Similarly, we asked participants which out of several sources they trusted the most concerning the outbreak [my doctor, my local hospital, Folkehelseinstitutt, (Norwegian) media, WHO, Norwegian government, state department of health, none of the above, other]. To further investigate respondent's confidence, we asked how much confidence they had in different sources: the Norwegian government providing full and accurate information, the Chinese government providing full and accurate information, and scientists and medical experts understanding the outbreak. All items were completed on a 10-point scale (not at all confident to very confident, and don't understand at all to understand very clearly).

Respondents were also asked about how confident they thought health authorities, and hospitals and medical services were able to manage the COVID-19 outbreak [from not at all confident (0) to very confident (100)]. The four items (excluding the item on the Chinese government) were averaged into a confidence score ($\alpha = 0.73$). The item focusing on the Chinese government was excluded as we mainly intended to focus on confidence in Norwegian health authorities. Additional analyses including the item are presented in the **Supplementary Materials**.

Perceived Risk

Respondents were asked how concerned or worried they were about the COVID-19 outbreak [not at all concerned (1) to extremely concerned (5)]. Participants indicated how likely they thought it would be that they themselves would get infected by COVID-19 and also how likely they thought it would be that close others (family/friends) would get infected [not at all likely (0) to extremely likely (100)]. Similarly, we asked how much participants thought they could do to protect themselves [effectiveness of behavior, I can't do anything to protect myself (0) to I can do a lot to protect myself (100)]. Asking about perceived severity, participants reported how serious they thought their symptoms would be if they got infected, and what the worst possible outcome could be for a family member or close friend that got the virus [no symptoms (1) to severe symptoms leading to death (6)]. Then, we asked whether participants had already wondered at some point whether they were infected [not at all (0) to very much so (100)]. Finally, we asked respondents whether they thought that too much fuss was being made about the risks of COVID-19 [strongly disagree (1) to strongly agree (5)]. This item was used previously to tap skepticism about warnings in public health crises (Rubin et al., 2015).

Emotional States

Affective reactions were captured with several items. Participants reported whether they felt fearful, frightened, anxious, optimistic, encouraged, hopeful, relaxed, furious, outraged, depressed, and sad [strongly disagree (1) to strongly agree (5)][4]. We averaged the first three items to create a fear score ($\alpha = 0.85$), items four to six to create a hope score ($\alpha = 0.69$), items eight and nine to create an anger score ($\alpha = 0.80$), and the last two items to create a sadness score ($\alpha = 0.61$). We included items on specific *basic* negative emotions (Ekman, 1992; Ahorsu et al., 2020) and future-oriented positive emotions (Fredrickson, 2001) that we expected to occur commonly in response to health epidemics (Kleinberg et al., 2020; though see Fiske, 2019 for a critique of this approach).

Knowledge

In order to test participant's knowledge about the COVID-19 outbreak, we first asked them to judge whether 16 statements about the virus and disease were true (answer alternatives true, false, and unsure). We then asked participants to indicate what the most common symptoms of COVID-19 were from a list of seven possible symptoms (fever, cough, sore throat, shortness of breath, nausea, vomiting, diarrhea)[5]. Afterward, respondents were prompted to indicate how COVID-19 could spread, according to their knowledge (by air, by water, by mosquitoes, droplets spread through coughing or sneezing, touching surfaces that have been recently touched by someone who is sick, and touching or shaking hands with a person who is sick). The symptoms and transmission items used the same scale (yes, no, unsure). Because the employment of face masks has been a popular debate, we asked who should be wearing a face mask to minimize transmission (healthy people - to prevent infection, sick people - to stop them spreading the virus, everyone, and no one)[6]. Finally, we asked participants to estimate what percentage of people who had been infected with COVID-19 had died from the

[3]https://www.vg.no/spesial/2020/corona/

[4]In a first version of the questionnaire the scale went from "strongly agree (1)" to "strongly agree (5)" due to a clerical error. This was corrected immediately after the first approximately 20 responses.

[5]At the time the survey was started, symptoms like nausea or diarrhea were not regarded as typical symptoms of COVID-19. However, as the outbreak proceeded the WHO added these to the list of possible symptoms (https://www.who.int/health-topics/coronavirus#tab=tab_3). Thus, these responses were not part of the final knowledge score.

[6]During the time the study was conducted there was a general recommendation that face masks should only be worn by infected people. This recommendation changed after the project was terminated, highlighting the usefulness of face masks also for healthy people.

virus. Respondents were able to provide an answer between 0 and 100%. Out of all correct answers[7] we constructed a knowledge sum score (ranging from 0 to 31). For the last item, we took the range between 1 and 5% as a correct answer, as official indications had been varying somewhat during the period the study was conducted.

Avoidance Behaviors

We then asked respondents to indicate whether they performed 24 different health-protective behaviors in response to the COVID-19 outbreak during the past 2 weeks. These behaviors consisted of physical distancing behavior (13 items, e.g., reduced or avoided going to work or university), hygiene behavior (6 items, e.g., used sanitizing hand gel to clean your hands more often than usual), prosocial behavior (3 items, e.g., helped buying groceries and supplies for people who are in quarantine), and two additional items (e.g., worn a face mask when going out in public)[8]. Responses could be made using four alternatives (yes, no, unsure, not applicable). For each type of behavior, we computed a sum score based on whether the behavior was performed or not. In addition, we computed an overall health/communal-protective behavior sum score based on the physical distancing, hygiene, and prosocial items (summing up all items). Finally, respondents were able to write down whether they did anything else in response to the COVID-19 outbreak.

Demographics and Health-Related Information

We collected several items on demographic information and health-related behavior and characteristics. First, participants were asked how likely they would be to get vaccinated in case an effective vaccine for COVID-19 had been developed [would definitely get the vaccine (1) to would definitely NOT get the vaccine (5)]. We then asked to what age groups respondents belonged to (e.g., 18–19, 20–24, 25–29, 30–34, . . ., 80+) and with what gender they identified (male, female, non-binary, different identity, prefer not to say). Participants then indicated how many children they had (none, 1, 2, more than 2) and the level of their highest education (less than high school, high school graduate, some college, BA degree, MA degree, professional degree, doctorate). We then asked what type of community they lived in (large city, suburb, small city/town, rural area) and how many people (including them) lived in their household (from 1 to 5 or more). Participants then completed some items about their health status, including how they would rate their health in general [poor (1) to excellent (5)], whether they had a flu vaccine within the last year (yes, no, unsure), whether they had been in an affected area with high transmission within the past 2 weeks, whether they had been in close contact with people who are suspected to be infected, whether they had experienced any COVID-19 symptoms, whether close others experienced any symptoms (on all yes, no, unsure), whether they had any chronic health problems that increased their risk, and whether close others had any chronic health problems (both items yes, no, unsure, prefer not to say). Finally, participants were thanked and provided with several links to websites from official sources (WHO, ECDC, FHI) that provided information about the COVID-19 outbreak.

Data Analysis

When analyzing data using null hypothesis significance testing (NHST), we set our alpha level at $p < 0.001$. This decision was based on the fact that we employed a considerably large dataset and our findings might have important health-psychological implications (see Lakens et al., 2018). As even small effects will reach statistical significance given large samples, we primarily focus on interpreting effect sizes and their direction and magnitude.

As said above, our analytic strategy was twofold: first a theory-driven step and second an exploratory data-driven machine learning step. For the theory-driven step, we used regular linear regression. The mediation models also tested in this first step employed a bootstrapping method ($n = 1000$) to calculate confidence intervals around the indirect effect.

For the data-driven step, the goal was to classify what variables predicted health-protective behavior out of all predictors we had available in a bottom-up fashion. To do so, we combined supervised machine learning with a partially confirmatory approach (split-half validation) as employed in previous research dealing with large numbers of predictors (e.g., IJzerman et al., 2018). As a supervised machine learning technique, we used conditional random forests, a bootstrap-like algorithm that assesses the relative contribution of each variable on the dependent variable (the signal), therefore being considered a supervised approach (Breiman, 2001). As the name suggests, the algorithm "plants a forest consisting of several trees" that represent the importance of a predictor randomly sampled from the dataset. This procedure is based on out of bag estimates, also called bagging, that features repeated sampling from the original data. In essence, the technique bootstraps several non-parametric regression models and summarizes the importance of each predictor by aggregating and weighting the predictors into a parsimonious set (see Breiman, 2001; IJzerman et al., 2016; Yarkoni and Westfall, 2016). As summarized by IJzerman et al. (2018), employing a supervised machine learning algorithm has several advantages in comparison to classical regression models, and especially using them for exploratory analyses. The algorithm is naive to non-linear relationships, does not assume the direction of a relationship, has less problems with multicollinearity, and has the advantage of assessing each predictors individual role, but also its multivariate interactions with other variables (Strobl et al., 2008).

For our analyses we employed R (Version 3.6.2) and several packages including: dplyr (Wickham and François, 2020), car (Fox et al., 2020), sjmisc (Lüdecke et al., 2020), tidyr (Wickham and Henry, 2020), and stringr (Wickham, 2019) for data recode and wrangling routines, ggpubr (Kassambara, 2020), sp (Pebesma et al., 2020), viridis (Garnier et al., 2018), cowplot (Wilke, 2019), fhidata (White, 2019) for plotting, apaTables (Stanley, 2018)

[7] https://osf.io/utk5y/

[8] Originally, we subsumed these under the label of *counterproductive behavior*. However, as the outbreak progressed and more people got infected, wearing a face mask if infected could be considered a behavior protective of others' health. Similarly, we added *prosocial* as an own category, but most physical distancing behavior can be regarded as prosocial in the long run (e.g., Pfattheicher et al., 2020).

for tables, lavaan (Rosseel et al., 2019) for mediation analyses, and randomForest (Breiman et al., 2018), party (Hothorn et al., 2020), tree (Ripley, 2019), lattice (Sarkar, 2008) for the machine learning analyses.

RESULTS

Descriptives

Considering respondents' information sources, the majority indicated that they received their information about the COVID-19 outbreak from several different sources – on average, participants indicated M = 3.15 different sources (SD = 1.21). A total of 95% reported news media as an information source, with a smaller number using official government websites (83%) or social media (63%). Less than half of all participants indicated that they used colleagues (42%) or family members (31%) as an information source. No participant reported relying on no source at all.

The majority of participants expressed trust in advice and information from the Norwegian health institute (FHI; 88%). This trust was much smaller for the Norwegian department of health (38%), the Norwegian government in general (34%), and the European Centre for Disease Prevention and Control (ECDC; 33%). A total of 20% of respondents reported trusting (Norwegian) media, and the overall lowest trust was indicated for one's doctor or general practitioner (10%), and one's local hospital (12%).

Respondents rated their own perceived likelihood of catching COVID-19 on average somewhat over the midpoint of the 100-point scale (M = 60.34, SD = 22.27). Assuming they would get infected, the majority predicted to have mild or moderate symptoms (82.7%), while a small proportion reported to expect no (0.4%) or more severe symptoms (14.2%). Participants saw it as even more likely that someone from their family or a close friend would get infected (M = 72.85, SD = 22.53). When imagining the worst possible outcome for a family member or friend who would get infected, the majority (70.9%) also foresaw potentially worse outcomes including severe symptoms or severe symptoms leading to hospitalization or death. Participants reported that they had already wondered whether they were infected somewhat lower than the midpoint of the scale (M = 43.59, SD = 35.97). Finally, on average respondents tended to disagree that too much fuss was being made about the risks of the COVID-19 outbreak (M = 1.84, SD = 1.12 on a 1–5 scale), with only around 10.9% tending to agree or strongly agree.

On average, participants indicated that they were moderately concerned or worried about the outbreak (M = 3.09, SD = 0.91), with 32.4% being very or extremely concerned. Similarly, on average respondents reported to show the highest levels of fear (M = 3.61, SD = 1.00), followed by sadness (M = 3.11, SD = 1.05), hope (M = 2.46, SD = 0.88), and anger (M = 2.26, SD = 1.16).

Considering behavior responses, the majority of respondents reported that they had reduced or avoided going to public events (84%), taking public transport (74%) or going to shops (79%). Similarly, a high percentage of participants disclosed that they had washed their hands more often (92%) and more thoroughly (92%), tried to stay away more than 1 m from others coughing or sneezing (90%), as well as tried to sneeze into the crook of their arm (86%). For prosocial behavior, a majority of respondents indicated that they talked to others and tried reminding them of protective behavior (76%). A rather low occurrence of participants reported that they had avoided Chinese restaurants or neighborhoods specifically (9%) or donated money to charity focusing on combating the COVID-19 outbreak (9%). An overview of all behaviors is provided in **Figure 2**.

Factors Predicting Health-Protective Behavior

In order to classify important variables predicting engagement in health-protective behavior we employed two different strategies: a highly confirmatory theory-driven strategy based on reviews and previous studies on the COVID-19 outbreak, and a highly exploratory data-driven approach using a supervised machine learning procedure combined with split-half validation.

Theory Driven Approach

In order to test hypothesis I, we conducted a linear regression using the health-protective behavior sum score as the outcome and gender, education, age, and household size as predictors (see **Table 1** and **Figure 3** for results). As predicted, reporting one's gender as female, indicating a higher education level, as well as a bigger household was associated with significantly more engagement in health-protective behavior. Contrary to our prediction, age showed a negative association with health-protective behavior. However, when inspecting the relationship between age and engagement in health-protective behavior, we observed a non-linear relationship showing first an increase in behavior with increasing age that leveled off at around 40–44 years of age (**Figure 3B**). Notably, our sample included few individuals over the age of 70, suggesting that these findings should be interpreted with caution. Similarly, when repeating the model with time as a covariate the age effect was not significant, while the other predictors still showed positive effects (see **Supplementary Material**).

To test hypothesis III, we regressed the confidence score (mean score based on ratings of confidence in Norwegian government, scientists, health authorities, and medical services) on engagement in health-protective behavior (**Table 1** and **Figure 3D**). Contrary to our prediction, we observed a small negative association. The more confidence respondents expressed in authorities, the less health-protective behavior they reported.

Mediation Analyses

We tested four mediation models. The tests are documented in detail in the **Supplementary Material** (**Supplementary Figure S1**). In all models, health-protective behavior was the dependent variable. The first three models tested separately whether the effects of gender, age, and education level, respectively, were mediated by two mediators, likelihood and severity of perceived risk. The fourth model tested whether the effect of household size on health-protective behavior was mediated by likelihood and severity of risk to close others.

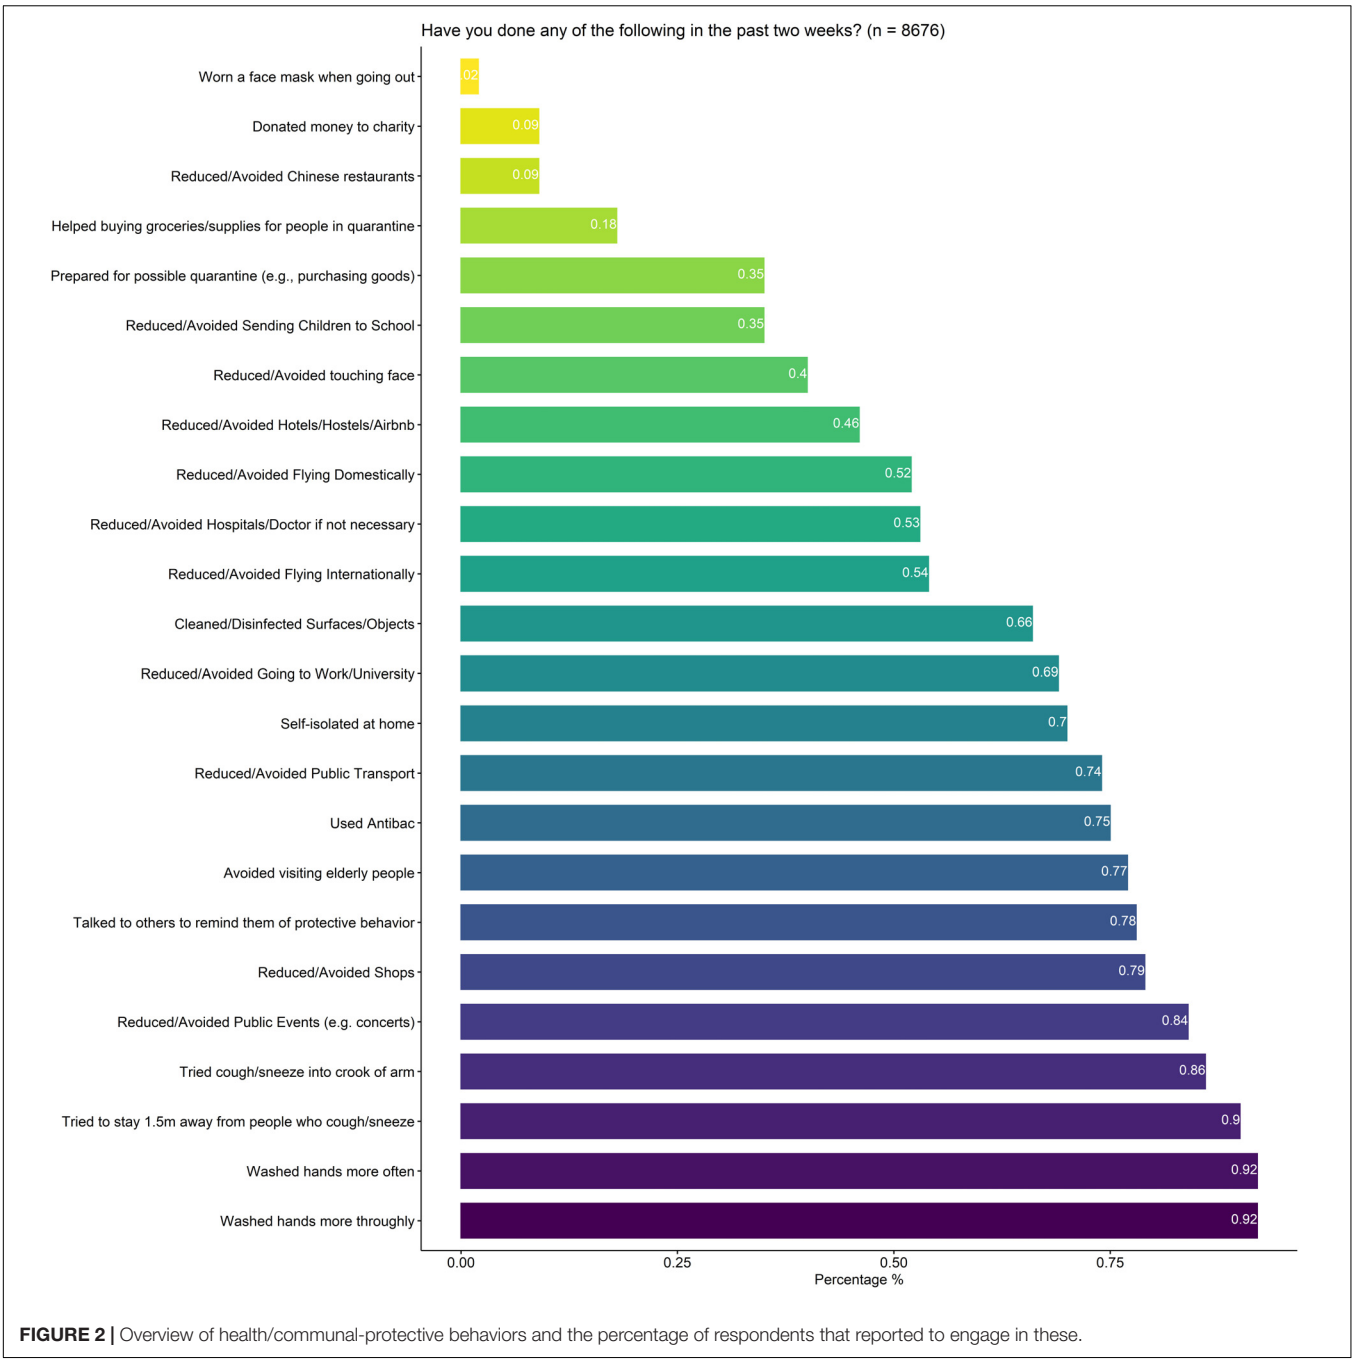

FIGURE 2 | Overview of health/communal-protective behaviors and the percentage of respondents that reported to engage in these.

In short, we found some evidence for mediation of the demographic variables gender, age and education level through likelihood and severity of risk, confirming classic notions of expectancy × value theories. This was especially true for age and education, and the mediation through likelihood. However, all observed mediations were small and partial, and the patterns varied between the different models. This suggests that the demographic variables impact behavior through other channels that were not captured by our measured constructs. We thus do not go into further detail on these here; see the **Supplementary Material** for further information.

Data Driven Approach

Following the strategy laid out above, we employed a data driven approach to identify the strongest predictors that parsimoniously predict health-protective behavior from all predictors we had available. For this purpose, we first split the dataset randomly in half and performed conditional random forests on one half, the training dataset (n = 4338). For reproducibility, we actually performed the algorithm using two different seeds and two versions of the amount of variables sampled at each tree (MTry, the square root of the number of variables, 5 or 6). The Spearman Rank correlation among the replications was between 0.96 and

TABLE 1 | Regression models results using health-protective behavior as the criterion.

0.98 and therefore considered as stable. According to this analysis of the training dataset, health-protective behavior was best predicted by (in order; see also **Supplementary Figure S2**):

> concern/worry, fear, household size, thinking that too much fuss is made, number of children, perceived effectiveness of behavior, media exposure, sadness, anger, age, relaxation, symptoms (close others), symptoms, perceived risk (likelihood), being to an area with a high number of cases, gender, contact to other individuals showing symptoms, community type, education level, perceived health, knowledge, perceived risk (severity), population density at municipality level.

We observed no evidence that perceived risk (severity) of close others, feeling hope, perceived risk (likelihood) of close others, amount of media sources consumed, actual number of cases per municipality, confidence in authorities and scientists, or taking a flu vaccine within the last year predicted better than random noise.

We then continued to run a regression analysis on health-protective behavior using the second half of the data, the test dataset (n = 4338) with the predictors found in training dataset. This was done to reduce random noise from the first step. An overview of the results is provided in **Table 2**. Health-protective behavior was positively and significantly (at the 0.001 level) predicted by household size, number of children, perceived effectiveness of the behavior, and media exposure, when controlling for all other variables. Similarly, we observed that thinking that people made a fuss about the outbreak and reported age showed significant negative predictions when controlling for the other predictors.

As mentioned earlier, the negative finding concerning age should be interpreted with caution since we sampled a small number of older adults exceeding 70 years of age and considering the relationship between age and health-protective behavior showed a non-linear association, resembling a reverse u-shaped curve. While other variables such as concern or fear showed the strongest variable importance in the first step, they did not emerge as significant predictors from the second step. However, they still showed a similar positive effect as for example media exposure and medium zero-order correlations. The same was true for symptoms and relaxation, with the latter showing a negative prediction.

We repeated the procedure of training machine learning and test using linear regression for hygiene and physical distancing behavior separately. Results differed only minimally and can be found in the **Supplementary Materials**. For physical distancing, perceived effectiveness of the behavior and respondent's symptoms had a stronger variable importance. For hygiene behavior, the amount of media sources they were exposed to and whether respondents received a flu vaccine within the last year were more important. Physical distancing was positively and significantly predicted by household size, number of children, whether the respondent experienced symptoms, and perceived effectiveness of one's own behavior. On the other hand, thinking that people made a fuss and age predicted physical distancing negatively. For hygiene behavior, concern/worry, fear, and media exposure showed a significant positive association when controlling for the other variables. Thinking that 'too much fuss' was being made about the risk of COVID-19 predicted hygiene behavior negatively. In general, it seemed that being surrounded with more people, and regarding staying away from others as effective, predicted physical distancing, whereas emotional reactions and media exposure were more important for in engaging in hygiene behavior.

Development of Behavior, Attitudes, and Affective Reactions Over Time

Finally, we explored the development of behaviors, attitudes, and affective reactions over time. We focused specifically on physical distancing and hygiene behavior (behavior), confidence in authorities, perceived risk likelihood, perceived risk severity (attitudes), and concern/worry, fear, and hope (affective reactions). We regressed each variable on day and day squared. We excluded dates that included less than 50 participants, which was true for the beginning (March 12, n = 18) and end of data collection (March 26, n = 20). The first day of the time series was thus coded as 1. Thus, we focused on 13 data points per variable (n = 8638). Notably, we did not employ a repeated measurement design. We can thus only model changes between participants, but not within, and changes observed over time

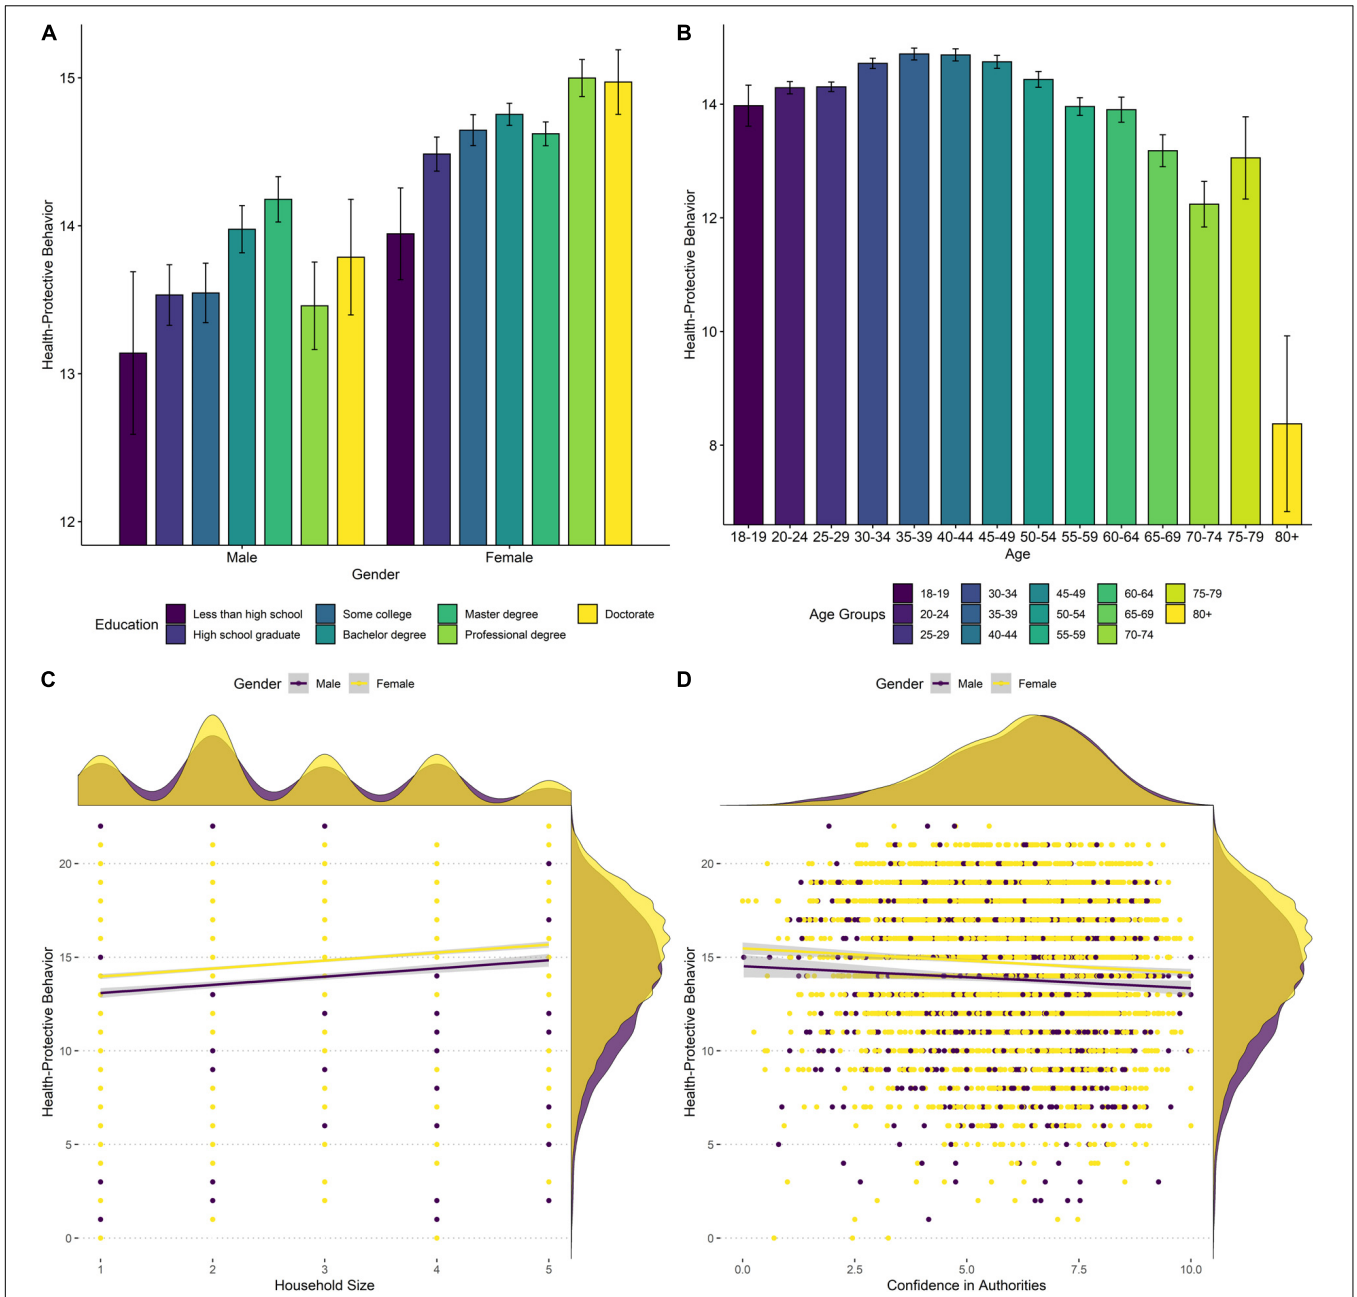

FIGURE 3 | (A) Health-protective behavior by gender and education level. **(B)** Health-protective behavior by age group. **(C)** Association of health-protective behavior and household size separately for gender. **(D)** Association between health-protective behavior and confidence in authorities separately for gender.

could be due partially to changes in the sample composition. In order to control for changes in demographics per day we computed four logistic regression models regressing age, gender, education level, and household size on day and day squared. We only observed statistically significant effects for age showing a negative linear effect ($B = -0.69$, $SE = 0.05$) and a positive quadratic effect ($B = 0.04$, $SE = 0.003$), suggesting that the sample in general became younger over time, but then increased in age at the end of the sampling period. As previous analyses suggested that age predicted health-protective behavior and other variables, we added age as a covariate to all models in order to control for it.

Results are provided in **Table 3** and time series can be found in **Figure 4**. For behavior, we observed that physical distancing showed a significant positive linear trend. Overall, engagement in physical distancing behavior increased during the days of data collection. On the other hand, hygiene behavior showed no significant linear or quadratic effect. Instead, it showed a small decrease during the first days, but remained rather stable.

Considering attitudes, we observed that confidence in authorities slightly increased during the testing period, though this effect was not statistically significant. Perceived likelihood of catching COVID-19 showed both a significant positive linear trend and a significant negative quadratic trend, first increasing, but later showing a small decrease. Severity of the disease combined a significant negative linear and a positive quadratic trend, first decreasing and then increasing. Taken together, it seems that the more likely catching COVID-19 was reported to be, the less severe respondents estimated it to be over time. Finally, experiencing concern or worry showed a significant negative linear effect decreasing over time. At the same time, we also observed a significant positive quadratic trend, suggesting that concern increased at the end of the testing period. Experiencing fear showed a small decrease over time. For experiencing hope, we did not find any significant linear or quadratic trends.

DISCUSSION

We sampled over 8.000 Norwegian participants in the first 2 weeks after schools were closed and many employees were sent to work from home, at the beginning of the COVID-19 outbreak in Norway. We observed self-reported health-protective behavior and emotions in real time, while numbers of registered infections rose from 805 to 3399, the number of hospitalized patients rose from 32 to 265, and the number of deceased patients rose from 1 to 14.

Although policy setting may be the main determinant of behavior, psychological factors play an important role in responses to health crises as they modulate how people adopt the guidelines. In the present project we focused on what factors are correlated to engagement in two variants of protective behavior: preventive, such as hygiene behavior, and avoidance, including physical distancing. We employed both a theory- and a data-driven approach, and we explored how attitudes, behavior, and affective reactions changed over the course of the 15-day sampling period. To protect us from overinterpreting spurious effects, which would be costly in the current situation, we set our significance level to $p < 0.001$.

Information Sources, Confidence in Authorities and Perceived Risk

In our sample, main news sources were news media, government websites, and social media in that order, more than colleagues and family members. When indicating whom they trusted most, participants mainly pointed to the Norwegian Institute of Health (FHI), more so than other Norwegian government sources or European sources. One's own doctor and hospital was rarely reported as the most trusted source. Confidence

was high that authorities, including the Norwegian government, scientists, health professionals, and medical services, were able to manage the outbreak. Despite the increase in infected cases, we observed that confidence stayed stable and even slightly (but not significantly) increased over the time of 15 days.

Respondents expected that they too would likely get infected, with an average above the midpoint on our likelihood rating scale (60%). This average was at the upper end of FHI's prediction for the general population from 12/03, and higher than the number in Wise et al.'s (2020) sample (M = 43) and the representative sample analyzed by Sætrevik (2020), suggesting that due to our sampling strategy our participants might be more concerned and engaged with the topic than the Norwegian population on average. At the same time, perceived severity was predominantly rated with mild or moderate symptoms. Ratings were higher for the perceived likelihood of close others catching the disease (73%) and similarly, a high proportion of respondents (71%) could imagine that someone from their family would show severe symptoms or even die when imagining the worst case. This was also in line with the observations made in parallel by Sætrevik (2020).

Health-Protective Behavior

Self-reported behavior was very much in line with policies asking for (but not mandating by law) physical distancing and protective hygienic behavior. Even behavior that is sometimes difficult to avoid like taking public transport and going to shops was reported as being reduced or avoided by more than 70% of the sample. More than 70% reported other-protective behavior in the form of reminding other individuals of proper behavior or not visiting older individuals. Fewer people actively helped others by for instance buying groceries or even giving money to charities combating COVID-19. Only a small minority reported irrational avoidant behavior (e.g., avoiding Chinese restaurants – given that the main group bringing infections into Norway were Norwegians coming from winter holidays in the Alps rather than travelers associated with China).

In line with previous findings during other pandemics and also COVID-19 (Bish and Michie, 2010; Harper et al., 2020; Wise et al., 2020), the elevated level of appropriate protective and avoidant behavior was predicted by demographic variables: female participants, higher education levels, and larger household sizes. To some extent, these effects were mediated by elevated perceptions of likelihood and severity of the disease for self and others, but these mediations did not explain much variance and indirect effects were considerably small. These models may underestimate the true effect, however, because expectations and behavior changed over the course of the sampling period. There might be other factors that explain this pattern of results. For instance, recent findings show that compassion and empathy play an important role for the engagement in physical distancing during the COVID-19 outbreak (Pfattheicher et al., 2020) and such reactions have been observed to a higher degree in women (Christov-Moore et al., 2014).

Previous studies also reported that older age predicted more engagement in health-protective behavior. We failed to find a clear replication in the current sample. In fact, our regression analyses point in the direction that older age is associated with less adoption of health-protective behavior. When exploring this association in more detail, we observed four important boundaries. First, we observed a non-linear relationship between age and protective behavior, suggesting that engagement in health-protective behavior increased with age as predicted by previous literature, but then leveled off at around the age of 40–44 and decreased with older age. Second, our sample included only a few participants above the age of 70. Their estimates are therefore highly imprecise compared to younger respondents (that we

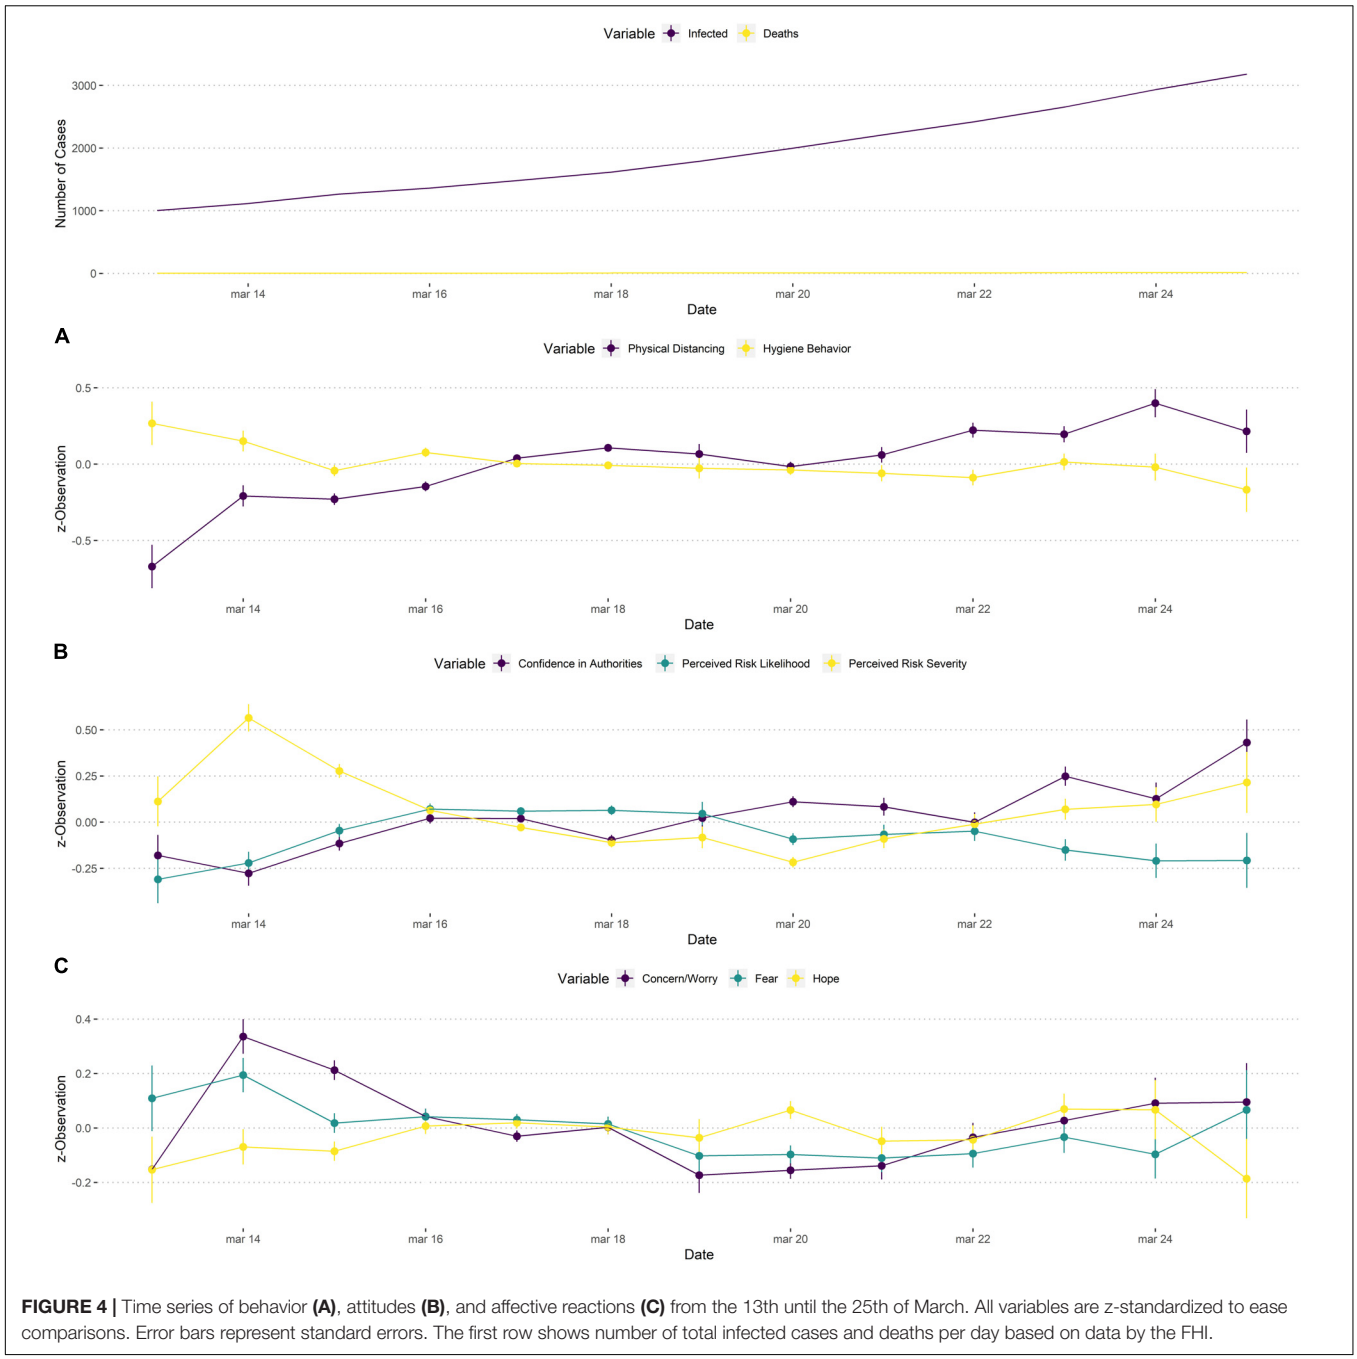

FIGURE 4 | Time series of behavior **(A)**, attitudes **(B)**, and affective reactions **(C)** from the 13th until the 25th of March. All variables are z-standardized to ease comparisons. Error bars represent standard errors. The first row shows number of total infected cases and deaths per day based on data by the FHI.

sampled around 100 times more often) and when excluding age groups with less than 50 participants the relationship between age and protective behavior was reduced to near zero. Third, the effect was reduced when controlling for time. Fourth, when constructing the main outcome variable in a different way in order to account for the possibility that some behaviors from our list were not applicable for older adults (e.g., avoiding work) we observed a weaker effect (see **Supplementary Material**). Thus, given the composition of our sample we can be more certain that respondents at the age of 40 engage in more protective behavior than respondents at the age of 20. However, whether engagement in health-protective behavior again decreases for individuals at the age of 50 should be interpreted with caution. If this is indeed the case, this would represent an important finding as risk factors and susceptibility increase with age. We recommend testing this question with a representative sample.

In a second step, we tested the influence of more than 30 variables on health-protective behavior employing a supervised machine learning algorithm. We observed that higher engagement in health-protective behavior was associated with (1) larger household size, (2) more children, (3) higher perceived effectiveness of the protective behavior, (4) more media

exposure, and (5) reduced belief that 'too much fuss' was made about the outbreak (i.e., discrediting the severity and credibility of the crisis, Rubin et al., 2015) above and beyond other factors such as knowledge, perceived risk, living in a municipality with a high amount of recorded cases or one's own perceived health. The simultaneous presence of demographic and psychological predictors indicates that the psychological mediators of the remaining demographic factors remain unclear.

When considering preventive and avoidance behaviors separately, we observed that household size (i.e., being surrounded by more people) and regarding staying away from others as effective predicted physical distancing, whereas emotional reactions such as concern, worry, or fear and media exposure had a stronger importance in engaging in hygiene behavior. Our findings replicate previous studies suggesting that high perceived effectiveness is important as a predictor of engaging in health-protective, and specifically avoidance behavior (Ajzen and Timko, 1986; Agüero et al., 2011).

The importance of household size and the number of children, especially for the adoption of avoidance behavior, points to the possibility that individuals might feel more personally responsible for their co-habitants. Literature on the effectiveness of health communications suggests that personal relevance represents an important factor for engaging in protective behavior, which is likely higher if more people within one's social proximity could be affected (Ruiter et al., 2001). Similarly, household size is typically conflated with age showing an inverse u-shaped curve, which fits our observations concerning the association between age and protective behavior. In addition, individuals that need to care for others might show more empathy or compassion, thereby increasing engagement of avoidance behavior as a means of prosociality (Pfattheicher et al., 2020).

On the other hand, engagement in preventive behavior such as hand washing or using hand sanitizing gel was associated less with social-contextual variables, but to a higher degree with felt concern, fear, or worry, as well as increased engagement with the topics. For both types of behaviors, we found that believing there is too much fuss made about the outbreak reduced it. This relation could have several reasons. Wise et al. (2020) identified a subgroup that was disengaged from the news, unaware of risks, and not practicing recommended behavioral change. Participants who indicated that "too much fuss was made" may have belonged to a similar subgroup. On the other hand, there might be a group of people who for some reason cannot change their behavior, and consequently adapt their attitudes to be consistent. In any case, if that group is large enough, it could counteract quarantine measures in communities. It thus seems important to follow up on this effect, again ideally with representative samples.

Contrary to our predictions, we observed that increased confidence in authorities reduced the adoption of health-protective behaviors. Similar findings were observed in the sister study of the current project with an Australian sample (Faasse and Newby, 2020). While confidence in governments, health professionals, and medical services has been reported as crucial for individuals to adopt behavioral change (Bish and Michie, 2010), it is possible that overconfidence results in reckless behavior, as it is assumed that everything will be under control no matter what individual actions are performed. This finding points at a dilemma, as confidence in authorities is needed to establish protective behavior in the first place and reduce panicking or intense fear of the outbreak (Asmundson and Taylor, 2020). Health communications therefore need to highlight the importance of individuals actions as part of greater societal outcomes, and simultaneously communicate conviction in recommended measures and risk.

During the 15-day sampling period, we observed a significant increase in avoidance behaviors. These changes could be explained by individual psychological factors such as increased personal relevance or concern, group behavior and attitudes (such as injunctive norms), or contextual factors. For instance, throughout Norway schools and universities were closed on the 12th of March, creating a uniform behavior change. Similarly, most public events such as sports or concerts were canceled. It is not possible for the present data to show whether changes in avoidance behavior were based on psychological factors or situational constraints. Interestingly, we observed little change in hygiene behavior during the sampling period. It could be possible that hygiene behavior was already quite high at the beginning of data collection: over 90% indicated engaging in more thorough hand washing behavior. On the other hand, increased self-isolation through avoidance behavior could have resulted in neglecting additional preventive behavior.

In contrast to previous studies on responses to pandemics or specifically COVID-19, we failed to find strong associations between perceived risk or knowledge and engagement in protective behavior. While perceived likelihood and severity showed positive relations with health-protective behavior, these effects were considerably small and smaller than factors such as the number of children or experienced concern. Similarly, knowledge showed no or even a negative relationship with engagement in protective behavior. As knowledge and media exposure were on average quite high, it could be that we simply did not have enough variation in the sample to detect a larger effect. Nevertheless, the implication seems to be that motivating people to practice protective behavior works best by emphasizing that it is effective, rather than by exaggerating risks of not engaging in it.

The present findings mostly replicate an earlier study using nearly identical methods in an Australian sample in an earlier stage of the pandemic (Faasse and Newby, 2020). Similar to this study, we found positive relations to media exposure, concern and worry, as well as effectiveness of behavior. In addition, we also replicated the finding that confidence in authorities and believing that too much fuss was made resulted in less health-protective behavior.

Our observed effect sizes ranged from zero-order correlations (r) of 0.26 between concern/worry and health-protective behavior to standardized regression coefficients (beta) of 0.07 for the prediction by media exposure when controlling for the other variables, or less. The estimated effect sizes are in line with published literature focusing on attitude-behavior relationships (Bosco et al., 2015) and can be considered as small to medium

effects. Similarly, our effects are comparable to previous research exploring predictors of health-protective behavior during the COVID-19 outbreak (Faasse and Newby, 2020; Harper et al., 2020; Wise et al., 2020). It would have been helpful to define a smallest effect size of interest in order to be able to conclude when an effect is absent by for example applying equivalence testing (Lakens, 2017). However, given the exponential nature of the growth of infections it is difficult to decide on a cut-off regarding which effects might not be of practical importance anymore. While standardized regression or correlation coefficients of 0.05 might be typically considered as too small to be of practical importance, they could still be informative in the current context. Answers to that can only come from models that integrate behavior and epidemiological effects (e.g., Poletti et al., 2012). In general, we note that our effects were on average comparable small.

Limitations

Our study has several limitations that should be considered when interpreting the findings. First, although large, our sample was not collected in a way that makes it representative. Women, younger people, and individuals with a higher education level are overrepresented; this should be taken into account when interpreting the presented findings. Nevertheless, our total sample size was large enough that we trust our estimates for male participants. Notably, percentage of people expecting to become infected, confidence in the government to handle the crisis, and percentage of those worried about family members are similar to numbers found in two representative survey studies among the Norwegian population (Kantar, 2020a,b), suggesting that our sample might be quite similar to the Norwegian population at large. Nevertheless, our study provides a snapshot of a 15-day period, focusing on a non-representative sample representing a specific culture with all its societal and normative implications, as well as certain healthcare systems and authorities that are hardly generalizable to different countries, healthcare systems, or timepoints in a pandemic.

Second, although time is a meaningful variable in the 15 days window that we observed, our sample is cross-sectional, not longitudinal. Changes over time can thus be caused by various confounding variables and simply be due to sampling variation, despite our efforts to control for that. Strong inferences about intra-individual change need repeated measures in a longitudinal design, which we do not have (Borsboom et al., 2003; Fisher et al., 2018).

Third, we did not pre-register our research methods and analysis plan. Indeed, we largely adopted an existing instrument and developed the literature review and hypothesis in parallel to data collection. The main research scope of the present project was exploratory in nature and we did our best to increase the reliability of our findings by conducting a split-half validation method (IJzerman et al., 2018). Due to the exploratory approach, we included several variables that have been found to predict protective behavior in past literature or were deemed important. Of course, it is possible that we failed to include important variables associated with health-protective outcomes, such as compassion or empathy (Pfattheicher et al., 2020).

Fourth, the measurement of some of the included variables, especially our outcome variable, could be improved. In the current project we assessed protective behavior using a dichotomous format (answer alternatives yes/no, we also added unsure, and not applicable). A Likert-scale type measurement might be superior in capturing the whole breadth of responses in the outcome variable. At the moment a respondent will answer yes if she avoided specific situations once or several times within the last 2 weeks. Using more response options would allow us to differentiate among such responses. Similarly, we focused on self-report of behavior, not actual behavior and there might be a gap between reported and actual health-protective behavior. However, recent research focusing on GPS movement data in the US during the COVID-19 outbreak suggests that self-report data might be used as a proxy for actual behavior (Gollwitzer et al., 2020).

Our measures of protective and avoidant behavior were much more comprehensive than our measure of other-supporting behavior. As the crisis proceeds, various behaviors that support the community through donating food, equipment, and money, making masks, supporting each other through buying food, and taking care of children become important, and it is known that such communal behavior emerges in crises and can be stifled by authorities reacting the wrong way (Solnit, 2009; Drury et al., 2019). Future studies should place more emphasis on such measures.

Finally, we believe that our understanding of the motives behind protective and avoidant behavior is not ideal. Unless one knows for sure whether oneself or another person is infected, most behavior serves both to protect oneself and others. For instance, the discussion about wearing non-clinical facial masks has moved from initial arguments that they are not providing total protection for the wearer to the insight that they do protect others if the wearer is infected - and if everybody protects everybody else, then everybody is protected. In our data, we are not able to tease apart motivation to protect the self and other-protection motivation, either for close others or the community. Again, this remains a crucial topic for future work.

CONCLUSION AND OUTLOOK

The present project provides a snapshot of individuals' attitudes, behavioral actions, and affective reactions during 2 weeks following the COVID-19 outbreak in Norway. While our findings do not generalize to the whole Norwegian population, nor to other countries with different courses of action responding to the outbreak or different healthcare systems, they provide important information on the nature of what psychological and demographic variables might influence health-protective behavior and how such variables change over time. The findings can provide insights and indications in order to improve healthcare communications:

(1) Perceptions of effectiveness of protective behavior are important; they emerge as crucial especially when trying to predict physical distancing. They could be increased

by tailoring communication strategies to various groups, emphasizing how different people can engage in effective preventive (hygienic) or avoidance (distancing) behavior.

(2) People differ, and these differences matter for the adoption of protective behavior: being female, household size, and number of children all seem to play a role. On one hand, these factors point to how early on in a crisis first changes can be reached quickly by targeting such response groups. On the other hand, this again shows that tailored messaging and targeted behavior change campaigns are indicated.

(3) Physical distancing and hygiene seem to be driven by somewhat different factors: the former more by social variables and beliefs of effectiveness, the second more by emotional processes. Again, campaigns targeting these complementary protections should be aware of that.

(4) In line with previous literature, there is a subset of the population that discredits severity and credibility of the crisis, indexed in our study as the belief that "too much fuss is being made" about this, which is in turn associated with less engagement in health-protective actions (cf. Rubin et al., 2015). It may be fruitful to model and investigate the potential impact such individuals can have on the spread of the disease, the reasons for their beliefs, and targeted ways to change their beliefs.

Finally, the present project highlights that although similar factors can be found across different countries or medical systems that seem to influence protective outcomes (e.g., Harper et al., 2020; Wise et al., 2020), it is important to take the specific trajectories and developments in each country or healthcare systems into account to be able to successfully model and identify important variables predicting health-protective behavior (see Mækelæ et al., 2020).

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/ **Supplementary Material**.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Internal Review Board, Institute of Psychology, University of Oslo. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

JG and KF devised the original method. JZ, TS, and AH adapted the original instrument for Norway, and AH translated it into Norwegian. JZ analyzed the data and wrote the first draft. All authors contributed to revisions.

FUNDING

Data collection was supported by funding provided by the Department of Psychology of the University of Oslo to TS.

ACKNOWLEDGMENTS

We thank Bjørn Saetrevik, Alf Børre Kanten, Gerit Pfuhl, Torleif Halkjelsvik, Øyvind Ihlen, and Beate Seibt for helpful comments on earlier drafts and Svein Harald Milde for help with promoting the survey.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fpsyg.2020.564083/full#supplementary-material

This study examines the mental health outcomes among the healthcare personnel and the general population and the role of socioeconomic status. Eight hundred and eighty-four (884) residents in Nigeria comprising 382 healthcare personnel and 502 general residents aged between 18 to 78 years (M = 28.75, SD = 8.17) responded to an online survey with measures of Impact of Event Scale-Revised (IES-R), Generalized Anxiety Disorder (GAD-7), Patient Health Questionnaire (PHQ–9), and Insomnia Severity Index. Collected data were subjected to statistical analysis using the SPSS v.25. Results revealed significant difference in the prevalence of depressive symptoms (χ^2 = 14.26; df = 4; $p < 0.01$), insomnia symptoms (χ^2 = 40.21; df = 3; $p < 0.01$), posttraumatic stress symptoms (χ^2 = 08.34; df = 3; $p < 0.05$), and clinical anxiety symptoms (χ^2 = 06.71; df = 1; $p < 0.05$) among healthcare personnel and the general population, with a higher prevalence reported by the healthcare personnel. Further, socioeconomic status significantly influences prevalence of depressive symptoms (χ^2 = 04.5; df = 4; $p < 0.05$). The study concluded that the prevalence of poor mental health outcomes during the COVID-19 crisis among Nigerians is worrisome. Also, the socioeconomic status of the citizens has serious implications on depressive symptoms. The study recommends that the government and stakeholders should pay attention to policy that will favor tele-mental health services and adequate palliative measures to cushion the psycho-economic impacts of COVID-19 on residents. Also, healthcare workers should be considered for better remuneration and other welfare benefits to sustain their well-being during the present and future pandemic.

INTRODUCTION

Since the outbreak of coronavirus, otherwise known as COVID-19, which was first reported in December 2019 in Wuhan China, declared as a Public Health Emergency of International Concern in January 2020 and later a pandemic in March 2020 by the World Health Organization (WHO), the world has not been the same (World Health Organisation, 2020). For instance, the statistics released on August 28, 2020, indicated that there had been more

than 24.6 million confirmed cases of COVID-19 and 835,000 deaths worldwide (Worldometer, 2020). Worldometer reported further that, at the end of August 2020 in Nigeria, more than 53,317 cases have been confirmed, while over 1,011 people have died (Worldometer, 2020). Despite the disturbing figures, it has been opined that the actual global incidence rate of COVID-19 cases is likely to be far higher than what the statistics show (Flaxman et al., 2020).

Being a novel disease that is highly contagious, spreading fast across the world, and the fact that there is yet to be an established cure for it, the COVID-19 pandemic has created a lot of panic in every part of the world. In response, many countries have put up different measures, especially those upholding social distancing order, to slow down the spread of the disease. Although there is evidence of the effectiveness of quarantine measures to control the spread of infectious diseases such as cholera, severe acute respiratory syndrome (SARS), or Ebola in the past (e.g., Twu et al., 2003), the effect of restriction of movement and lockdown on socioeconomic activities across different countries of the world has generated different opinions about the impact on the general citizens (Goldman et al., 2018; Forbes and Krueger, 2019; Mbamalu, 2019; The World Bank, 2020).

From the foregoing, emerging evidence has implicated the ongoing COVID-19 pandemic in the mental health outcomes among different populations such as the healthcare professional and the general public worldwide (e.g., Ji et al., 2017; Brooks et al., 2020; Lai et al., 2020; Olaseni et al., 2020; and Rossi et al., 2020). Besides, the social-distancing and self-isolation during the COVID-19 pandemic place more challenges on the mental health and general well-being of the people (Mukhtar, 2020). In addition, it is crucial to assess the mental health outcomes of people during a global crisis such as the COVID-19 pandemic alongside the socioeconomic status and attributes of the people. This is because several studies have established strong relationships between socioeconomic status (SES) and mental well-being. More importantly, low SES have been implicated in poor self-reported mental health including depression, anxiety, sleep problems, and psychological distress in adults and adolescents (Richter et al., 2009; Salami and Walker, 2014; Pappas, 2020).

Having a holistic understanding of the mental health outcomes of all members of the society, not only focusing on direct victims (patients) and healthcare providers in response to any major event, is crucial to the recovery of the people. This position was emphasized by the proposition of the Canadian National Advisory Committee on SARS and Public Health in 2003 that a "systemic perspective," focusing on the general population and not just medical staff and patients should be embraced in addressing the SARS epidemic (Naylor et al., 2003). Nevertheless, the literature shows that many studies addressing the psychological consequences of COVID-19 are focusing exclusively on either the healthcare professionals or the general public, therefore limiting the opportunity of comparison between the two populations concerning the mental health outcomes during the COVID-19 crisis.

Furthermore, the situation in Nigeria calls for special attention because being a developing country where small medium enterprises (SMEs) contributed 48% of the national gross domestic products (GDP) that account for 96% of the businesses and 84% of employment (Public Works Corporation, 2020), the effect of the present COVID-19 pandemic and lockdown on socio-economic activities is likely to be severe on the well-being of the people, many of whom rely on daily income to cater for their personal and family financial needs. Hence, the significance of this study addresses that the interaction between socioeconomic status and mental health outcomes of Nigerians during the COVID-19 pandemic cannot be overemphasized. Specifically, the following objectives guided this study:

1. To investigate the interaction between socioeconomic status of respondents and mental health outcomes during the COVID-19 crisis.
2. To compare the mental health outcomes of healthcare workers with the general public during the COVID-19 pandemic.

MATERIALS AND METHODS

Design

This research was a web-based cross-sectional survey that was conducted via social media (Facebook and WhatsApp posts) using a Google form from March 20 to April 19, 2020. This was found appropriate to enable the investigators to assess the psychological distress experienced by participants during the COVID-19 pandemic without manipulating the variables of interest.

Sampling

A snowball sampling technique was utilized in this study. This method was considered appropriate due to the imposed restrictions of movement and lockdown in Nigeria during the period. Key persons (e.g., known healthcare workers or frontline staff, friends, colleagues, and those on the contact of the researchers) across each category of respondents (healthcare workers and the general population) were considered the seed in the study, and they were encouraged to disseminate the links with others in the same category accordingly. The online semi-structured questionnaire developed using Google forms with an appended consent form was sent through emails, WhatsApp, and Facebook platforms to potential respondents on the contact of the investigators. Those prospective individuals were then encouraged to roll out the survey to other colleagues or residents in Nigeria.

Participants

Eight hundred and eighty-four (884) participants were involved in the current study. The sampled respondents cut across healthcare personnel and the general public. Healthcare personnel were 43.21% (n = 382), while the general public constituted 56.79% (n = 502) of the study respondents. Considering the gender disparity, the majority of the respondents were male, which constituted the 54.5% of the total respondents, while the female counterparts constituted 45.5%. There was

a disparity in the distribution of geo-political zones of the respondents; the majority of the respondents were from the southern part of Nigeria, constituting 85.2% of the sample, 10.9% were from the northern part of Nigeria, while 4% were foreign residents in Nigeria. The disparity across respondents' marital status and level of education were also reported (see **Table 1**).

Instrument

Data were collected via an online self-reported questionnaire designed by the investigators. The questionnaire contained six sections related to the mental health outcome of health workers in Nigeria amid the coronavirus pandemic. The first section consisted of information assessing demographic attributes such as sex, age, religion, and marital status of participants.

The second section contained the 22-item of the Impact of Event Scale-Revised (IES-R) (Weiss, 2007). The scale was developed to measure the subjective response of an individual to a specific traumatic event, especially the response to sets of intrusion, avoidance, and hyperarousal, as well as total subjective stress. The IES-R is not a diagnostic tool but just a screening measure. The total IES-R score was divided into 0–23 (normal), 24–32 (mild psychological impact), 33–36 (moderate psychological impact), and >37 (severe psychological impact). Briere (1997) affirmed the validity and reliability of the scale. Cronbach's alpha 0.82 was established as the reliability coefficient for the scale in this study.

Section three of the questionnaire was the GAD-7 (Spitzer et al., 2006). It consisted of 7 questions assessing generalized anxiety disorder. The items focused on the frequency of symptoms during the preceding 2-week period of COVID-19 lockdown in Nigeria. The GAD-7 requires approximately 1–2 min to administer and for each symptom queried provides the following response options: "not at all," "several days," "over half the days," and "nearly every day" and these items are scored as 0, 1, 2, or 3, respectively. A score ranging from 0 to 21 is obtainable by respondents. Scores of 5, 10, and 15 are taken as the cut-off points for mild, moderate, and severe anxiety, respectively. Cronbach's alpha 0.81 was established as the reliability coefficient for the scale in this study.

The fourth section contained the Patient Health Questionnaire (PHQ–9). The PHQ–9 is a nine-item depression scale that has the potential of performing a dual-purpose of the instrument. It can establish the diagnosis of a depressive disorder and reveal the grade of symptom severity (Kroenke et al., 2001). Statements measuring depressive symptoms such as "little interest/pleasure in doing things" were rated from 0 (not at all) to 3 (nearly every day) by respondents as applicable to them over the past two weeks during the lockdown. PHQ-9 scores can range from 0 to 27. The scale has strong psychometric properties (e.g., Botha, 2011) and has been widely used. Cronbach's alpha 0.87 was established as the reliability coefficient for the scale in this study.

The fifth section contained the Insomnia Severity Index; this is a 7-item self-report questionnaire assessing the nature, severity, and impact of insomnia. Participants were required to rate their sleep condition in the last 2 weeks as described by each item of the scale. Questions on the ISI cut across the severity of sleep onset, sleep maintenance, and early morning awakening problems, sleep dissatisfaction, interference of sleep difficulties with daytime functioning, noticeability of sleep problems by others, and distress caused by the sleep difficulties. The scale is responded to on a 5-point Likert scale with a score ranging from 0 to 4, thus yielding a total score ranging from 0 to 28. The total score is interpreted as follows: the absence of insomnia (0–7); sub-threshold insomnia (8–14); moderate insomnia (15–21); and severe insomnia (22–28). Previous studies have reported adequate psychometric properties for both the English and French versions (e.g., Bastien et al., 2001). Cronbach's alpha 0.78 was established as the reliability coefficient for the scale in this study.

TABLE 1 | Socio-demographic characteristics of the study participants.

Characteristics	Overall (*N* = 884/%)	Healthcare personnel (*n* = 382/%)	General population (*n* = 502/%)
Sex			
Male	482 (54.5)	207 (54.2)	269 (53.6)
Female	402 (45.5)	169 (44.2)	225 (44.8)
Religion affiliation			
Christianity	609 (68.9)	272 (71.2)	337 (67.1)
Islam	261 (29.5)	102 (26.7)	159 (31.7)
Others	14 (01.6)	08 (2.1)	06 (1.2)
Regional affiliation			
Southern, Nigeria	753 (85.2)	319 (83.5)	433 (86.3)
Northern, Nigeria	96 (10.9)	44 (11.5)	47 (9.4)
Foreigner	35 (4.0)	17 (04.4)	22 (4.4)
Marital status			
Single	297 (33.6)	132 (34.6)	165 (32.9)
Married	577 (65.3)	244 (63.9)	333 (66.3)
Separated/divorced	10 (01.1)	06 (01.6)	04 (0.8)
Level of Education			
Bachelor degree and its equivalent	352 (39.8)	154 (40.3)	198 (39.4)
Diploma and its equivalent	236 (26.7)	100 (26.2)	136 (27.1)
Postgraduate education	254 (28.7)	108 (28.3)	146 (29.1)
Secondary school education	42 (04.8)	20 (05.2)	22 (04.4)

Procedure

The study was an online cross-sectional survey study. Only adults (aged between 18 and 78 years) who were either healthcare workers or Nigerian residents with access to the internet were involved in this study. Also, participants must be able to read and understand in basic English language and be willing to click the agree button to participate before having to access the survey. A link to the survey on Google form was sent to all participants. On receiving and clicking the link, the participants got auto-re-directed to the survey items. A detailed informed consent form was attached at the beginning of the online questionnaire and only individuals who gave their consent participated in the study. The data collection was initiated on March 20, 2020, and closed on April 19, 2020. The sampling technique utilized allowed the investigators to collect data from across various states of Nigeria. Eight hundred and eighty-four (884) correctly filled

questionnaires were recovered through the Google form and processed for statistical analyses.

Data Analysis

The collected data were analyzed using the Statistics Package of Social Sciences (SPSS; version 25). The analyzed data responded to the two research questions stated earlier in this study. The analyses included reliability coefficients of the used scales, prevalence estimate analysis, and chi-square analysis.

RESULTS

This section presents the results and interpretation of the data collected. The analyses of the interaction between socioeconomic status and mental health outcomes of selected respondents (healthcare personnel and the general population) in Nigeria during the COVID-19 pandemic lockdown were conducted. The results captured the socio-demographic characteristics of the respondents as well as the interaction between socioeconomic status and mental health outcomes of respondents which are presented in **Tables 1**–**3**.

Outcomes of the study (see **Table 2**) revealed that there was a significant difference in the prevalence of depressive symptoms among respondents with different socioeconomic status (χ^2 = 04.05; df = 4; $p < 0.05$). Furthermore, it was found that the prevalence of clinical depressive symptoms was significantly higher among respondents with the standard income compare to those above standards and below standard incomes (61.5% vs. 22.8% and 20.2%; 95% CI, 0.63–4.60; $p < 0.05$). Further findings revealed that there was no significant difference in the prevalence of insomnia symptoms among categories of socioeconomic status (χ^2 = 02.38; df = 3; $p > 0.05$). However, the prevalence of clinical insomnia symptoms was insignificantly higher among respondents with standard income compared to respondents with the above standard and below standard incomes (60.1% vs. 24.9% and 15.3%; 95% CI, 0.20–1.68; $p > 0.05$).

Similarly, study findings revealed that there was no significant difference in the prevalence of posttraumatic stress symptoms (PTSS) among different socioeconomic classes (χ^2 = 01.50; df = 3; $p > 0.05$). However, the prevalence of posttraumatic symptoms was insignificantly higher among respondents with standard income compared to respondents with the above standard and below standard incomes (48.3% vs. 43.3% and 47.9%; 95% CI, 0.53–2.98; $p > 0.05$). Insignificant difference was also reported in the prevalence of clinical anxiety symptoms among classes of socioeconomic status (χ^2 = 0.19; df = 1; $p > 0.05$). However, the prevalence of anxiety symptoms was insignificantly higher among respondents with standard income compared to respondents with the above standard and below standard incomes (46.9% vs. 45.3% and 47.3; 95% CI, 0.49–2.83; $p > 0.05$).

Another objective of the study proposed to examine the comparative analysis of mental health outcomes among the healthcare population and the general population was presented in **Table 3**.

Responses from 884 participants in the study (i.e., both healthcare personal and the general population) were screened for depression, anxiety, insomnia, and posttraumatic symptoms constituted the outcome of the analysis. Outcomes of the study (see **Table 3**) revealed that there was a significant difference in the prevalence of depressive symptoms among healthcare personal and the general population (χ^2 = 14.26; df = 4; $p < 0.01$). Further, it was found that the prevalence of clinical depressive symptoms was significantly higher among healthcare personnel than the general population (35.1% vs. 23.5%; 95% CI, 0.54–1.03; $p < 0.01$). Finding further revealed that there was a significant difference in the prevalence of insomnia symptoms among healthcare

TABLE 2 | Showing the interaction between socioeconomic status of respondents and the prevalence of depression, insomnia, and posttraumatic stress symptoms and anxiety in Nigeria (*N* = 884).

Outcome	Above standard income (*n* = 201*%)	Standard income (*n* = 516*%)	Below standard income (*n* = 167*%)	Prevalence ratio (95% CI)	χ^2	*p*
Depression	46 (22.8)	155 (61.5)	51 (20.2)	0.63 – 4.60	04.05	<0.05
Insomnia	50 (24.9)	122 (60.1)	31 (15.3)	0.20 – 1.68	02.38	>0.01
PTSS	87 (43.3)	249 (48.3)	80 (47.9)	0.53 – 2.98	01.50	>0.05
Anxiety	91 (45.3)	242 (46.9)	79 (47.3)	0.49 – 2.83	00.19	>0.05

Note: Clinical severity in the study outcomes are the reference categories of all variables.

TABLE 3 | Prevalence of depression, insomnia, and posttraumatic stress symptoms and anxiety in healthcare personnel and general population (*N* = 884).

Outcome	Healthcare personnel (*n* = 382*%)	General population (*n* = 502*%)	Adjusted prevalence ratio (95% CI)	χ^2	*p*
Depression	134 (35.1)	118 (23.5)	0.537 – 1.034	14.26	<0.01
Insomnia	127 (33.2)	76 (15.1)	0.289 – 0.579	40.21	<0.01
PTSS	201 (52.6)	215 (42.8)	0.847 – 1.519	08.34	<0.05
Anxiety	223 (58.4)	249 (49.6)	0.719 – 1.307	06.71	<0.05

Note: Clinical severity in the study outcomes are the reference categories of all variables.

personal and the general population (χ^2 = 40.21; df = 3; $p < 0.01$). Such that, the prevalence of clinical insomnia symptoms was significantly higher among healthcare personnel than the general population (33.2% vs. 15.1%; 95% CI, 0.29–0.58; $p < 0.01$).

Similarly, study findings revealed that there was a significant difference in the prevalence of PTSS among healthcare personal and the general population (χ^2 = 08.34; df = 3; $p < 0.05$). Such that, the prevalence of posttraumatic symptoms was significantly higher among healthcare personnel than the general population (52.6% vs. 42.8%; 95% CI, 0.85–1.52; $p < 0.05$). A significant difference was also reported in the prevalence of clinical anxiety symptoms among healthcare personal and the general population (χ^2 = 06.71; df = 1; $p < 0.05$). Such that, the prevalence of anxiety symptoms was significantly higher among healthcare personnel than the general population (58.4% vs. 49.6%; 95% CI, 0.72–1.31; $p < 0.05$).

DISCUSSION

The objectives of this study are to investigate the interaction between socioeconomic status and mental health outcomes of respondents during the COVID-19 pandemic and to make a comparison between the mental health outcomes of healthcare workers and the general public in Nigeria during the COVID-19 pandemic. Consequently, our study revealed significant differences among the three socioeconomic status classes on depression only, invariably, this means that no significant difference was found among the three socioeconomic status classes on insomnia, posttraumatic stress symptoms and anxiety in Nigeria during the COVID-19. In detail, our study revealed that the standard income socioeconomic class reported almost two-thirds (62%) higher prevalence of depression as against the above standard income and below standard income class (22.8% vs. 20.2%).

Consistent with our findings, various studies have reported the relationship between socioeconomic status and mental health during COVID-19, but there has been a disparity in the class that is most affected. While our study reported the standard (middle) income socioeconomic class having the highest prevalence of depression during the COVID-19 pandemic, Heath (2020) reported 45% of the above standard (upper) income socioeconomic status class reported their emotional well-being harmed by coronavirus as against 34% and 36% from the lower and middle socioeconomic status class. Besides, contrary to our findings, Pappas (2020) suggested that people with lower socioeconomic status have a higher tendency to have mental health issues; however, the low socioeconomic level has been associated with death and high illness rates in several studies, regardless of the cause of death being from infectious or non-infectious diseases and indices for measuring socioeconomic status (Kaplan et al., 2007; Oguntayo et al., 2018).

The reason for our result could be associated to the fact that the standard (middle) income socioeconomic class in Nigeria is the largest socioeconomic group, occupying the wide inequality gap between the haves and the haves not. These individuals are mostly business owners (SMEs) and major salary earners from the private and government establishments; therefore, they are the most hit by the closure of businesses and lockdown in the country. Besides, there is speculation of a looming recession due to the COVID-19 pandemic (The World Bank, 2020), which has spurred some organizations to lay off staff and reduce the salary of the retained staff while so many have not received any salary since the lockdown in Nigeria. In this respect, Holmes et al. (2020) argued that serious psychological distress is anticipated from potential global economic crisis following the COVID-19 pandemic. This argument is substantiated by previous evidence linking the socioeconomic status of the people to their mental health outcome following the SARS epidemic in 2003 (e.g., Nickell et al., 2004; Tsang et al., 2004; Yip et al., 2010; Kanter and Manbeck, 2020). These are valid reasons why this group may have reported a higher prevalence of depression compared to the above standard (high) income class who are mostly politicians and big industrialists that have no fear of layoff or reduction in salary and below standard income class.

The unbalanced prevalence of depression among the socioeconomic classes in our study (22.8% vs. 61.5% vs. 20.2%) confirmed the assertion of Kanter and Manbeck (2020) that a large population may develop inequitably distributed depression due to the stressors of the COVID-19 crisis. Fear of inability to feed, pay house rent, and purchase of basic safety materials such as sanitizer and mandatory nose mask to fit into the new norm have added to the economic burden of the standard income and below standard income class, thereby leading to the prevalence of higher depressive states compared against the above standard income class. Importantly, the above standard income class in Nigeria holds the economic power of the country and economic power translates into political power, thereby giving control of state structure into the hands of the above standard income class. Moreover, various studies have confirmed that mental health deteriorates in line with the level of socioeconomic status (Goldman et al., 2018) and economic recessions (Forbes and Krueger, 2019).

Our study further revealed differences in the mental health outcomes between the Nigerian healthcare workers and the general population during the COVID-19 pandemic. In specifics, the prevalence of depression, insomnia, posttraumatic stress symptoms, and anxiety was higher among the healthcare workers (35.1%, 33.2%, 52.6%, and 58.4%, respectively) as against the prevalence of depression, insomnia, posttraumatic stress symptoms, and anxiety of the general population (23.5%, 15.1%, 42.8%, and 49.6%, respectively). The higher prevalence of mental health outcomes among healthcare workers during the COVID-19 pandemic can hereby be connected with their role as caregivers and essential workers during the pandemic. Interestingly, a similar higher prevalence of mental health outcomes was reported among healthcare workers in China caring for COVID-19 patients as against lower prevalence of mental health outcomes among the Chinese general population (Lai et al., 2020; Wang et al., 2020).

Healthcare workers are essential workers that have to care for the infected despite the impending risk during a pandemic, due to the duty and obligation to care. Compared against the general

population that has restricted movement and discontinued working due to the COVID-19 pandemic, healthcare workers are required to be at work, despite the human-to-human transmissible nature of the virus, wear uncomfortable personal protective equipment, work overtime, and observe directly, the devastation of the virus on their patients. These experiences have a more social, emotional, and psychological effect on healthcare workers than the general population as revealed in this study.

CONCLUSION

This study exposed the prevalence of mental health outcomes among Nigerians during the COVID-19 pandemic. Specifically, the result revealed a disproportionate prevalence of depression among the three socioeconomic classes, whereby the standard income (middle) socioeconomic class recorded the highest prevalence of depression. Besides, the prevalence of mental health outcomes (depression, insomnia, posttraumatic stress symptoms, and anxiety) was higher among the Nigerian health care workers when compared against the general population in Nigeria.

LIMITATION OF THE STUDY

This study established the association between socioeconomic status and stress-related behaviors; however, there are still some probable limitations. The participants were relatively few; therefore, this result should be carefully generalized as there is a possibility that outcomes would vary if measured on more numbers of participants. Also, response biases which most times are difficult to eliminate in a self-report survey study like this might have affected respondents' opinions, thereby limiting the results of this study. All these shortcomings might have influenced this result and limit the external validity of this study.

RECOMMENDATIONS

Looking at the results of the current study, these recommendations are suggested to alleviate the mental health challenges among the residents and health workers during the pandemic period:

1. Federal and state governments in Nigeria should initiate a bill honoring the tele-mental health services to manage present and future pandemic psychological implications. This will help to integrate psychological and medical health services in the fighting against any disease outbreak in the country, especially when face-to-face appointments are risky.
2. Healthcare stakeholders needed to collaborate with psychotherapists in the management of pandemic or disease outbreak to regulate residents' emotions and that of self to promote wholistic well-being in Nigeria.
3. Stakeholders in government should pay attention to policy that will favor adequate palliative measures to cushion the economic impacts of COVID-19 on the mental health of residents in Nigeria. Also, healthcare workers should be considered for better remuneration and other economic benefits to sustain their well-being during the present and future pandemic.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/ Supplementary Material.

ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. Written informed consent was implied via completion of the questionnaire/survey.

AUTHOR CONTRIBUTIONS

RO and SA contributed to the conception and design of the study. SA, OA, RO, and AO contributed to the acquisition of data. AO contributed to the analysis and interpretation of data. RO, OA, and SA contributed to the drafting of the manuscript. OA contributed to the critical revision of the manuscript. All authors read and approved the final manuscript for publication.

Front. Psychol. 11:584645. doi: 10.3389/fpsyg.2020.584645

On March 10, 2020, Italy went into lockdown due to the Coronavirus Disease-19 (COVID-19) pandemic. The World Health Organization highlighted how the lockdown had negative consequences on psychological well-being, especially for children. The present study aimed to investigate parental correlates of children's emotion regulation during the COVID-19 lockdown. Within the Social Cognitive Theory framework, a path model in which parenting self-efficacy and parental regulatory emotional self-efficacy mediated the relationship between parents' psychological distress and both children's emotional regulation, and children's lability/negativity, was investigated. A total of 277 parents of children aged from 6 to 13 years completed an online survey that assessed their psychological distress, regulatory emotional self-efficacy, and parenting self-efficacy. Parents reported also children's emotional regulation and lability/negativity. A structural equation model (SEM) using MPLUS 8.3 was tested. Results showed that the hypothesized model exhibited excellent fit, chi-square (83) = 140.40, $p < 0.01$, RMSEA = 0.05, CFI = 0.97, TLI = 0.96, SRMR = 0.04. The influences of parents' psychological distress and parents' regulatory emotional self-efficacy on children's emotional regulation and lability/negativity were mediated by parenting self-efficacy. The mediation model was invariant across children's biological sex and age, and geographical residence area (high risk vs. low risk for COVID-19). Results suggested how parents' beliefs to be competent in managing parental tasks might be a protective factor for their children's emotional well-being. Implications for intervention programs are discussed.

Keywords: pandemic, parents, children, psychological distress, parents' self-efficacy, parenting, emotion regulation, COVID-19

INTRODUCTION

The spread of the pandemic COVID-19 in Italy from February 2020 and the subsequent health emergency led to several restrictive measures. Schools and universities have been closed at the end of February, and starting from March 9th, 2020, a quarantine measure became necessary leading to a general closure of almost all public businesses and work activities.

Children and families have been deprived of their educational, work, and sport activities, but also from all their friendship and relational contacts. Suddenly parents had to manage their children at home from school 24 h a day and, at the same time, most of them had to start smart-working from home, still carrying out their children's school commitments. Many parents also had to manage difficulties and pain related to having sick or dead relatives, having had wages reductions, or in some cases, having lost their work. It is easy to understand how Italian families have been exposed to a very strong emotional and psychological stress.

This situation had relevant repercussions on daily life of families, especially of children that have been deprived of their socialization and play spaces. The parents suddenly became the only point of reference for their children since the other references and educational figures were no longer available.

As enlightened by the World Health Organization (WHO, 2020a,b), this situation could have long-term negative consequences on psychological well-being and there is a need to invest in mental health services and other services. A recent review stressed how people all over the world can show many different psychological disorder symptoms related to the pandemic (Shahyad and Mohammadi, 2020). The WHO (2020a) highlighted that children were also showing signs of mental illness. In fact, both international and domestic studies showed that, during the lockdown, children exhibited several problems, such as anxiety and emotional and behavioral disorders (Jiao et al., 2020; Spinelli et al., 2020; Xie et al., 2020).

The European Pediatric Association–Union of National European Pediatric Societies and Associations (EPAUNEPSA; Jiao et al., 2020) has stressed the importance to address children's psychological needs during the pandemic due to the negative repercussions on their psychological well-being, highlighting the relevant protective role of parents in decreasing their fear and stress. Research on psychological consequences of traumatic events, such as the terroristic attack of September 11, 2001, showed how children can also experience long-term effects on psychological well-being, reporting mental disorders after 6 months (Hoven et al., 2005).

All these data highlight the importance of not underestimating the psychological risks that children and their families could face. In a report on May 13th, 2020, the United Nations also underlined how, during the COVID-19 pandemic, the emotional problems of children and adolescents were exacerbated by family stress, social isolation, interruption of school and educational activity, and uncertainty for the future which occurred in critical moments of their emotional development (United Nations, 2020). Understanding how to strengthen parents and families in this situation, with the aim to protect children, represents an important goal that researchers should have in this period because it is possible that other future pandemics will affect humanity (Cluver et al., 2020).

The limited research conducted to date on the effects of the COVID-19 pandemic on well-being of parents and their children both in China and in Italy showed that COVID-19 related risks, such as (a) living in a red zone (i.e., a high-risk zone like Lombardia and Veneto for Italy), (b) being a parent positive to SARS-COV-2, (c) having relatives or friends positive to the SARS-COV-2 or who died from the SARS-COV-2, and (d) living in a high-risk environment (i.e., not having an open space in the home during the lockdown, losing a job during the pandemic, having a low income, not having internet connection), did not have strong negative direct effects on families' well-being (Spinelli et al., 2020) or on children's symptoms and problematic behaviors *per se* (Jiao et al., 2020). Actually, the research conducted by Spinelli et al. (2020) in Italy showed that it was the parenting stress related to the health emergency, the pandemic, and the lockdown that increased children's psychological, emotional, and behavioral problems. In line with these findings, Wang et al. (2020) suggested the need to deeply understand the family functioning and processes that can promote children's psychological well-being during the pandemic.

For this reason, this study focused on identifying which parental psychological variables can mediate the relationship between parents' psychological distress during the pandemic and the lockdown and their children's emotional regulation, in order to understand which possible intervention should be implemented to ameliorate families' well-being. Two recent meta-analyses highlighted the relevant role that the parent–child relationship can have in promoting children's effortful self-regulation (Pallini et al., 2018) and in decreasing children's behavioral problems, specifically attention problems (Pallini et al., 2019).

The stress of quarantine can affect psychological well-being of adults, as confirmed in a recent review (Brooks et al., 2020), and might also have long-term effects (Liu et al., 2012). A study conducted on parents and children quarantined in 2009 during the H1N1 influenza showed that the high-stressful isolation increased parents' psychological distress that in turn had an impact on their children's well-being (Sprang and Silman, 2013). Children who have parents with high levels of stress showed more externalizing problems and developed less emotion regulation (Deater-Deckard and Panneton, 2017).

As reported by Leary and Hoyle (2009), psychological distress upsets the ability to self-regulate (Tillema et al., 2001; Scott and Cervone, 2002) but regulatory emotional self-efficacy is crucial in the self-regulation of relationships and behavior (Bandura et al., 2003). According to Bandura (1997), psychological distress, such as lack of social support or parental depression, can affect parenting self-efficacy, which is the belief that parents have to be able to manage their parental tasks successfully and that it is, in turn, related to children's adjustment (Jones and Prinz, 2005).

Some previous studies showed that the relationship between parental mental health and children's emotional and behavioral well-being is mediated by positive parenting strategies (Giallo et al., 2014). According to Eisenèberg et al. (2005), parents'

positivity and warmth can promote effortful control in children, reducing their externalizing behaviors. Likewise, self-efficacy, specifically parenting self-efficacy, can function as a mediator between environmental variables or psychological conditions related to an external situation (e.g., the stress related to the pandemic) and parenting competence. In fact, environmental aspects might also indirectly affect parents' belief to be competent in managing parental tasks, and this could lead to less psychological well-being of the children (Jones and Prinz, 2005). For this reason, it is important that parents have a good parenting self-efficacy in order to display positive parenting strategies that can foster adaptive functioning and emotion regulation in children (Stack et al., 2010).

Aims and Hypotheses

Within the theoretical framework of Social Cognitive Theory (Bandura, 1997), the present study aimed to investigate a path model in which parenting self-efficacy and parents' regulatory emotional self-efficacy (related to COVID-19 lockdown) mediated the relationship between parents' psychological distress and both children's emotional regulation, and children's lability/negativity, in line with a previous study that stressed how parenting self-efficacy can mediate the relationship between parents' psychological distress and children's adjustment (Giallo et al., 2014). Additionally, in our model parents' psychological distress was also predicted by being exposed to several risks related to COVID-19 quarantine and the pandemic.

Moreover, the second aim was to assess whether children's biological sex, children's age, and geographical area (Northern Italy, which is the most at-risk area for the spread of the pandemic and for the risk of contagion, vs. the rest of Italy) moderated the structural paths of the model. There is evidence that children's biological sex can affect parents' way to respond to children (Sanders and Morawska, 2018) and that parenting self-efficacy can change over time (Deater-Deckard and Panneton, 2017), growing during early childhood (Weaver et al., 2008), and decreasing when children become adolescents (Glatz and Buchanan, 2015). Conversely, we did not expect to find any differences regarding living (or not living) in a high at-risk zone for the COVID-19 (i.e., Northern Italy), as found by recent Italian and Chinese studies (Jiao et al., 2020; Spinelli et al., 2020).

MATERIALS AND METHODS

Participants

The present study was conducted in Italy, via an online survey, during April 2020 when there was a lockdown related to the health emergency due to the COVID-19 pandemic. Specifically, Italian parents with a child aged between 6 and 13 years were recruited through a snowball sampling procedure to complete the online survey. At the time of data collection, Italy had been in quarantine for more than 1 month. A link to the survey was shared among parents using different social networks (e.g., Facebook, WhatsApp), also asking parents to share the link among their contacts. Overall, 417 parents have had access to the survey, and a total of 277 valid questionnaires were used in the present investigation, yielding a response rate of 66.4%. Parents' age ranged from 30 to 58 years old (M_{age} = 43.36, SD_{age} = 4.76) and the recruited sample mostly consisted of mothers (n = 248; 89.5%). As abovementioned, children were aged between 6 and 13 years (M_{age} = 9.66, SD_{age} = 2.29) and were almost equally distributed for biological sex (48% were boys and 52% were girls). Parents' socioeconomic status (SES) was predominantly medium-high (92.1%; n = 255). 14.1% (n = 39) lived alone at home with children during the quarantine. 62% (n = 171) of parents were from northern Italy, the Italian area most affected by the pandemic, and 37.9% (n = 105) were from Central and Southern Italy which were areas less affected by the pandemic (although they were also put in lockdown). Regarding their work situation, 195 parents (70.4%) continued to work and earn as before the quarantine, while 82 parents (29.6%) lost their works or have had wage reductions or layoffs. 7.9% (n = 22) were health workers and 5.8% (n = 16) were health workers in a hospital department that treated SARS-COV-2-positive patients. 91.7% of parents (n = 254) did not have any relative tested positive for the SARS-COV-2, and 8.3% (n = 23) had at least one relative that tested positive for the SARS-COV-2. 96.8% (n = 268) have not-hospitalized relatives due to SARS-COV-2, and 3.2% (n = 9) have at least one hospitalized relative. Finally, 32.5% of parents (n = 90) did not have any acquaintance or a loved one that tested positive to SARS-COV-2, and 67.5% (n = 187) had at least one acquaintance or a loved one that tested positive for SARS-COV-2. Each parent gave his/her consent by clicking "Yes, I accept to participate in the study" on the first page of the survey. This study was approved by the Ethics Committee of Sapienza University of Rome, Department of Developmental and Social Psychology, protocol number: 427, April 16, 2020.

Two power analyses were conducted to determine the recommended minimum sample size: (1) for detecting a significant bivariate effect and (2) for conducting a structural equation model (SEM; Cohen, 1988). A moderate effect size of 0.25 was anticipated with a power level set at 0.80 and a significant alpha level set at 0.05. The minimum sample size necessary to detect a significant bivariate effect was N = 124. Regarding the SEM, with five latent and fifteen observed variables, using the software developed by Soper (2020), results indicated that the required minimum sample size to run a SEM and detect a significant effect was N = 229.

Measures

COVID Risk Index

Using a similar procedure as used by Spinelli et al. (2020), we created an *ad hoc* index that assessed risks related to the COVID-19 pandemic. Specifically, a composite index was created given one point for each of the following risk factors, if present: (a) relatives that tested positive for SARS-COV-2, (b) friends or acquaintances that tested positive for SARS-COV-2, (c) hospitalized relatives due to SARS-COV-2, (d) living in northern Italy, which was the most at-risk area for the spread of the pandemic and for the risk of contagion, (e) being a health worker, and (f) being a health worker in hospital departments that treated SARS-COV-2 positive patients.

Family Risk Index

Again, using a similar procedure as used by Spinelli et al. (2020), we created an *ad hoc* index that assessed risks related to family situation during the quarantine and the pandemic. Specifically, a composite index was created given one point for each of the following risk factors if present: (a) a lower SES, (b) a worsened working situation during the quarantine, and (c) being a single or divorced parent who had to manage her/his own children at home alone during the quarantine. Both the family risk index and the COVID risk index are intended as summative rating scales that were created *ad hoc* for this research.

Parents' Psychological Distress

Parents' psychological distress during the lockdown was evaluated using the Perceived Stress Scale (Cohen et al., 1983; Italian validation by Mondo et al., 2019). Parents were asked to think about the last month. The scale is composed of 10 items that parents rated on 5 point-Likert scales from 1 (*never*) to 5 (*very often*). An example item is "During last month how do you usually feel nervous and stressed?" The scale showed a good reliability and validity also in the Italian validation (Mondo et al., 2019). In the present sample, the measure showed a good reliability, Cronbach's alpha of 0.84.

Parents' Regulatory Emotional Self-Efficacy

The Regulatory Emotional Self-Efficacy Scale (Caprara et al., 2013b) is a 13-item scale that evaluates the belief of parents to be able to manage with their negative emotions (i.e., anger, sadness, fear, and guilt) during the COVID-19 lockdown on a 5 point-Likert scale from 1 (*Not able*) to 5 (*Able*). The scale was modified asking parents to think about the quarantine period related to COVID-19 health emergency, and the following item was added to the scale "How do you feel able to manage the anxiety caused by hearing the news about coronavirus that is given on TV or that you read on the internet?" The scale showed good validity and reliability (Caprara et al., 2013a,b). In the present sample, the scale showed a good reliability: Cronbach's alpha of 0.87.

Parenting Self-Efficacy

Parents completed the Parenting Self-Agency Measures (Dumka et al., 1996; Baiocco et al., 2017) which is an 8-item scale that evaluates the belief of parents to be able to manage with daily parental demands (i.e., feeling to be a good parent, working to face and solve difficulties with their children) during the month of lockdown on 7-point Likert scales from 1 (*seldom*) to 7 (*always*). The scale was modified, asking parents to think about the quarantine period related to COVID-19 health emergency, and three items were added to the original scale. These three items asked parents how they feel able to reassure their children about the health emergency, to organize their children's daily life during the quarantine, and to explain to their children what is happening. The scale showed good validity and reliability (Baiocco et al., 2017, 2018). In the present sample, the scale showed a good reliability: Cronbach's alpha of 0.87.

Children's Emotion Regulation

Parents were asked to think about their child during the quarantine and to complete a short version of the Emotion Regulation Checklist (Molina et al., 2014). This is a 10-item scale that evaluates two sub-dimensions, namely, emotional regulation (i.e., positive emotions, being able to give voice to his/her negative emotions) and lability/negativity (i.e., anger, disruptive behaviors, excessive exuberance) of children during the COVID-19 lockdown on a 4 point-Likert scale from 1 (*Almost never*) to 4 (*Almost always*). The scale showed good validity and reliability (Molina et al., 2014; Di Maggio et al., 2016). In the present sample, both emotional regulation and lability/negativity scores showed acceptable reliability, respectively Cronbach's alpha of 0.65 and 0.78.

Data Analysis

Firstly, bivariate correlations among variables were calculated along with descriptives. Afterward, a mediation analysis with latent variables was performed via SEM, employing a parceling strategy (e.g., Bagozzi and Heatherton, 1994; Little et al., 2002). A parcel represents an aggregate of different items measuring a specific construct (Little et al., 2002; Coffman and MacCallum, 2005). Two or three parcels were constructed for each of the latent variables using the "item-to-construct" balance approach (Little et al., 2002), which means building each parcel by examining the item–construct relationships as represented by factor loadings in the item-level factor analyses (for a detailed description of this procedure, see Little et al., 2002). In such a way, parcels typically contained a balanced number of items and had comparable reliabilities. Therefore, our model comprised three latent variables with three parcels each and two latent variables with two parcels each. Summative indexes (such as the CRI and FRI) were treated as manifest variables.

Model fit was evaluated with the following indices: (a) the Comparative Fit Index (CFI); (b) the Tucker–Lewis index (TLI); (c) the root mean squared error of approximation (RMSEA); (d) and the standardized root mean square residual (SRMR). In general, for TLI and CFI, values between 0.90 and 0.95 are considered acceptable (e.g., Bollen, 1989; Byrne, 1994; Marsh et al., 2004) and values above 0.95 are deemed to be very good (Hu and Bentler, 1999). On the other hand, RMSEA and SRMR values smaller than (or equal to) 0.08 indicate a good fit (e.g., Bollen, 1989; Browne and Cudeck, 1993; Hu and Bentler, 1999; Marsh et al., 2004).

In order to evaluate the statistical significance of indirect effects, which represented the "mediated" effects, the bootstrapping procedure was used employing 5000 samples with replacement from the full sample to construct bias-corrected 95 percent confidence intervals (CI) (Preacher and Hayes, 2008; Hayes, 2009). Mediation typically occurs if the indirect effect is significant, that is, the zero value is not included in the CI (Preacher and Hayes, 2008; Hayes, 2009).

Finally, to test possible moderation effects of children's biological sex and age, and living in a geographical area with high COVID-19 risk, a multigroup approach within SEM was employed as suggested by Baron and Kenny (1986). In this procedure, the invariance of the structural parameters of the proposed model was tested separately for (a) boys and girls; (b) different levels of children's age; (c) geographical residential area, that is, living (vs. not living) in Northern Italy. A detailed

description of the procedure will be given in the "Results" section (see also Sauer and Dick, 1993; Cattelino et al., 2019). All analyses were run with statistical software SPSS 25 and MPLUS 8.3.

RESULTS

Correlations Among Variables

The family risk index was positively related with parents' psychological distress and positively with lability/negativity. Parents' psychological distress was negatively related with parenting self-efficacy, parents' regulatory emotion self-efficacy, and children's emotion regulation and was positively related with children's lability/negativity. Parenting self-efficacy was positively related with parents' regulatory emotion self-efficacy, and children's emotion regulation, and was negatively related with children's lability/negativity. Parents' regulatory emotion self-efficacy was positively related with children's emotion regulation and negatively related with children's lability/negativity. Finally, children's emotion regulation was negatively related with children's lability/negativity. Correlations, means, and standard deviations are reported in **Table 1**.

Mediation Model

A SEM was employed to test the hypothesized mediation model in which parenting self-efficacy and parents' regulatory emotional self-efficacy (related to the COVID-19 lockdown) mediated the relationship between parents' psychological distress and both children's emotional regulation and children's lability/negativity. Moreover, parenting self-efficacy mediated the relationship between parents' regulatory emotional self-efficacy and both children's emotional regulation and children's lability/negativity.

In the present paper, the mediation analysis strategy recommended by James et al. (2006) was followed. In the first step, the mediation model was tested (i.e., model without the direct effects, indicated with M_{med}). In the second step, a full model, including all the direct effects, was tested (indicated with M_{full}). The two nested models were compared via the chi-square difference test, contrasting M_{med} with M_{full} ($\Delta\chi^2$, Satorra and Bentler, 2001). A non-significant $\Delta\chi^2$ would reveal that the full model does not significantly increase the fit and therefore the mediation model is to be preferred since it is more parsimonious.

The mediation model (M_{med}) showed an overall good fit, chi-square (83) = 140.40, $p < 0.01$, RMSEA = 0.05, CFI = 0.97, TLI = 0.96, SRMR = 0.04. The full model including direct effects (M_{full}) did not apparently improve the model fit, chi-square (79) = 134.52, $p < 0.001$, RMSEA = 0.05, CFI = 0.97, TLI = 0.96, SRMR = 0.04. In fact, the two models were contrasted, and the chi-square difference test was not significant, $\Delta\chi^2$ (4) = 5.88, $p = 0.20$. Therefore, the mediation model (M_{med}) should be preferred due to being more parsimonious compared to the full model.

In **Figure 1, all measurement** and **structural** parameters of the mediated model (M_{med}) are reported.

Parents' psychological distress (ppd) was significantly, although modestly, affected by both COVID and family risk indexes. In turn, parents' psychological distress significantly and negatively affected both parents' regulatory emotional self-efficacy (pser) and parenting self-efficacy (pse). Parents' regulatory emotional self-efficacy significantly and positively affected parenting self-efficacy. Finally, parenting self-efficacy positively and significantly influenced children's emotional regulation (er_c) and negatively children's lability/negativity (ln_c). More importantly, parenting self-efficacy mediated the effect of parents' psychological distress and parents' regulatory emotional self-efficacy on both children's emotional regulation and children's lability/negativity. With the exception of those involving the COVID and family risk indexes, all other indirect effects were statistically significant, supporting the mediated model (see **Table 2**). In **Table 2**, a full decomposition of total and specific indirect of the mediated model (M_{med}) are reported. The COVID and family risk indexes displayed no significant effects on the other variables except for the aforementioned influence on parents' psychological distress.

Moreover, referring to the full model (M_{full}), we also decomposed total, direct and indirect effects (see **Table 3**) with the aim to report the ratio of indirect to the direct effect and the proportion of mediated effect (MacKinnon et al., 1995).

In regard to the relationship between ppd and er_c, the ratio of indirect to the direct effect was 1.06 (−0.18/−0.17 = 1.06), while with respect to the relationship between ppd and ln_c the ratio was 0.64 (0.09/0.14 = 0.64). In regard to the relationship between ppd and er_c, about the 51.42% of the effect was mediated (−0.18/−0.35 = 0.5142), while with respect to the relationship

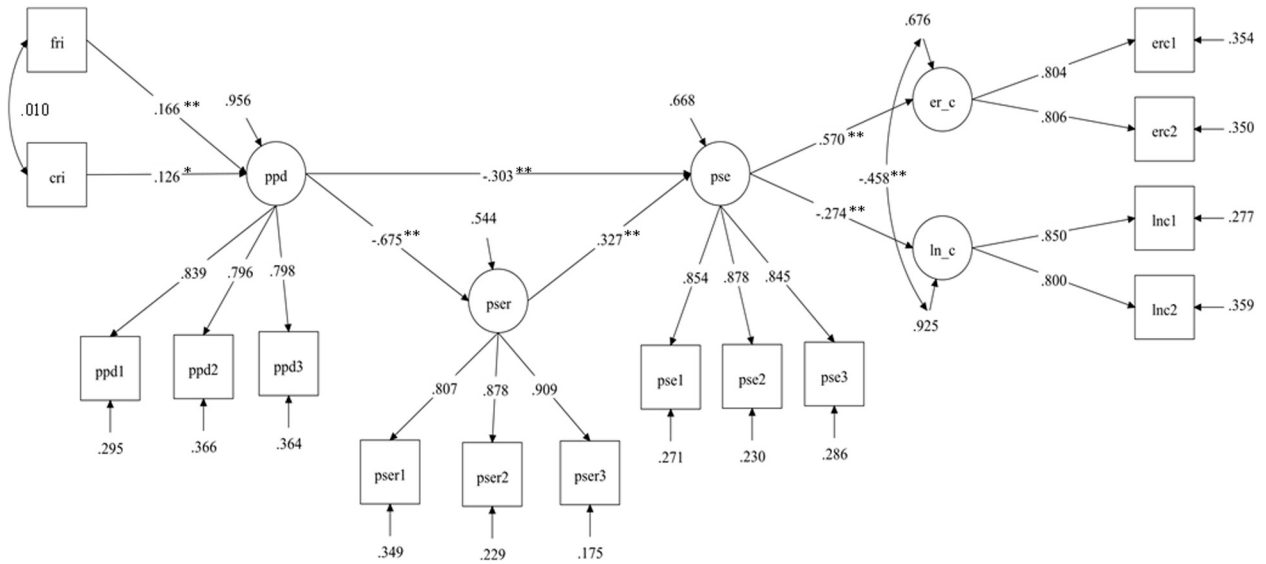

FIGURE 1 | Multivariate mediation model with structural equation modeling. Standardized coefficients are reported. Fri, family risk index; Cri, COVID risk index; ppd, parents' psychological distress; pser, parents' regulatory emotional self-efficacy; pse, parenting self-efficacy; er_c, emotional regulation of children; ln_c, lability/negativity of children. All measurement parameters were statistically significant for $p < 0.01$. Fit Indexes Chi-square (83) = 140.40, $p < 0.01$, RMSEA = 05, CFI = 0.97, TLI = 0.96, SRMR = 0.04. *$p < 0.05$; **$p < 0.01$.

between ppd and ln_c about the 39.13% of the effect was mediated (0.09/0.23 = 0.3913).

In regard to the relationship between pser and er_c, the ratio of indirect to the direct effect was −1.11 (0.20/−0.18 = −1.11), while with respect to the relationship between pser and ln_c the ratio was −3.5 (−0.07/0.02 = −3.5). More problematic was to estimate, in the same fashion, the amount of mediated effect regarding the relationship between pser with both er_c and ln_c since in those cases the indirect and the direct effects have opposite signs (as can be seen in **Table 3**), and therefore, they tend to suppress each other, resulting in a reduced non-significant total effect (pser er_c:0.02 = −0.18 + 0.20; pser ln_c: −0.05 = −0.07 + 0.02). With respect to non-significant total effect, scholars have pointed out that mediation can occur also in the absence of a detectable total effect if the indirect effect is significant (e.g., MacKinnon, 2008; Hayes, 2009). This is apparently the case. In this perspective, although it cannot be absolutely claimed that effects were totally mediated and despite the presence of null total effects, it is worth to note that indirect effects were significant and that mediation has occurred.

Overall, we can conclude that the hypothesized mediation model (M_{med}), reported in **Figure 1**, is consistent with the data.

TABLE 2 | Decomposition of indirect effects of the mediated model.

	Effect	SE	Bootstrap 95% CI
total indirect effect: ppd er_c	−0.30	0.05	[−0.39, −0.20]
specific indirect effect: ppd pse er_c	−0.17	0.06	[−0.29, −0.07]
specific indirect effect: ppd pser pse er_c	−0.13	0.04	[−0.20, −0.05]
total indirect effect: ppd ln_c	0.14	0.04	[0.06, 0.23]
specific indirect effect: ppd pse ln_c	0.08	0.03	[0.02, 0.16]
specific indirect effect: ppd pser pse ln_c	0.06	0.03	[0.02, 0.12]
indirect effect: pser pse er_c	0.19	0.06	[0.07, 0.29]
indirect effect: pser pse ln_c	−0.09	0.04	[−0.17, −0.02]

All effects are standardized coefficients. If the zero value is not included in the bootstrap 95% CI, the effect is significant at p < 0.05. ppd, parents' psychological distress; pser, parents' regulatory emotional self-efficacy; pse, parenting self-efficacy; er_c, emotion regulation of children; ln_c, lability/negativity of children.

TABLE 3 | Decomposition of total, direct, and indirect effects in the full model.

	Effect	SE	Bootstrap 95% CI
ppd er_c			
total effect	−0.35	0.08	[−0.50, −0.17]
direct effect	−0.17	0.07	[−0.37, 0.02]
indirect effect	−0.18	0.10	[−0.32, −0.02]
ppd ln_c			
total effect	0.23	0.08	[0.07, 0.37]
direct effect	0.14	0.07	[−0.07, 0.37]
indirect effect	0.09	0.04	[0.009, 0.20]
pser er_c			
total effect	0.02	0.11	[−0.22, 0.23]
direct effect	−0.18	0.10	[−0.38, 0.01]
indirect effect	0.20	0.06	[0.07, 0.33]
pser ln_c			
total effect	−0.05	0.10	[−0.23, 0.15]
direct effect	0.02	0.10	[−0.17, 0.24]
indirect effect	−0.07	0.04	[−0.17, −0.003]

All effects are standardized coefficients. If the zero value is not included in the bootstrap 95% CI, the effect is significant at p < 0.05. ppd, parents' psychological distress; pser, parents' regulatory emotional self-efficacy; er_c, emotion regulation of children; ln_c, lability/negativity of children.

Moreover, the mediation did not fit significantly worse than the full model (M_{full}) and therefore it was retained since it is more parsimonious (James et al., 2006). Additionally, all indirect effects of the mediated model (M_{med}) were significant, indicating that mediation has occurred (e.g., Preacher and Hayes, 2008; Hayes, 2009).

Multigroup Analysis

Within SEM, the test for a moderator effect can be performed using a multigroup analysis of the model in which the structural parameters are constrained equal across groups. Firstly, the structural parameters are freely estimated across groups to test for the baseline model. Secondly, the structural parameters are constrained to be equal across groups to test for the invariant model. In order to compare the fit of the two models, the chi-square difference test was used (Satorra and Bentler, 2001). A non-significant chi-square indicates that the parameters cannot be ruled out to be equal, then the invariant model should be retained and no moderation occurs. Instead, if the chi-square difference between the invariant and the baseline models is significant, which would mean that the invariant model fits significantly worse. Therefore, parameters are not equal across the groups and there is a moderation effect. Results of chi-square difference tests of multigroup analyses with SEM are reported in **Table 4**.

Regarding children's biological sex, the fit of the baseline model was chi-square (134) = 185.88, $p < 0.01$, RMSEA = 0.05, CFI = 0.97, TLI = 0.97, SRMR = 0.07, whereas the fit of the invariant model was chi-square (139) = 187.98, $p < 0.01$, RMSEA = 0.05, CFI = 0.98, TLI = 0.97, SRMR = 0.08. The chi-square difference test was not significant showing that the invariant model could not be rejected (**Table 4**). This finding suggests that biological sex of the children was not a moderator variable.

In regard to children's age (6–10 y.o. vs. 11–13 y.o.), the fit of the baseline model was chi-square (134) = 169.55, $p < 0.01$, RMSEA = 0.04, CFI = 0.98, TLI = 0.98, SRMR = 0.06; conversely, the fit of the invariant model was chi-square (139) = 179.32, $p < 0.01$, RMSEA = 0.05, CFI = 0.98, TLI = 0.98, SRMR = 0.07. The chi-square difference test was not significant showing that the invariant model could not be rejected (**Table 4**). Therefore, children's age did not appear to moderate the mediational effects tested in our model.

Finally, turning to geographical area (Northern Italy vs. rest of Italy), the fit of the baseline model was chi-square (134) = 172.56, $p < 0.01$, RMSEA = 0.05, CFI = 0.98, TLI = 0.98, SRMR = 0.06. Instead, the fit of the invariant model was chi-square (139) = 182.53, $p < 0.01$, RMSEA = 0.05, CFI = 0.98, TLI = 0.98, SRMR = 0.09. The chi-square difference test was not significant, showing that the invariant model did not fit significantly worse and therefore could not be rejected (**Table 4**). This result suggested that living in a high at-risk area for COVID-19, as it was Northern Italy at the time of data collection, did not significantly affect the structural parameter of our hypothesized model.

DISCUSSION

The health emergency related to the COVID-19 pandemic and the consequent restrictive measures of quarantine have upset our lifestyles and our daily life. In particular, families with children had to face an unprecedented and completely new situation in which parents suddenly remained the only reference point for their children. Results of the present study, indeed, showed that the COVID risk index and the family risk index partially contributed to the psychological distress of parents, although their impact was modest in terms of accounted variance. Specifically, parents with higher levels of psychological distress tendentially had a lower SES, had seen their working situation worsened during the quarantine, and were single or divorced parents who had to manage their children at home alone during the quarantine. Furthermore, regarding the COVID-19 risk index, parents with more psychological distress more likely had relatives, friends, or acquaintances tested positive for the SARS-COV-2, had hospitalized relatives because of the SARS-COV-2, lived in northern Italy which was the most at-risk area for the spread of the pandemic and for the risk of contagion, were health workers, and worked in hospital departments that treated SARS-COV-2-positive patients.

However, our SEM showed that parents' psychological distress impacted on the emotional regulation and lability/negativity of their children passing through the mediators' effect of parenting self-efficacy and parents' regulatory emotion self-efficacy. These findings suggested that what could have a positive effect on children's well-being and positive emotional regulation was not just being exposed to low level of parents' psychological stress, but it was the fact that parents felt able to manage and carry out their parental role and the related tasks. Our results suggest that self-confident parents can successfully activate many personal resources that in turn seem to prevent their children's emotional dysregulation, even in emergency situations such as the pandemic that increased their levels of psychological distress.

Furthermore, three multigroup analyses were performed to test the possible moderation effects of children's biological sex and age and of geographical area (i.e., living or not living in Northern Italy, which is the most at-risk area for the spread of the pandemic and for the risk of contagion). The multigroup analyses showed that the hypothesized model was robust and invariant across children's biological sex, and age, and living (or not living) in Northern Italy. Thus, in line with Spinelli et al. (2020), parents' and children's psychological distress was not affected by living in the high at-risk zone for COVID-19 (vs. not living in the high at-risk zone). We can speculate that, regardless of living in a more risky area, relationships among variables remained stable because this unprecedented situation characterized by the isolation and quarantine measures was perceived in the same way throughout Italy. Alternatively, it is also possible that our study did not have enough power to detect differences in parameters between groups.

Parents should be supported to improve their strengths and to feel able to manage their parental role and their emotions. During the quarantine, parents were the unique reference point for their children aged between 6 and 13 years who rely much on

TABLE 4 | Multigroup analyses for children's biological sex and age.

	χ^2	*p*	χ^2_{diff}
Children's biological sex (Boys vs. Girls)

Model 1: Baseline, Parameter Freely Estimated	$\chi^2(134) = 172.56$	<0.01	
Model 2: Invariant, Structural Parameter Constrained Equal	$\chi^2(139) = 182.53$	<0.01	
			χ^2_{diff} (5) = 9.97; $p = 0.08$

their parents in this life stage. It is important that parents know that they can protect their children, preventing their emotional dysregulation, using their strengths and self-confidence, even if they are experiencing fear and severe stress for the health emergency. Moreover, even if parents are exposed to high levels of stress, they can still promote a positive emotional functioning in their children if they feel able to reassure their children about the health emergency, to organize their children's daily life during the quarantine, and to explain them what is happening.

Despite these important findings, this study had some limitations. We collected a convenience sample that was not representative of the Italian population. Moreover, emotion regulation and lability/negativity of children were reported by parents and this could be less informative. However, many other scholars have used this type of data collection which is very common in this kind of studies (e.g., Trumello et al., 2018; Spinelli et al., 2020). Moreover, our data are correlational and it is also conceivable that parental distress and self-efficacy could be affected by children's lack of emotion regulation and lability/negativity. Furthermore, we assessed the parent's own judgment of their children's well-being and it is possible that parents who experience (according to themselves) a lot of distress also tend to judge their children's well-being more negatively irrespective of the children's actual well-being. Finally, it is not possible to infer causal relationships among variables because of the correlational nature of data. Future longitudinal study can be conducted in order to deeply test the possible long-term effects of parents' psychological distress related to the health emergency on their children's psychological well-being and the possible reverse causation effect.

However, despite these limitations, the present study presents many implications for prevention and intervention programs. In order to prevent children's distress, intervention programs should start from family and parents. This programs should be aimed at increasing parents' regulatory emotional self-efficacy and parenting self-efficacy, by activating their adaptive strategies and resources to deal with daily tasks and reinforcing their strengths. These parents' skills could be taught and learned, representing an important resource even in emergency situations such as a pandemic, in which parents remain the only points of reference and education for their children. These prevention programs should be primarily addressed at (but not limited to) parents who are health workers, who lived alone with children during the quarantine, who have sick relatives, and who have a low SES and a worsened work situation, in order to prevent the impact of their psychological distress on their children, reinforcing their belief to be able to face this difficult situation and to manage both their parents tasks and their unavoidable negative emotions.

These findings suggest how clinicians should give psychological support to parents remotely during a lockdown, reinforcing their personal strengths and working on effective parenting and regulatory efficacy strategies. Indeed, parents with beliefs of self-efficacy in parenting behaviors and emotional regulation have children more emotionally regulated and psychologically healthy.

Likewise, the present results can be used to implement psychological and educational intervention for parents in order to prevent their children's psychological distress. These results can also give pediatricians and psychologists important indications on how to specifically support families during the quarantine due to a global pandemic, providing advice to parents who in this period turn to pediatricians or psychologists to understand what to do to improve the well-being of their children. Telling parents that, even if they experience negative emotions, they can do a lot to help their children could empower parents, activating their skills and strategies. Intervention programs should be aimed to explain parents how to communicate to their children what is happening in the world around them. Using the correct words is more probable when parents have high levels of parental self-efficacy and emotional regulation self-efficacy (Jones and Prinz, 2005), and this could be very useful for parents' and children's well-being. Talking about the fear and the negative emotions related to the pandemic and the isolation would represent an important protective factor for families' well-being. If parents understand which is the right way to communicate about the pandemic with their children, they can probably feel more self-confident in managing their parental tasks and their children's emotion, and this aspect can have in turn positive effects on their children's positive adjustment.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethics Committee of the Department of Developmental and Social Psychology, Sapienza University of Rome. Written informed consent was not provided because data were collected via an online survey and participants were recruited via a snowball sampling. Thus, participants gave their informed consent by clicking "Yes, I accept to participate to this study" on the first page of the online survey.

AUTHOR CONTRIBUTIONS

MM, AC, EC, and RB conceptualized the study and organized the data collection. MM, AC, EC, RB, CT, AB, and CC collected the data. AC and MM run the analyses and wrote the methodological and results section. MM wrote the first draft of the manuscript. EC, CT, AB, and CC contributed to revision of the final version of the manuscript. All authors contributed to the article and approved the submitted version.

During the outbreak of the coronavirus disease 2019 (COVID-19), the medical staff was facing severe work pressure, which led to a negative emotional state. The purpose of this study was to explore the relationship between the family environment and the emotional state of the medical staff members during the COVID-19 outbreak. Due to the importance of self-efficacy in regulating mental health, the mediating role of self-efficacy in the association between family environment and emotional state was also explored. A cross-sectional survey was performed, using an online questionnaire, on 645 medical staff who participated in the epidemic prevention and control tasks during the COVID-19 outbreak in Beijing. Family environment, self-efficacy, anxiety, and depressive symptoms were measured by the Family Environment Scale-Chinese Version (FES-CV), the General Self-Efficacy Scale (GSES), the Generalized Anxiety Disorder Scale-7 (GAD-7), and the Patient Health Questionnaire-9 (PHQ-9), respectively. Correlation analysis and mediating effect analysis were used to explore the relationships between them. First, a higher prevalence of anxiety (39%) and depressive (33%) symptoms were confirmed among the medical staff. Second, the symptoms of anxiety and depression were negatively correlated with the dimensions of cohesion and expressiveness and positively correlated with the dimensions of conflict in the FES-CV scale. Third, self-efficacy significantly mediated the association between the family environment and anxiety symptoms ($P < 0.001$) as well as the family environment and depressive symptoms ($P < 0.001$). These findings show that a negative family environment was the main predictor of symptoms of anxiety and depression in the medical staff during the COVID-19 outbreak. Furthermore, we found that self-efficacy played a critical mediating role between the family environment and the symptoms of anxiety and depression. Our study also indicates that improvements in the family environment benefit the mental health care of the medical staff, and high self-efficacy enhances this effect.

INTRODUCTION

The outbreak of coronavirus disease 2019 (COVID-19) continues to attract worldwide attention (Wang et al., 2020). To date, COVID-19 cases have been confirmed in more than 200 countries around the world, and it has become a public health emergency of international concern. Many people who have directly faced this large-scale public crisis, especially the medical staff involved in the prevention and control of this epidemic, showed anxiety symptoms (Huang et al., 2020). They faced a high risk of getting infected at their workplace and the possibility of their family members at home getting infected through them (Xiang et al., 2020). Medical staff working in a high-pressure environment suffer from psychological problems, especially anxiety and depression (Kang et al., 2015; Wang et al., 2020). Although guidelines on the care of the mental health issues in medical staff have been issued in China (Kang et al., 2020), some of the staff refused to receive mental health care (Chen et al., 2020).

It has been reported that the incidence of anxiety and depression was high among the medical staff during the outbreak of COVID-19, with prevalence rates of anxiety and depressive symptoms being 44.6% and 50.4%, respectively (Lai et al., 2020). Due to the stigma around mental health problems in China (Bai et al., 2004), many members of the medical staff community were reluctant to accept professional psychological help (Chen et al., 2020). However, they preferred to seek help from their family members. Some medical staff was far away from their families because of the fear of infection, and they were reluctant to have close contact with them. Others were isolated and cannot return home for a long time (Raven et al., 2018). It has shown that family support is very important for medical staff involved in epidemic prevention (Mohindra et al., 2020). However, there has been no research on how family members can help medical professionals suffering from mental health issues and what kind of family environment can be useful in relieving negative emotions in these individuals during an epidemic. The family, which is the basic social unit, may affect the mental health of family members (Cheng et al., 2017). In Chinese culture, family relations are highly valued, and family is a very important support system (Poulin et al., 2012). It means that the importance of family is the core feature for most Chinese people. Previous studies have shown that the family environment can directly affect the emotions in family members, especially the dimension of cohesion (Harris and Zakowski, 2003; Burnett et al., 2017), expressiveness (Luebbe and Bell, 2014), and conflict (Yap et al., 2014; Yap and Jorm, 2015; Fosco et al., 2016). However, whether the family environment has an effect on the mental health of medical staff during the epidemic is still not clear.

Self-efficacy refers to an individual's judgment about his or her ability to complete a certain task successfully, and it reflects the self-confidence of an individual to cope with various difficulties and setbacks in life (Tang et al., 2019). Previous research has shown a positive correlation between the family environment and self-efficacy (Mahmoudi, 2012). Individuals with a better family environment were shown to be more likely to have higher levels of self-efficacy (Hemati et al., 2020). For example, individuals can freely communicate with family members, express more about themselves, and have a frequent high contact of intimacy with other family members, which will lead to a high level of self-efficacy (Hemati et al., 2020). Studies show that increasing self-efficacy is an essential aspect of the psychological intervention to protect the mental health of individuals (Caldwell et al., 2009). It seems that the higher the self-efficacy in an individual, the better the mental health (Sebastian, 2013; Jiang et al., 2020). High self-efficacy can improve an individual's mental health (Bandura, 2012). However, a low level of self-efficacy harms a person's psychological well-being (Cieslak et al., 2008; Sachs-Ericsson et al., 2011). Importantly, studies have shown that self-efficacy is one of the critical factors that modulate an individual's emotions, especially feelings of anxiety and depression (Bandura et al., 1982; Kanfer and Zeiss, 1983; Cybulski et al., 2017; Schönfeld et al., 2019). These studies suggested that higher levels of self-efficacy are associated with lower levels of feelings of anxiety and depression. During the outbreak of SARS, medical staff with low self-efficacy often had a higher fear of the epidemic, which was positively correlated with their poor mental health status (Ho et al., 2005). Self-efficacy can predict the significant difference in mental health during the epidemic. The lower the self-efficacy, the worse the mental health status (Yıldırım and Güler, 2020). It has been found that lower psychological stress among dentists during the COVID-19 epidemic is associated with being in a stable relationship and having a higher sense of self-efficacy (Shacham et al., 2020). It suggests that family relationships and self-efficacy during the epidemic may both affect the mental health of medical staff. The partial mediating role of self-efficacy in some psychological trait relationships has been supported by relevant research (Haj-Yahia et al., 2019). Indeed, it has been found that self-efficacy was a mediator for the association of daily stress and mental health (Schönfeld et al., 2019). However, there has been no study focusing on the relationship between family environment, self-efficacy, and the emotional state of medical professionals during an epidemic. The relationship between family environment, self-efficacy, and depression and anxiety, and whether the influence of family environment on anxiety and depression is regulated by self-efficacy needs to be further studied.

Therefore, the purpose of this study was to further explore the direct and indirect impact of the family environment on symptoms of anxiety and depression among the medical staff involved in controlling the epidemic. When examining the indirect effects, we took self-efficacy as an intermediary variable. Mediating effect analysis was performed to explore the role of self-efficacy in the relationship between family environment and symptoms of anxiety and depression. Based on our findings, we provide viable strategies for the family based psychological intervention of the medical staff during an epidemic that will help to improve our psychological crisis intervention system.

MATERIALS AND METHODS

Participants

This research was a cross-sectional study using the convenience sampling method to collect survey results through an online

questionnaire. The online survey was conducted in Beijing from February 28, 2020 to March 9, 2020. Inclusion criteria for the study were as follows: (1) Chinese, working in Beijing; (2) 18–65 years old; (3) medical staff including doctor or nurse involved in COVID-19 epidemic prevention and control; and (3) has read and agreed to the online informed consent. The protocol of this study was approved by the Ethics Committee of the Beijing Huilongguan Hospital.

Study Instruments

The Family Environment Scale-Chinese Version (FES-CV)

This scale was based on the Family Environment Scale (FES) developed by Moss (Moos and Moos, 1994), which was translated into Chinese by Wang et al. (Wang et al., 1999). The scale has 90 entries in total, including 10 dimensions (cohesion, expressiveness, conflict, independence, achievement orientation, intellectual-cultural orientation, active-recreational orientation, moral-religious emphasis, organization, and control), with nine entries for each dimension. Each entry has a true and false option. The higher the score of a particular dimension, the more prominent the characteristics of the family in that aspect. The scores of conflict and control were negatively correlated with the family environment, whereas others positively correlated with the family environment. This scale has been shown to have good structural, content, and external validity when applied to the Chinese population (Phillips et al., 1998). In this study, we selected three dimensions of this scale that were closely related to emotions investigated in previous studies: cohesion, expressiveness, and conflict (Harris and Zakowski, 2003; Burnett et al., 2017).

The General Self-Efficacy Scale (GSES)

This scale was developed by German psychologist Schwarzer (Schwarzer, 1995), which was translated and revised for the Chinese version by Wang et al. (Wang et al., 2001). The scale comprises of 10 items with four answer options, and the answer options range from 1 (not at all true) to 4 (completely true). Higher scores mean higher levels of self-efficacy; a score of 1.0–2.0 means low level, 2.1–3.0 means medium level, and 3.1–4.0 means a high level of self-efficacy. The revised scale has been shown to have excellent reliability and validity in the Chinese population (Wang et al., 2001). The Cronbach's alpha of this scale is 0.87, the retest reliability is 0.83, and the correlation coefficient between the 10 items and the total scale score is 0.60–0.771.

The Generalized Anxiety Disorder Scale-7 (GAD-7)

This scale was developed by Spitzer et al. (Spitzer et al., 2006). Previous research demonstrated that the Chinese version of GAD-7 has good reliability and validity, and the sensitivity and specificity of this version were 0.86 and 0.95, respectively (Huang et al., 2019). This scale is composed of seven items, and each item has a 0–3 points scale. The total score range is 0–21 points; 0–4 for no anxiety, 5–9 for mild anxiety, 10–14 for moderate anxiety, and more than 15 for severe anxiety.

The Patient Health Questionnaire-9 (PHQ-9)

The scale was developed based on the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (Kroenke et al., 2001). We used the Chinese version of this scale. This scale is composed of nine items, and each item has a 0–3 points scale. The symptom severity is determined by the total score, with 5–9 being mild, 10–14 being moderate, 15–19 being moderately severe, and 20–27 being severe. Cronbach's alpha of the PHQ-9 in the Chinese population is 0.86, and the retest reliability is 0.86, which indicates that this test has excellent reliability and validity (Wang et al., 2014).

Statistical Analysis

All of the analyses were performed using SPSS for Windows 23.0. We reported means and standard deviations for continuous variables showing normal distribution and frequencies and proportions for categorical variables. The original scores of the dimensions of conflict in FES-CV were not normally distributed and were presented as medians and quartiles. A chi-squared test was used to test the relationship between the demographic data of the participants and their anxiety and depressive symptoms. The study participants were grouped based on whether they showed/did not show anxiety or depressive symptoms. The inter-group comparison of the scores of FES-CV and GSES was carried out using the independent sample t-test and the independent sample Kruskal-Wallis test. Spearman correlations were calculated to determine the relationships between the scores of the various scales. We categorized the family environment (cohesion, expressiveness, and conflict) as an independent variable, anxiety and depression symptoms as dependent variables, and self-efficacy as an intermediary variable. After controlling for demographic variables, the direct, indirect, and total effects of the family environment on the symptoms of anxiety and depression were examined. The mediation analysis was run on the PROCESS macro for SPSS (Preacher and Hayes, 2004), using 5,000 bootstrap samples for bias correction and to establish 95% confidence intervals. All of the tests were two-tailed, and the significance level was set at $p < 0.05$.

RESULTS

The medical staff involved in this study mainly includes two groups. One is the staff of the hospital involved in treating patients infected with COVID-19; the other is the staff at the isolation point, whose main task is nucleic acid testing and medical services for the quarantined personnel. A total of 653 medical staff members completed the online questionnaire, out of which six individuals did not complete the basic information, and two took more than 5 min to answer the questionnaire. Thus, 645 medical staff members participated in the study, of which 485 (75%) were women, and 160 (25%) were men, aged 21–65, with an average age of 35.88 ± 8.64. Most of the participants were under 40 (75%), had a bachelor's degree (61%), were married (73%), and were living with their families (83%). Among these participants, 251 (39%) had anxiety symptoms, and 215 (33%) had depressive symptoms. The symptoms of anxiety and

depression were closely related to the gender of the medical staff and whether they lived with their family members or not. The prevalence rate of anxiety and depression symptoms was higher in women ($X^2 = 9.25$, $p = 0.002$; $X^2 = 4.09$, $p = 0.043$) and in those who did not live with their families ($X^2 = 5.38$, $p = 0.02$; $X^2 = 4.35$, $p = 0.037$) (**Table 1**).

We divided the participants into two groups: one group with anxiety symptoms (GAD-7 score $>$ 4) and the other group without anxiety symptoms (GAD-7 score $\leq$ 4). We then investigated the significance of the differences in the scores of the two groups for the FES-CV and GSES scales. Next, the participants were divided into two groups according to whether they had depressive symptoms or not (depressive symptoms: PHQ-9 score $>$ 4; no depressive symptoms: PHQ-9 score $\leq$ 4). Like the anxiety symptoms, we investigated the significance of the difference between the scores of FES-CV and GSES scales in the two groups. The results, which show the significant differences among groups, are shown in **Table 2**.

Next, we used correlation analysis to determine the correlation between the scores of each scale. The results showed that there were statistically significant relationships between the anxiety and depressive symptoms of medical staff, their family environment, and their sense of self-efficacy. Anxiety and depressive symptoms showed a significant positive correlation with the dimension of conflict in FES-CV scale ($r = 0.29$, $p < 0.001$; $r = 0.25$, $p < 0.001$), and a significant negative correlation with the dimension of cohesion ($r = -0.31$, $p < 0.001$; $r = -0.38$, $p < 0.001$), expressiveness ($r = -0.23$, $p < 0.001$; $r = -0.30$, $p < 0.001$), and self-efficacy ($r = -0.25$, $p < 0.001$). More specifically, individuals with bad family environments and low self-efficacy were more likely to show symptoms of anxiety and depression. Besides, self-efficacy positively correlated with the dimension of cohesion and expressiveness and negatively associated with the dimension of conflict (**Table 3**).

After controlling for demographic variables, we examined the mediating effects of self-efficacy (**Figure 1**). Self-efficacy was significantly associated with the symptoms of anxiety and depression. It significantly mediated the association between the family environment and anxiety symptoms ($\beta = -0.12$; 95% CI, -0.19 to -0.06; $\beta = -0.10$; 95% CI, -0.16 to -0.05; and $\beta = 0.06$; 95% CI, 0.02 to 0.11). Similarly, it mediated the association between family environment and the depressive symptoms ($\beta = -0.09$; 95% CI, -0.16 to -0.03; $\beta = -0.08$; 95% CI, -0.14 to -0.03; and $\beta = 0.06$; 95% CI, 0.02 to 0.11). When controlling for self-efficacy, the association between the family environment and anxiety symptoms were still significant ($\beta = -0.62$, $p < 0.001$; $\beta = -0.52$, $p < 0.001$; and $\beta = 0.55$, $p < 0.001$) and similarly for family environment and depressive symptoms ($\beta = -0.87$, $p < 0.001$; $\beta = -0.84$, $p < 0.001$; $\beta = 0.55$, $p < 0.001$). Thus, self-efficacy partly mediated the relationship between the family environment and the symptoms of anxiety and depression.

DISCUSSION

In the current study, we conducted an online questionnaire survey of some medical staff involved in COVID-19 prevention and control in hospitals and isolation sites in Beijing. We found that a considerable proportion of medical professionals had anxiety (39%) and depressive symptoms (33%), as noted in previous studies (Huang et al., 2020; Lai et al., 2020). Moreover, our results showed that the family environment of medical staff and their symptoms of anxiety and depression during the epidemic were closely related to self-efficacy, and self-efficacy partly mediated the relationship between the family environment and the symptoms of anxiety and depression.

In this present study, we found that the self-efficacy of male medical staff was significantly higher than that of female medical staff ($t = 3.245$, $p = 0.001$). However, the symptoms of anxiety ($p < 0.001$) and depression ($p = 0.002$) during COVID-19 were significantly lower than that of female medical staff, which was consistent with previous research results. For example, it showed that female medical workers experience higher levels of anxiety, depression, and distress during COVID-19 (Lai et al., 2020). It also reported that the self-efficacy of male medical staff is significantly higher than that of female medical staff (Tang et al., 2019). It should also be noted that medical staff who did not live with their families were more likely to have symptoms of anxiety and depression during the epidemic. Thus, our study suggests that we should pay more attention to such medical staff and provide them psychological intervention. This observation also indicates that the family plays a certain role in regulating negative emotions. Furthermore, our study showed a close relationship between the family environment of the medical staff and their symptoms of anxiety and depression. The medical staff members with low cohesion and expressiveness, as well as high conflict in

the family environment, were more likely to show anxiety and depressive symptoms during the epidemic.

Notably, in this present study, the relationship between the family environment and the symptoms of anxiety and depression reveals that the family environment can, directly and indirectly, affect the emotions of medical staff during an epidemic. The family environment can significantly predict the emergence of anxiety and depressive symptoms directly, which is consistent with previous results. For example, some studies found that there was a correlation between cohesion in the family environment and depression in family members (Burnett et al., 2017); families with high cohesion, which have high levels of family support and ties, likely reduce depression (Park et al., 2018; Cano et al., 2020). In contrast, low family cohesion and conflict between parents increased the risk of depression and anxiety in family members (Park et al., 2018; Cano et al., 2020). In families with a high degree of cohesion, individuals can get more psychological help and emotional support within the family (Birgisdóttir et al., 2019), so that the psychological pressure can be appropriately relieved. Positive emotional expression within the family can prevent suppression of inner feelings and buffer internal conflicts, especially in the face of stressful events. In contrast, negative emotional expression and low emotional expression within the family are associated with higher anxiety and depression (Luebbe and Bell, 2014; Park et al., 2018). In a high-conflict family, family members are prone to conflict between each other, leading to anxiety. Therefore, the results in this study support the hypothesis that the family environment can influence the emotional state of the family members and that a negative family environment is a psychological risk factor for the rising emotional distress of the medical staff during an epidemic.

Additionally, the influence of the medical staff's family environment on their symptoms of anxiety and depression during the COVID-19 epidemic is partly through the role of self-efficacy, which means self-efficacy plays a critical role in mediating the effect of family environment on symptoms of anxiety and depression. Indeed, previous studies supported that self-efficacy had a protective effect on mental health (Bandura, 2012) and played a vital role in the regulation of stress (Bandura et al., 2003). High self-efficacy was related to better psychological adjustment (Bandura, 2012) and lower emotional distress (Benight and Harper, 2002). Individuals with high self-efficacy had positive expectations and beliefs, had successful experiences, generated positive emotions, and were more likely to seek psychological support to modulate their emotions when facing stressful situations (Tsang et al., 2012). A bad family environment can reduce an individual's self-confidence and ability (Hemati et al., 2020). Self-efficacy is the embodiment of such confidence and ability (Tang et al., 2019). That is to say, the family environment affects self-efficacy by affecting people's self-confidence and ability, thus affecting individuals' behavioral patterns and emotional responses to stress (Tsang et al., 2012). For example, a medical worker with a good family environment has confidence in the success of the fight against the epidemic and also believes that he is capable of doing his job, which will ease his fear of the epidemic and anxiety about the high-risk work of infection. Self-efficacy played a partial mediating role between the family environment and symptoms of anxiety and depression, indicating the existence of other variables between them. Future studies should, therefore, include other relevant variables that are likely involved in the relationship between the family environment and negative emotions. This

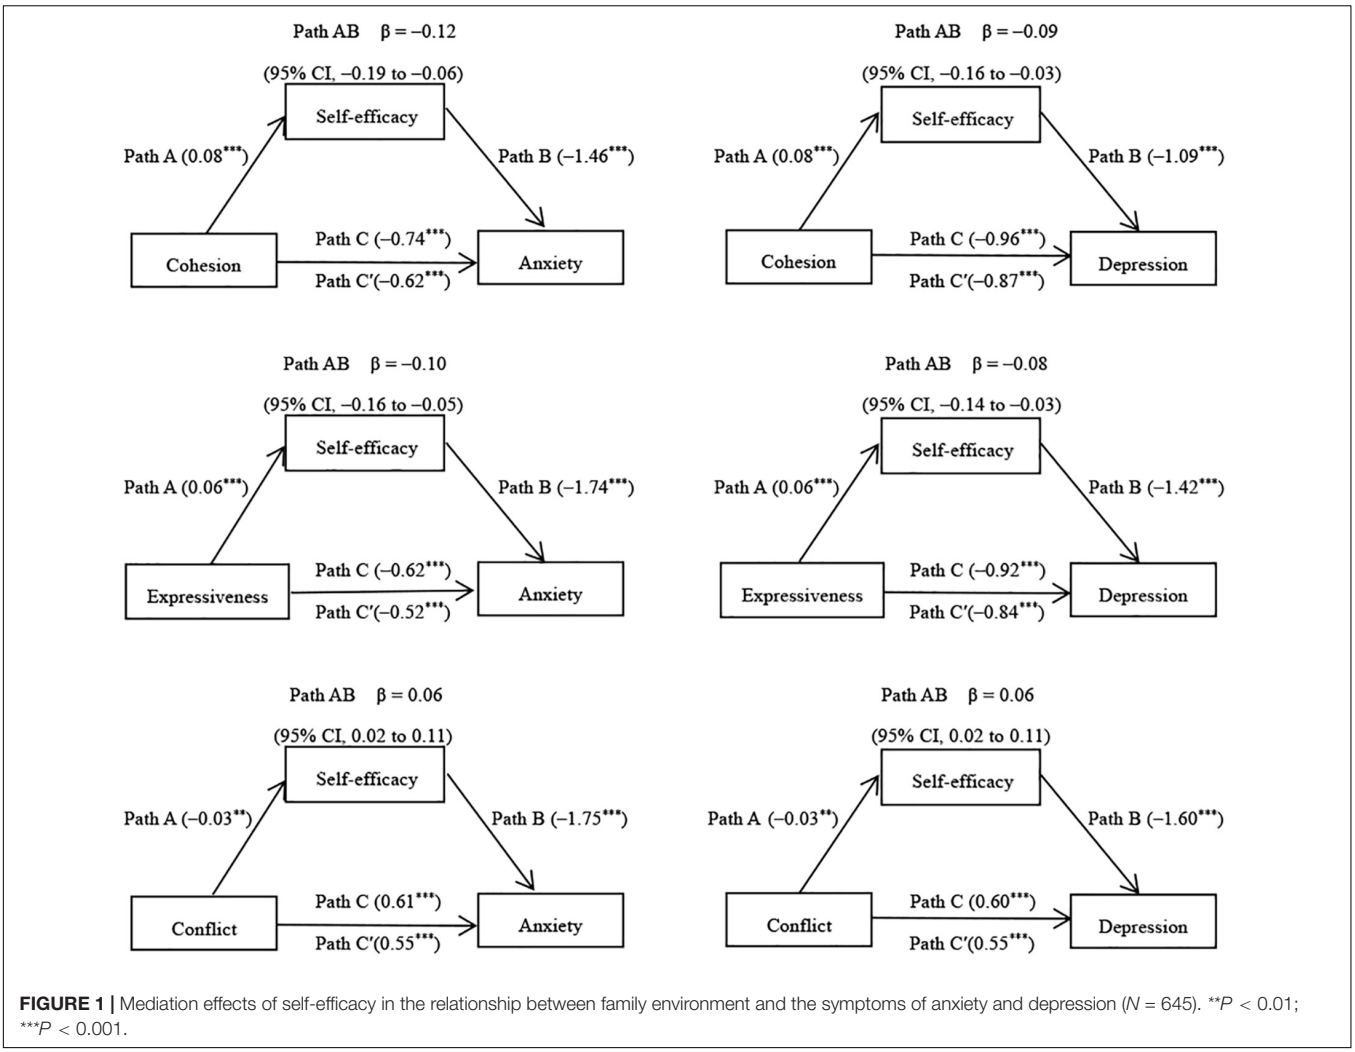

FIGURE 1 | Mediation effects of self-efficacy in the relationship between family environment and the symptoms of anxiety and depression ($N = 645$). $^{**}P < 0.01$; $^{***}P < 0.001$.

study indicates that adjusting self-efficacy is a meaningful way to regulate the anxiety and depressive symptoms of medical staff during an epidemic.

Because of the close correlation between the family environment and the symptoms of anxiety and depression of medical staff during an epidemic, we need to pay more attention to psychological assistance for medical staff from the perspective of their family situation. When providing psychological assistance to medical staff during the epidemic, we should not only focus on the medical staff but also care about their family members and family relations. By improving the family environment and increasing the active support of the family, their emotional problems can be effectively alleviated (Mohindra et al., 2020). The focus of the medical staff's treatment of family relations should be to enhance the intimacy between family members, increase their interaction, encourage them to talk to each other, resolve the family conflicts in time, and create a good family atmosphere. Based on the results of this study, we propose the following suggestions for medical staff. First, we suggest that medical staff should have time to communicate with their families and that they should be encouraged to share their feelings with family members and get their support and encouragement. For example, they should be encouraged to record their routines in the hospital and share them with their families (Chen et al., 2020). The hospital or isolation point shall provide relevant communication conditions and equipment for this purpose. Second, during the epidemic period, the staff of the relevant departments of the hospital should be aware of the difficulties existing in the family of medical staff, and they should guide these staff members and help them solve those problems to avoid family conflicts. Third, the family members of medical staff should be aware of the mental health issues of the staff member. Family safety plays the most important role in reducing the pressure of medical staff during the epidemic (Cai et al., 2020). Therefore, the staff members should stay connected with their families through WeChat, SMS, and other apps to understand their health status, which will help lessen the negative mental state of the medical staff during the COVID-19 pandemic outbreak. These Suggestions can bring medical staff closer to their families, have more emotional communication, and reduce family conflicts. With the implementation of these measures, the medical staff's sense of self-efficacy will also be improved.

Besides, our results suggest that improving self-efficacy will help to alleviate the anxiety and depressive symptoms of medical staff during the COVID-19 outbreak. Manipulating self-efficacy is an important way to prevent mental health problems when dealing with stress (Schönfeld et al., 2019). Previous studies have focused on the effects of self-efficacy on the mental health and work quality of medical staff (Amiri et al., 2019; Tang et al., 2019), and it suggested that necessary interventions should be implemented to improve the self-efficacy of medical staff. In the prevention and control of COVID-19, medical staff is faced with two main difficulties. On the one hand, medical staff has heavy work tasks, great pressure, high risk of infection, and lack of support (Spoorthy et al., 2020). On the other hand, most of the medical staff are required to be isolated in hospitals or isolation points. Their families will face more prominent problems (Mohindra et al., 2020). Some positive motivation factors can boost morale and improve the self-efficacy of medical staff, such as family and social support, positive example, recognition, and appreciation from others, successful experience, self-identity (Spoorthy et al., 2020). Positive feedback and encouragement from others could also effectively improve self-efficacy (Bandura, 1997; Zinken et al., 2008; Brown et al., 2012). The pre-job training, encouragement from colleagues and family, affirmation from patients and society, and sufficient material support were all helpful ways to improve the self-efficacy of medical staff during the COVID-19 outbreak. Medical staff in a good family environment can get better family support. The support reduces the sense of uneasiness caused by isolation, and improve self-efficacy, increase work confidence, improve work efficiency and quality, and reduce the negative emotions caused by epidemic infection.

It has been reported that the mental health status of Chinese medical staff is poor (Zhou et al., 2018), and they are exposed to immense workplace pressure and face complex doctor-patient relationships. The reason lies in the contradictions in the current medical system reform in China, such as the uneven distribution of medical resources (Lu et al., 2019), the disequilibrium between health care needs and medical development (Zhou et al., 2018), and the imperfection of the medical system (Ta et al., 2020). During an epidemic period, protecting the mental health of the medical staff would benefit their health as well as the control of the epidemic worldwide (Kang et al., 2020). The National Health Commission of China has published a national guideline of psychological crisis intervention for COVID-19, which is guided for the protection of the mental health of the medical staff (Kang et al., 2020). However, the family environment is particularly important to the mental health of the medical staff, and self-efficacy plays an important role in regulating the relationship between them. Appropriate guidelines should be issued nationally to improve the family environment of the medical staff and for the improvement of their self-efficacy.

There are some limitations to the current study that need to be addressed. First, there are limitations to the method of sampling. Sampling bias may have occurred by using a convenient sampling method. Second, we have a small sample size, and all participants are from Beijing, so the research participants in this study may not be sufficiently representative of the population we are interested in studying, which may limit the conclusion of research results. Third, online questionnaire surveys cannot observe the participants' answering process, there is the possibility of random answer and perfunctory answer, cannot guarantee the complete authenticity of data. Fourth, we did not measure other potential confounding variables that may exist between the family environment and the emotional state of medical staff during the COVID-19 outbreak. Finally, the researchers are all medical staff, and the design of the survey may be more based on clinical observation. In the future, the research design can be combined with clinical observation and the existing theoretical framework.

CONCLUSION

In the current study, we found that the anxiety and depressive symptoms of medical staff during the COVID-19 outbreak was closely related to their family environment, and their self-efficacy regulated the relationship between them. This study provides a new direction for the psychological intervention in medical staff during the epidemic that mainly focuses on improving their family environment and their self-efficacy.

In December 2019, an outbreak of the novel coronavirus pneumonia infection occurred in Wuhan City, Hubei Province, China, and it has received substantial attention globally. Few studies have investigated the psychological stress of students in Health University during the COVID-19 outbreak, and almost no work has attended to the influencing factors that may cause their psychological stress risk. This cross-sectional, survey-based, region-stratified study collected demographic data and mental measurement from 2,498 medical students and 1,177 non-medical students in 31 provinces from March 5, 2020, to March 10, 2020, in China. The psychological stress was measured using the Chinese Perceived Stress Scales (CPSS) under a self-design questionnaire. Sociodemographic, major characteristics, and knowledge of the novel coronavirus pneumonia were also identified as potential influencing factors of stress. The study revealed that medical students are suffering from more stress than non-medical students almost in all provinces of China. Four influencing factors including level of familiarity with the novel coronavirus, family income, major of students, and status of the intern student can be significantly related to students' stress in the medical group by using the univariate and multivariate analysis. Further analysis showed that students with low stress had a greater number of positive psychological emotions and a lower number of negative psychological emotions than with medical students with high stress. In addition, high stress caused low enthusiasm for learning in these medical students and lead to little/no willingness to do professional medical work in the future. In conclusion, we need to increase the level of our knowledge related to the novel coronavirus pneumonia to reduce stress and strongly focus on the special populations in medical students with certain features, such as intern students, clinical nursing students, and low-income families, to improve their learning attitudes and establish positive professional mental outlooks.

Keywords: novel coronavirus pneumonia, medical students, stress, perceived stress scales, influencing factors

INTRODUCTION

In December 2019, an outbreak of the novel coronavirus pneumonia infection occurred in Wuhan City, Hubei Province, China, and has spread to the rest of the country. This speedy onset crisis was accompanied with strong infectivity, rapid rate of course changes of the disease, and the general susceptibility of the population. On January 20, 2020, the National Health Committee included pneumonia caused by the new coronavirus infection as a Class B infectious disease under Category A of Infectious Disease Management (Drosten et al., 2003; Zaki et al., 2012; Chang et al., 2020). The World Health Organization 2020 has identified the novel coronavirus infection as a Public Health Emergency of International Concern and named it "COVID-19" (World Health Organization [WHO], 2020). As of March 6, 2020, more than 3000 medical staff in Hubei Province have been infected with COVID-19, of which 40 and 60% have been infected in hospitals and communities, respectively. All of them were local medical staff in Hubei Province, and most of them specialize in non-communicable diseases (The State Council Information Office of the People's Republic of China, 2020). As of 19:00 on March 25, 2020, China had confirmed 81,896 cases of COVID-19, including 3287 dead and 73,793 recovered (National Health Commission of the People's Republic of China, 2020).

From January 25, 2020, 30 provincial-level administrative units have initiated major public health emergency level responses for effective prevention and control (Li Z. et al., 2020). On January 27, 2020, the Minister of Education issued a notice on the extension of the spring semester (Ministry of Education of the People's Republic of China, 2020). Colleges and universities in each region have to start in accordance with the control of the local epidemic and the unified deployment of the local education administration and government (Rothe et al., 2020). Many college students would be required to take home isolation because of the implementation of strict traffic control and the postponement of the opening of colleges. However, these young students in the learning stage are still in the mature period of psychological development. In the face of such a ferocious epidemic and heavy academic work, they will be burdened by the pressure caused by COVID-19 or social isolation and interruption of normal school activities. In addition, cyberspace rumors can exacerbate psychological stress on students due to being unfamiliar with the novel disease. The widespread news also causes more concerns related to the severity of the disease. Lazarus and Folkman showed that when someone has to face huge hazards that are beyond their ability to handle, the physical and mental health are affected directly (Liu et al., 2015). As the first mental problem, stress can change students' feelings through further physical and mental symptoms (Yuan and Lin, 2009). Therefore, focusing on the particularity of stress is helpful to improve the ability of early prevention of mental illness.

Among these students, medical students are considered a special population. Although the COVID-19 epidemic is very dangerous, there are still many other factors that would affect students' psychological stress. Firstly, during the outbreak response, online teaching approaches have been launched successively to avoid delays in study progress. But the lack of interaction and teaching materials and the unfamiliar classroom environment increase the concerns and discomfort among the students (Yang et al., 2020). Secondly, based on expectations for the future, medical students may suffer more stress than other professional students in academic and employment in the current environment (McGuire, 1966; Dyrbye and Shanafelt, 2011; Dyrbye et al., 2011; Voltmer et al., 2012). Furthermore, some medical interns were even required to be on the frontline to fight the COVID-19 in some cities of China. The poor situation of frontline medical workers has attracted much more attention from medical students, which furtherly enhance the stress perception of medical students. Additionally, a lot of basal characteristics of personal students can also change the personal psychological stress, such as family incoming, student's age and gender, etc. For these factors, seeking the sources of students' stress with a great importance are worth exploring.

As we know, psychological stress can effect the overall mental health of these medical students (Al-Rabiaah et al., 2020), such as anxiety and depression, etc. (Cao et al., 2020; Liu J. N. et al., 2020). This outbreak has highlighted the fragility of mental resilience. For now, there are many researches focusing on the mental health of medical care workers who were exposed to COVID-19 with increasing frequencies of mental symptoms (Liu C. Y. et al., 2020). The rates of anxiety and depression among medical students are almost 12.5–23.48% (Chen et al., 2014; Zhao et al., 2018) and 13.2–48.7% (Chi et al., 2019; Xiong et al., 2019), respectively. Meanwhile, the researchers also show that the numbers of psychological mental health are generally increasing among college students (Cao et al., 2020). Therefore, to explore the correlation analysis between these mental health symptoms in medical students would bring huge benefits to the comprehensive management of students in the pandemic period.

Of note, if high psychological stress and poor employment environment both were part of a vicious circle, it may lead to the decline of academic and employment performance and obviously reduce the quality of life of medical students (Dyrbye et al., 2005). To clarify, if the perceived stress of medical students has existed for a long time, it would directly affect the choice of medical career (McGuire, 1966; Kumar et al., 2019). In extreme cases, mental illness of these students during this period may even lead to students' suicide (Singh et al., 2016; Kumar et al., 2019; Li H. Y. et al., 2020).

Despite the importance of these issues, only a few studies have investigated the psychological stress of medical students in Health University in the COVID-19 outbreak in China. Therefore, this study's aim is to design an online survey based on the CPSS questionnaire by collecting the demographic data (such as gender, age, educational background, nationality, monthly income of families and understanding of the disease, etc.) to describe the distribution of the psychological stress of medical students and to identify its influencing factors in China during the pandemic period. In addition, we also focus on exploring the relationship between stresses with psychologies phenomena and the changing of attitudes of learning and employment. Our findings might help governments, schools, or health authorities to recognize the causes of increased stress and their influences in medical students, and then to provide early effective measures to reduce that stress.

MATERIALS AND METHODS

Study Population

Using the cross-sectional research method, online students were investigated anonymously online by snowballing through questionnaires sent to WeChat and QQ. We restricted the IP address of each device (mobile phone, computer, and tablet) to answer the survey only once. The survey period is from March 5, 2020, to March 10, 2020. The questionnaire survey platform was developed by Changsha Ranxing Information Technology Co., Ltd. In total, 3,680 questionnaires were distributed and 3,675 valid questionnaires were recovered, with an effective rate of 99%. The inclusion criteria of this study were as follows: (1) Full-time college students aged 16∼31 years old; (2) Be able to read and write; (3) Those who are willing to participate in this project. The exclusion criteria included: (1) Those who were unable to complete the study due to severe visual or hearing impairment, mental disorder, etc.; (2) Those with cognitive dysfunction.

Pilot Survey

Four medical administrators, four medical students, and four non-medical students were selected to conduct a pre-survey to understand the use of the questionnaires in this study. According to the feedback of the respondents, the questionnaire was modified appropriately.

Data Collection

Using the online questionnaire preparation method, the questionnaire items are entered one by one, and online release and questionnaire were collected. Before the input of the collected data, the errors were checked, and omissions were made up and the logic checked. Additionally, the questionnaires with obvious logic errors and more missing items were eliminated.

Questionnaire Contents

The first part included the general situation, such as gender, age, educational background, nationality, average monthly income of family members, learning attitude, and professional attitude. For the education background, we divided full-time college students into medical major and non-medical major. The medical major mainly includes clinical medicine and clinical nursing. Non-medical major mainly includes information management and high-speed rail crew, etc. The second part consisted of the Chinese version of perceived stress scale (CPSS). Previous PSS is widely accepted and used for psychological stress assessment. Cohen et al. (1983) developed the PSS in 1983. The Cronbach coefficient of the scale is 0.78, indicating good reliability and validity. Now, the scale has been sinologized by Yang Yanzhong of Zhejiang University (Yang and Huang, 2003). The CPSS can quickly judge the individual stress state through 14 designed questions. The 4, 5, 6, 7, 9, 10, and 13th questions were reverse items, and the total score range was 0–56. A high score indicates high psychological stress. A total score of ≥25 points is defined as high stress. In the current study, we used the CPSS as the subjective index of psychological stress assessment. The Cronbach coefficient of this questionnaire was 0.827 to show good reliability.

Statistical Analysis

In this questionnaire, the continuous variables were reported as mean and standard deviation (SD) and compared by using the Student's *t*-test or ANOVA test in two or more groups. LSD test was used to detect the multi-comparison after ANOVA test. The dichotomous data were presented as frequency (%) and compared by using the chi-square or the Fisher's exact test in two groups. The distribution of mean CPSS score of the students from each province was also calculated. We firstly compared the CPSS score between the medical and non-medical student groups. Then, univariate analysis methods, such as the Student's *t*-test and chi-square or Fisher's exact test, were used to explore the candidate variables that related to the high CPSS score in the medical students. The standard mean difference (SMD) of these candidate variables between the two groups was calculated by the "tableone" package in R. Then, the multivariate logistics regression analysis was performed to determine the independent risk factors of the CPSS score. We presented the results of the multivariate analysis on a forest plot for all the comparative Odds Ratio (OR) values with it 95% confidence interval (CI) of the associations. Lastly, the bar plots of some potentially related variables were also used to analyze the differences between high CPSS and low CPSS groups. The main packages, including "forestplot," "glm," "ggolot2," "maps," "mapdata," and "tableone," were applied to visualize and analyze the results and conclusions. All the reported *P*-values with a significance level of 0.05 were defined based on two-sided tests. All statistical processes were performed in the R software (R Foundation for Statistical Computing, Vienna, Austria, and version 3.6.0).

RESULTS

Questionnaires Collection and Study Design

This is a cross-sectional, survey-based, region-stratified study and collected demographic data and CPSS measurement from 3,680 students in 31 provinces from March 5, 2020, to March 10, 2020, in China. Specifically, a total of 3,680 questionnaires were distributed and 3,675 valid questionnaires were recovered to analysis, with an effective recovery rate of 99%. To fully demonstrate the role of stress in medical students during the pandemic period, a comprehensive analysis with a flowchart was designed in **Supplementary Figure S1**.

Distribution of CPSS Score of Medical and Non-medical Students in China

Exactly 68.2% (2,498/3,675) of the students were medical students, whereas the remaining were non-medical students (31.8%, 1,177/3,675) in the questionnaire. First, we presented the distribution of CPSS score of all students in 31 provinces of China (**Figure 1A**), as well as the medical students (**Figure 1B**). Apparently, we found a regional heterogeneity in these provinces

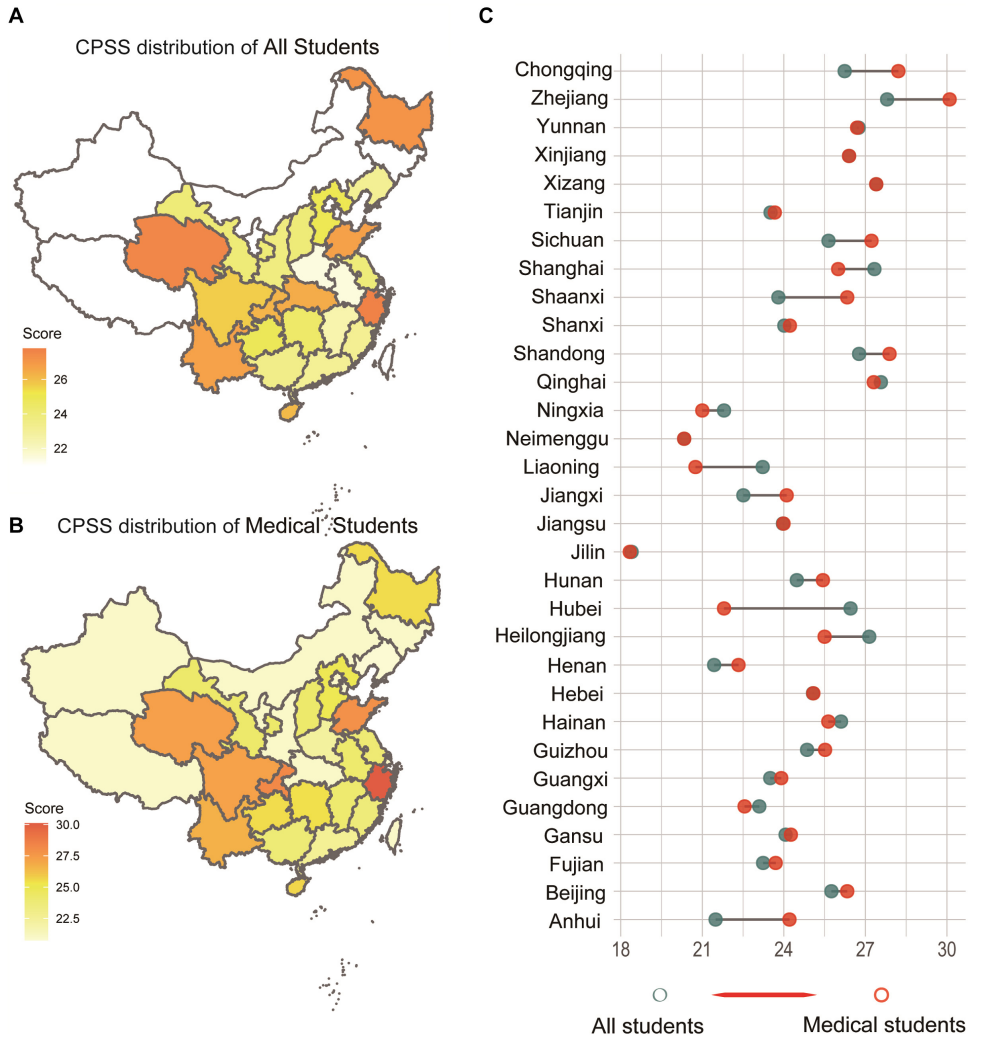

FIGURE 1 | The distribution and difference of the CPSS score of all students in each province of China. **(A)** The distribution of all students. **(B)** The distribution of the CPSS score of medical students. **(C)** CPSS score Changing from all students to medical students in each province of China.

through the different depth of colors in the distribution map of CPSS score. From **Figure 1C**, we clearly found an increasing trend of CPSS score in the medical students by comparing with the total students in each Chinese province. The detailed digital results of these figures are included in **Supplementary Table S1**.

Demographic Comparison of Medical and Non-medical Students

To detect the basal demographic characteristics of the medical and non-medical students, we compared collecting variables in **Table 1**. The differences of some variables, such as sex, age, race, source of the student, and the family income, also were detected between the two groups. By using the *t*-test the gaps between medical and non-medical students in the CPSS score were investigated. We found that the medical students had a higher mean CPSS score than the non-medical students (**Figure 2A**, CPSS score, medical: 24.14, non-medical: 22.63; $P < 0.001$). We stratified all the students into two groups, namely, the high- and low-CPSS group, by using the cutoff (value = 25) of the CPSS score (Yang and Huang, 2003). Therefore, based on the cut-off of CPSS in our study, the rate of high CPSS was 44.8% (1,648/3,676) in all students. Among them, the rate of medical students with high CPSS was 48.7% (1,219/2,499), and the rate of the students with low CPSS was 36.4% (429/1,178). The bar plot with the chi-square test can also detect the differences between two groups (**Figure 2B**, medical: 48.8%, non-medical: 36.4%; $P < 0.001$).

Univariate and Multivariate Analysis for High CPSS Score Among Medical Students

To select the impact factors that related to the CPSS score among the medical students, we firstly compared the differences in the variables in the medical students with High CPSS score or Low CPSS score. **Table 2** showed that five factors (i.e.,

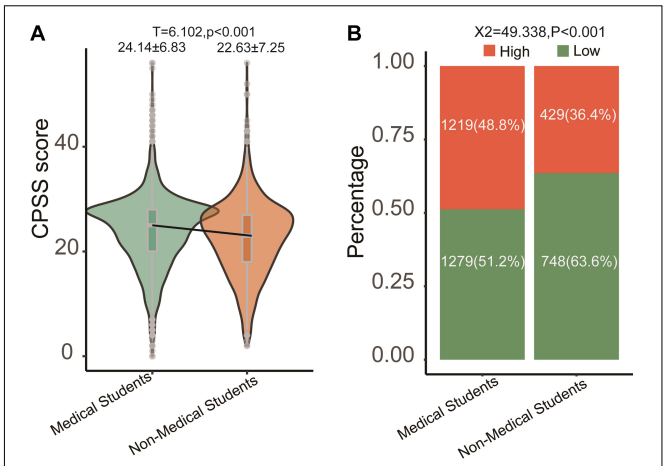

FIGURE 2 | Comparison of medical students with non-medical students. **(A)** Continuous CPSS score; **(B)** category CPSS score (high > 25 vs. low ≤ 25).

age, family income, level of familiarity to COVID-19, major of students, and status of the intern student) could be the candidate variables related to the CPSS score in medical students (all $P < 0.01$). Then, we obtained the ranking of the five most relevant factors to CPSS by using the method of SMD in the package of "tableone" in R (**Figure 3A**). Thereafter, we included the five significantly related variables into multivariate logistic regression analysis. Finally, it showed that four variables were the independent risk factors of the CPSS score in the medical students (**Figure 3B**, all $p < 0.05$). As a supplement, we also tested the relationship between the continuous CPSS score with these factors by using the *T*-test and the LSD test and obtained results similar to those of the regression and general chi-square tests (**Figures 3C–F**, $P < 0.05$).

Relationship of CPSS Score With Psychological Phenomena Among Medical Students

In general, stress and other emotions interacted in an individual person, and we still detected the relationship of the positive and negative effects of psychologies with CPSS score in our study. With the increasing number of positive psychologies, the frequency of high CPSS score is less and less in the medical students (**Figure 4A**, $P < 0.001$). Separately, we found that concern for other people (**Figure 4C**), keeping protection from COVID-19 (**Figure 4D**), and keeping good health (**Figure 4F**) could significantly reduce the CPSS score ($P < 0.001$) in the medical students, but not for unlike public morality (**Figure 4B**, $P = 0.07$) and following the epidemic news (**Figure 4E**, $P = 0.36$). Unlike positive phenomena, the negative phenomena of medical students including anxiety, depression, worried about health, boring, fear, helplessness, loneliness, and insomnia in the high CPSS score group were all higher than that in the low CPSS score group (**Figures 5A–I**, all $P < 0.001$).

TABLE 2 | The relationship of influencing factors with CPSS score (high vs. low) in medical students.

Influencing factors	High CPSS score (*n* = 1,219)	Low CPSS score (*n* = 1,279)	*P*-value
Sex (%)			0.086

We also aimed to detect the relationship between CPSS and the attitude of learning and professional medical career. Then, learning and professional medical career attitudes with five levels were filled in by the subjects of the questionnaire. We could find that a high CPSS score led to the low enthusiasm for learning among medical students (**Figure 6A**, $X^2 = 196.49$, $P < 0.001$). A five-level category for the attitude of professional medical career, including very, relatively, general, slightly willing, and unwilling, was further analyzed (**Figure 6B**). Although most of the medical students in the high- and the low-CPSS score groups (80.26 and 88.42%, respectively) continued their medical career, a high CPSS score still could cause a high proportion of students to be slightly willing and unwilling to do medicine-related work in the future (**Figure 6B**, $X^2 = 68.61$, $P < 0.001$). To better comprehend the differences in the professional medical career attitude in the high- and the low-CPSS score groups in medical students, we also required the subjects to support the diversity of reasons for being unwilling to select the medical career in the questionnaire. Then, we divided these reasons into two parts, good and bad. The good reasons, such as "meaningful work" and "devotion of love," were significantly higher in the medical student with low CPSS score. However, the poor reasons, such as "Disrespect by Patients," "low salary," "hard work and serving people," "high academic requirements," "Non-conformity for Career Planning," and "Career without Future" were all higher in the medical students with high CPSS score (**Table 3**, all $P < 0.05$).

DISCUSSION

As we know, COVID-19 is highly contagious with 20% severe illness and 2% mortality rate. In such a short period, the sharply increasing number of COVID-19-infected people may lead to students who are suffering from psychological strain of disease outbreak, anxiety, and other disruptive emotions. As we can see in most cities in China, the government had to shut down schools and some entertainment or gathering place at all levels and did not allow students to participate in various forms of social activities and entertainment for nearly 2 months. "Homestay" was really against normal learning tools but was necessary in the pandemic period. Importantly, we can easily clarify the stress situations of college students by using the CPSS tool, which is a brief assessment of someone's stress level in any aspect of life situation (Cohen et al., 1983). Considering that medical students suffer a huge amount of stress from academics and employment, they deeply need to learn medicine knowledge in the available online courses. Thus, these reasons would raise the levels of their stress during the pandemic, especially for medical students with their extensive duties (Arora, 2015). Of note, mild, moderate, and high levels of stress and even burnout have been reported among medical students and healthcare professionals in other countries (Al Khalidi and Wazaify, 2013; Muzafar et al., 2015; Aamir et al., 2017; Alkot et al., 2017; Syed et al., 2019). In total, understanding of the distribution and reasons of high stress in students during the COVID-19 outbreak may be helpful to governments, schools, or health authorities.

This study firstly evaluated the distribution and huge differences of stress levels between medical and non-medical students in almost 31 provinces of China. To demonstrate the source of the high stress in medical students, we obtained four influencing factors, which could be significantly related to the progression of CPSS score in medical students by using the univariate and multivariate analysis, such as major of students, status of the intern student, family income,

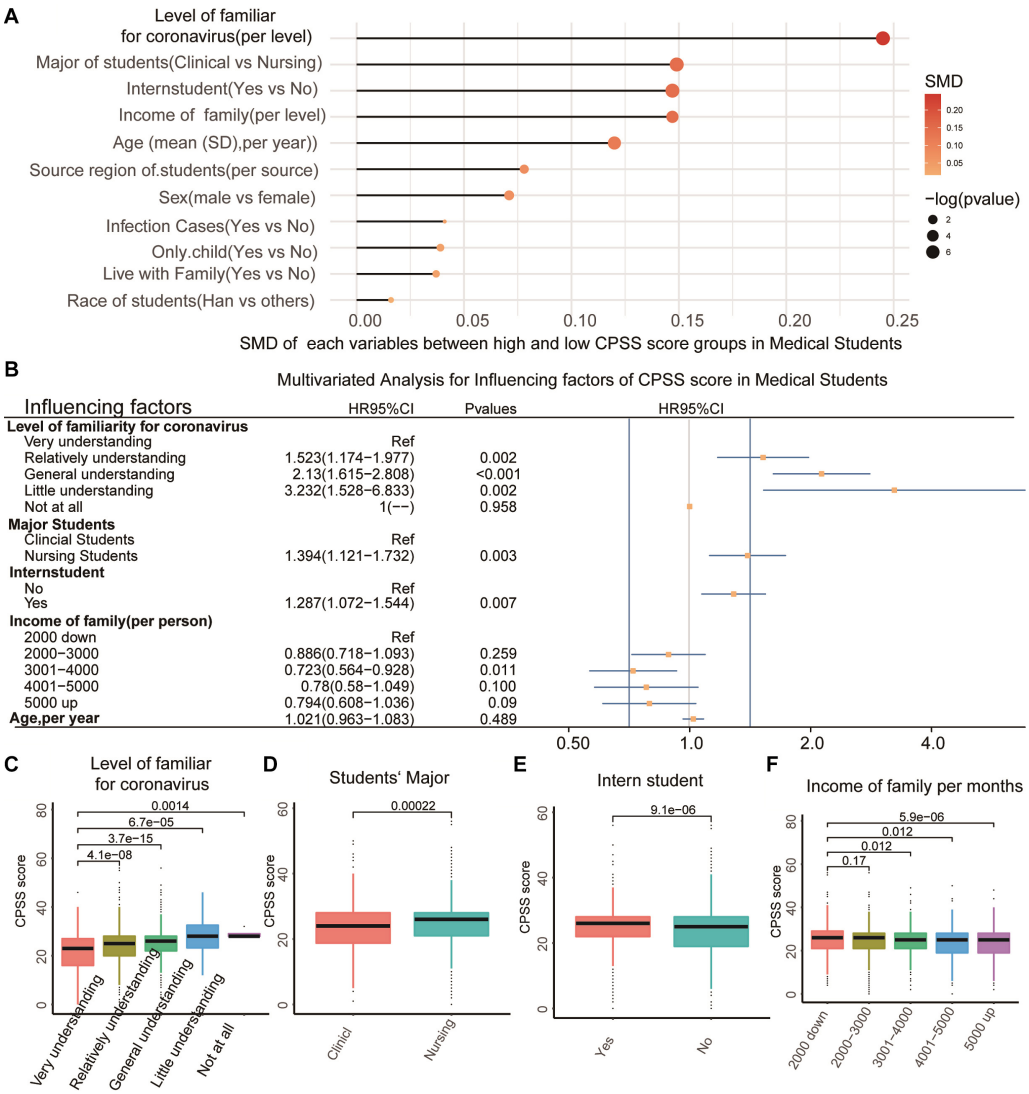

FIGURE 3 | Association of common variables with the CPSS score. **(A)** The SMD value of each variable between high CPSS score and low CPSS score in medical students. **(B)** The multivariable regression for the high CPSS score in medical students. **(C–F)** The significant difference of CPSS scores with four influencing factors.

and level of familiarity with COVID-19. By comparing the female and older students with the male or young students, it was indicated that they have more mental problems, which is similar to the previous study (Cao et al., 2020; Li H. Y. et al., 2020; Liu C. Y. et al., 2020); however, statistical analysis showed no significant difference. In our study, approximately 85% of them were female medical students who could respond to the results. Among the population who answered the questionnaire, 66% of the students are nursing majors. Obviously, compared with other clinical majors, nursing students would face higher stress when they are undergoing the strictly learning and work environments (Magnavita and Chiorri, 2018). Additionally, medical interns have higher stress than the non-interns medical students (Babar et al., 2004; Liselotte et al., 2006; Guo et al., 2019; Shadid et al., 2020). Not only the clinical practice and emergencies in hospital, but also the task of publishing a graduation dissertation sends these intern students into a high-stress situation. What's more, medical intern students need to avoid making mistakes because of the importance of patients' life, because during the throat swab collection and medical operations, safety is uncertain all the time. Thus, responsible teachers and hospital managers should attend to these students, especially the nursing interns, regardless of school and hospital. It's easy to understand that there is another reason that low family income tends to make students feel inferior, resulting in high stress in most instances (Wang et al., 2019). Finally, it is exceedingly profound to know that the higher level of familiarity with COVID-19 can lessen the anxiety and depression level of these students (Huang et al., 2020), as well as the stress in our study. People becoming familiar with things will significantly

reduce psychological stress, fear, and other pessimistic moods. Therefore, it becomes much more important to reduce psychological stress through the comprehensive and accurate education of medical students in the prevention and control of the COVID-19 pandemic.

The survey also asked students to fill other positive and negative psychological emotions in the form voluntarily in the study. The negative psychological emotions included depression, worry, boredom, fear, anxiety, helplessness, loneliness, and insomnia, and these were all significantly related to the higher CPSS score in the medical students. Previous studies have reported that stress is closely related to negative psychology that can lead adolescent students to avoid coping, and avoidance of coping enhances the severity of psychological stress (Ozawa, 2010; Arsenio and Loria, 2014). Positive psychological emotions including five psychological aspects, namely, "health protection measures," "following the epidemic news," "health condition," "concern about public morality," and "caring for others" were also related to psychological stress. It is obvious that the positive states of students are lower under the high pressure in the pandemic period. Therefore, it is equally important to find other psychological changes to improve the status of the students' physical and mental health.

The attitudes of learning and professional medical career were also reduced by the high stress brought by the epidemic. For the attitude of learning, medical students with low CPSS scores are more comfortable with learning than those with high CPSS scores. Researches showed that the lower psychological stress for learners who take the initiative to study in professional courses or read extracurricular books in online learning, the more efficient

of the studying (Zhang et al., 2020). We also proved that most of the medical students both in the high- and the low-CPSS score groups would continue their medical careers. However, a higher proportion of medical students would be slightly willing and unwilling to do work related to medicine in the medical students with high stress. The medical students with low CPSS scores had a more stable professional mentality that was extremely helpful in controlling their occupational risks, and their motivation reasons are undeniable. In the pandemic period, for instance, from the arrival of the first medical team in Wuhan on New Year's Eve on March 1 (Li Z. et al., 2020), a total of 42,322 medical staff used their spirit of selflessness and careers professionally, and this affected these medical students to reduce their stress. After COVID-19 in China, medical students would enhance their sense of social responsibility and professional attitude awareness. Thus, we strongly recommend that experts address these problems to improve the attitudes of learning and professional work by completing the formulation of sound incentive schemes.

Limitations

This cross-sectional study had certain limitations. Although we have collected much demographic information and made a lot of data analysis, we cannot determine the causal relationship between stress and these indicators, the same as the relationship between positive psychology and negative psychology and stress. Further longitudinal research is needed to obtain the final causality and improve decision-making ability. In addition, data was collected by using self-administered questionnaires/instruments. Hence, we cannot rule out information bias. To enhance the applicability of the research results, we should further expand the sample size and improve the representativeness in the follow-up research. Despite these limitations, this study provided invaluable information related to the students during the COVID-19 outbreak across 31 provinces and autonomous regions in China, and our results can be used as a historical reference.

CONCLUSION

Our study showed that the distribution of psychological stress (CPSS score) of the college students was obviously different among the different provinces in China during the outbreak of COVID-19. Among them, medical students suffer from higher stress than non-medical students in total and in most of the provinces. The top four independent risk factors related with psychological stress, including the lower level of familiarity with COVID-19, older age, lower family income, and the intern student, could significantly increase the psychological stress in the medical students in the pandemic period. Meanwhile, stress was related to some common positive and all the negative psychological phenomena significantly. Finally, timely decreasing of medical students' stress can correct their learning attitudes and establish positive professional attitudes in the outbreak of COVID-19. The findings of the present study mainly could arouse the concern of policymakers, especially in the department of governments, schools, or health authorities.

From Shattered Goals to Meaning in Life: Life Crafting in Times of the COVID-19 Pandemic

Elisabeth M. de Jong, Niklas Ziegler and Michaéla C. Schippers*

Department of Technology and Operations Management, Rotterdam School of Management, Erasmus University, Rotterdam, Netherlands

The novel COVID-19 pandemic has created an extraordinary situation for our generation, with many countries being on lockdown. With this, new situation comes many psychological challenges not only for health care workers and people suffering from COVID-19 but also for the general population. Adapting to the new situation can be demanding. Experts have suggested that emotions during this situation are very similar to grief, and people experience emptiness and sadness about the loss of their normal lives, which can even lead to a loss of meaning in life. In this paper, we argue that life crafting could offer a way to help people cope with the situation and renew their sense of meaning. A life crafting intervention is based on theoretical insights from multiple areas of research, like positive psychology, expressive writing, and the salutogenesis framework. Life-crafting interventions help people find meaning in life by focusing on their ideal future, and helping them set goals, and make concrete plans to achieve those goals and overcome obstacles. Since having a clear purpose or meaning in life has been shown to have many benefits, we propose that it can also help people to cope with the psychological effects of the pandemic. A life-crafting intervention can offer people a chance to evaluate their goals in a time of uncertainty and rediscover meaning in life to guide them through these difficult times.

INTRODUCTION

The COVID-19 pandemic has caused a unique situation in the world. There are many different measures being taken to contain the virus. Most countries around the world have implemented a "lockdown" in some form, and although some countries have stricter regulations than others, most of them involve at least some type of so-called "social distancing" (Hale et al., 2020). In a short period of time, the normal life that people were used to living has been drastically and unexpectedly changed. This has consequences for people's mental and physical well-being (for a review, see Schippers, 2020).

Grief experts have suggested that emotions during the COVID-19 pandemic are very similar to grief, as in the case of losing a loved one (Berinato, 2020). Kessler described the current situation as follows: "Our world as we knew it has died and we are feeling the sadness"

(Amanpour and Company, 2020; Berinato, 2020). In accordance with these statements, scientific research has also shown that grief is not only experienced after a bereavement but can also play a role after other life changing losses, such as a divorce or job loss (Papa et al., 2014). Although these forms of grief are rather individual, more collective forms of grief that are not necessarily related to direct individual experiences of bereavement can also occur, for example, in refugees when they need to adjust to a host country (Baškauskas, 1981).

There are several ways grief might play a role during the COVID-19 pandemic. Needless to say, people who are directly affected by the virus or have loved ones who have suffered from or even passed away because of the virus experience grief. However, these grief processes are not the focus of this paper. Rather, this paper is directed at the collective grief processes that might be present in the general population, as a result of a loss of normalcy, caused partly by the many containment measures. This loss of normalcy and the grief over what is no longer possible can lead to a sense of emptiness, and even a loss of meaning in life (Berinato, 2020; Taha, 2020). Some researchers have even suggested that isolation measures that take more than 10 days may lead to post traumatic stress syndrome (Schippers, 2020). In accordance with this, different theories have shown that finding meaning is an important element for recovery in a grief process, and have suggested that it can help in finding post-traumatic growth instead of post-traumatic stress (Hogan and Schmidt, 2002; Janoff-Bulman, 2006; Updegraff et al., 2008; Kessler, 2019). As the mental health effects can be quite severe (Fegert et al., 2020; Schippers, 2020), restoring a sense of meaning in life can be an essential part of the healing process (e.g., Hogan and Schmidt, 2002; Updegraff et al., 2008). However, research also suggests that people might need guidance to find meaning in a structured manner (Steger et al., 2008). Therefore, in this perspective paper, we argue that a life crafting intervention, which is aimed at finding meaning in life, could be helpful to guide people through this grief-like process.

GRIEF AND FINDING MEANING

Finding meaning seems to be a central theme in the grief and trauma literature. However, the term "meaning" has been defined and operationalized differently across different fields of study. In their review, Martela and Steger (2016, p. 531) distinguished between three main types of meaning in life: coherence, purpose, and significance. Coherence refers to "a sense of comprehensibility and one's life making sense." Purpose means having "a sense of core goals, aims, and direction in life," and significance refers to "a sense of life's inherent value and having a life worth living".

In the literature about grief and trauma, finding meaning often refers to the first type of meaning, coherence, conceptualized as making sense of what has happened. One well-known theory in the literature on grief and trauma is the theory of shattered assumptions, developed by Janoff-Bulman (1992). According to this theory, there are three fundamental human assumptions about the self and the world that form a person's assumptive world, and that guide our day-to-day thoughts and behaviors. These assumptions are that the world is benevolent and meaningful, and that the self is worthy. A traumatic event can shatter these fundamental assumptions. To recover, assumptions should be rebuilt. One way to do this is to find meaning in the traumatic event, or, in other words, a way to make sense of it. Schwartzberg and Janoff-Bulman (1991) showed that the greater the ability of a bereaved individual to find meaning, defined as making sense of the loss, the less intense their grief. Although this theory is usually referred to in studies about individual grief or trauma, research by Updegraff et al. (2008) showed that finding meaning is also of importance after a collective trauma, in this case the 9/11 terrorist attacks. They found that in the general population (i.e., the majority of their sample consisted of people who were not directly exposed to the attacks), finding meaning, again defined as making sense of what happened, in the early aftermath of the event was related to lower post-traumatic stress symptoms in the 2 years following. This effect was mediated by reduced fears of future terrorism, which the authors saw as a sign that finding meaning led to rebuilding of assumptions about security and invulnerability. This definition of meaning thus refers to finding meaning in the events that have occurred and rebuilding assumptions of a meaningful and coherent world.

Another kind of meaning that seems important in the grief process is the meaning in one's own life, which corresponds more with meaning in the sense of purpose and significance, as defined by Martela and Steger (2016). Besides making sense of the event itself and rebuilding assumptions about the world, rebuilding the assumptive world seems to entail more. Janoff-Bulman (2006) also suggested that rumination about questions regarding the meaning of life itself may later shift to rumination about finding meaning in one's own life. In general, having a clear sense of purpose in life has been shown to have many benefits for mental as well as physical well-being (for a review, see Schippers and Ziegler, 2019). In the context of trauma, Sawyer and Brewster (2019) also showed that meaning in life was positively related to post-traumatic growth after bereavement. In the specific context of the COVID-19 pandemic, Trzebiński et al. (2020) have shown that a higher level of meaning in life (i.e., having a clear purpose and meaning in life, having life goals, not being afraid of the future; comparable to what Martela and Steger define as "purpose") was related to lower anxiety and emotional distress during the crisis. Therefore, the authors argue that meaning in life (i.e., purpose), among other factors, may work as a buffer against stress reactions to the pandemic. Notably, whereas they assessed meaning in life as a stable factor, the authors argue that in the face of a prolonged crisis, meaning in life may be affected as well.

In the present paper, we predominantly focus on the second and third type of meaning as distinguished by Martela and Steger (2016): purpose and significance. In line with the reasoning of Trzebiński et al. (2020), we expect that the sense of purpose and in severe cases even significance in life for many people in the general population might have already been affected during the pandemic. The UN agency has estimated that in

the second quarter of 2020, 305 million jobs have already been lost worldwide, mainly caused by prolonged containment measures (Straus, 2020). Furthermore, the IMF has predicted a severe worldwide economic crisis (International Monetary Fund, 2020). In addition, as described earlier, grief-like emotions over the loss of normalcy can also lead to a loss of purpose in life. In accordance with this, one study has shown that during the COVID-19 pandemic, the sense of purpose in life of students in higher education decreased in the second half of the academic year, whereas in the cohort of students from the year before, it remained stable (Schippers et al., in preparation).

We expect that there are individual differences in the degree to which purpose and significance are affected by the pandemic and the containment measures. For some people, life may have remained relatively normal, and their purpose in life may have stayed intact. However, because of the containment measures, some of their underlying goals might have been compromised. For example, someone's purpose in life might be to become a psychologist, but because of the containment measures they cannot do their internship as planned (i.e., cannot attain this intermediary goal), and they need to find new ways and set new goals to reach their purpose. For others, who have, for example, lost their job or even their company (i.e., their life's work) during the pandemic, their purpose or even significance in life itself might also be harmed. Consequently, the individual might experience a loss of directionality in their life as "goal are signals that orient a person to what is valuable, meaningful and purposeful" (Emmons, 2003, p. 107) and can be seen as a key element in human functioning (Emmons, 2003; Schippers and Ziegler, 2019). Some might even lose their sense of significance in life. Purpose and significance in life are often entangled. Significance is partly dependent on purpose, but also on other factors such as relationships with friends or family (Martela and Steger, 2016). However, since the containment measures mainly comprise of social distancing, this may make it more difficult to maintain social connections and support, which potentially makes the threat to the sense of significance even larger. Since many studies have shown that having purpose in life is essential to well-being and health (e.g., Hill and Turiano, 2014; Kim et al., 2014; for a review, see Schippers and Ziegler, 2019), we argue that it should be rebuilt. We propose that a life-crafting intervention could help people in rebuilding their sense of purpose and significance in life.

WHAT IS LIFE CRAFTING AND HOW CAN IT HELP TO FIND MEANING?

Individuals searching for meaning are often unlikely to do so in an organized manner and might be more focused on the past and present than particularly concerned about the future (Steger et al., 2008). Relatedly, while the presence of meaning in life is associated with positive outcomes, the actual (prolonged) search for meaning is associated with greater negative outcomes, and such a search could be indicative of meaninglessness (Updegraff et al., 2008; Linley and Joseph, 2011).

A more structured approach to finding meaning and purpose in life, called "life crafting," was recently proposed by Schippers and Ziegler (2019, p. 3). They defined the term life crafting as "a process in which people actively reflect on their present and future life, set goals for important areas of life – social, career, and leisure time – and, if required, make concrete plans and undertake actions to change these areas in a way that is more congruent with their values and wishes." Subsequently, the authors discuss an expressive-writing intervention to aid individuals in finding a purpose in life, while at the same time ensuring that they make concrete plans to work toward this purpose. This type of expressive writing exercises has shown to have benefits for (mental) health as well as academic performance (e.g., Lepore and Smyth, 2002; Morisano et al., 2010; Morisano and Shore, 2010; Schippers et al., 2015, 2020), and has roots in the fields of positive psychology, expressive writing (King and Pennebaker, 1996; Pennebaker, 1997; King, 2001), and salutogenesis (Antonovsky, 1996). Participants usually take part in such a life crafting intervention *via* an online questionnaire that guides them through the different writing exercises (e.g., Schippers et al., 2015), but could also be delivered by a chatbot (Dekker et al., 2020). A central part of the life crafting intervention described by Schippers and Ziegler (2019) is based on the Japanese concept of "Ikigai;" which can be defined as a sense of "a life worth living" (Sone et al., 2008, pp. 709). The term ikigai directly relates to the significance of one's life, which has been defined as the third facet of meaning in live, next to purpose and coherence (Martela and Steger, 2016, pp. 537). As the authors describe, significance "is about evaluating one's life as a whole, including past, present, and the future, while the other (purpose) is distinctively future-oriented: it is about evaluating the potential future value of one's life through sustained goals that give life direction and momentum". As such, the life-crafting intervention proposed by Schippers and Ziegler (2019) does not only strive to provide a framework which can help the individual in structuring their search for a (renewed) purpose in life but also lets the individual reintegrate this new purpose into their life as a whole (significance).

How Can Life Crafting Help to Find Meaning During the COVID-19 Crisis?

Important elements of a life-crafting intervention are: (1) discovering values and passions, (2) reflecting on one's ideal future, (3) writing about specific goal attainment and "if-then" plans, and (4) making public commitments to the goals set (Schippers and Ziegler, 2019; see also **Table 1** and **Figure 1**). In general, people often have difficulty with finding meaning in life, and therefore, a life-crafting intervention could be beneficial to many people. As it seems that the timing of interventions is crucial (Wilson, 2011), this may be particularly useful when people experience a loss of meaning. For the current pandemic situation, we propose several adjustments to the original intervention. First, it should be assessed what exactly has been shattered for the individual. Is it just their

TABLE 1 | Elements and description of a life-crafting intervention.

Part	Elements	Tasks involved
1. Discovering values and passion	Values and passion	Writing about: (1) What they like to do, (2) what kind of relationships they would like to have, both in their private life and their work life, (3) what kind of career they would like to have, and (4) lifestyle choices
	Current and desired competencies and habits	(1) Qualities they admire in others, (2) competencies they have or would like to acquire, and (3) their own habits they like or dislike
2. Reflecting on one's ideal future	Present and future social life	(1) Relationships that energize and de-energize them, (2) kinds of friends and acquaintances they would like to have in the future, and (3) what their ideal family life and broader social life would look like
	Possible future career (path)	(1) What is important in a job, (2) what is it they like to do, (3), what kind of colleagues do they want, and (4) whom do they want to meet through their work?
	Ideal vs. less ideal future	Best possible self and future when there are no (self-imposed) constraints. Contrast this with future if no changes are made
3. Writing about specific goal attainment and "if-then" plans	Goal attainment and "if-then" plans	(1) Formulating, strategizing, and prioritizing goals, (2) identifying and describing ways to overcome obstacles, and (3) monitoring progress toward goals
4. Making public commitment to the goals set	Public commitment to goal	Photo with statement, which communicates their goals to the world; communicating goals to friends, coworkers

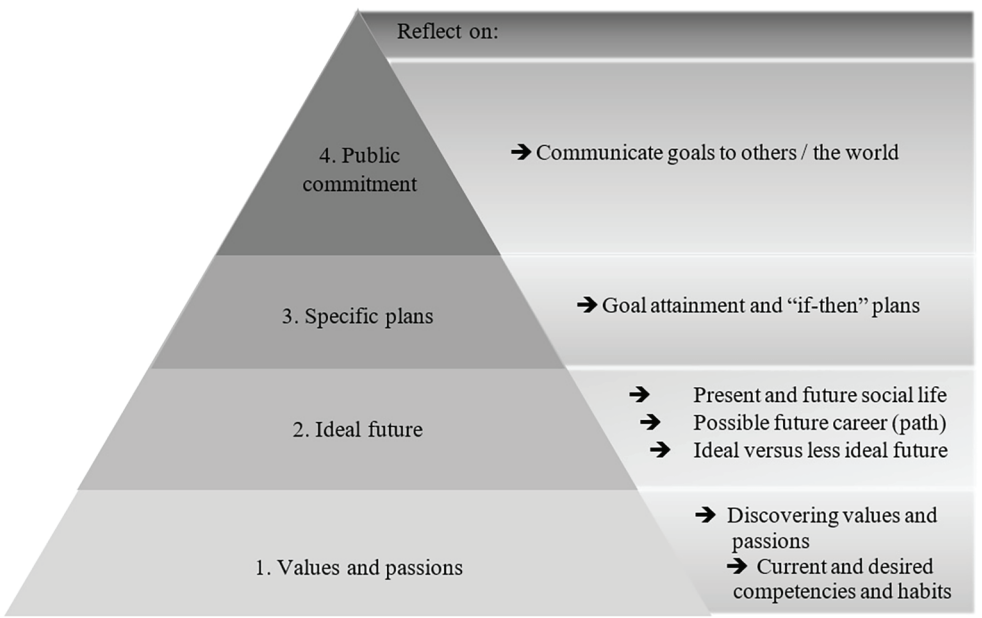

FIGURE 1 | Overview of a life-crafting intervention (adapted from Schippers and Ziegler, 2019).

goals, or also their purpose in life or even their sense of significance in life? Second, based on this assessment, a custom intervention could be presented to the individual. For individuals with compromised goals only, but purpose intact, an emphasis could be placed on part 3 (see **Table 1**) of the intervention. For example, someone's purpose in life may be to become an Olympic champion in athletics. During the crisis, (s)he might not be able to pursue the intermediary goal to train three times a week at a running track. Though the purpose remains intact, the athlete should formulate new intermediate goals, for example, through an adapted scheme that focuses on an alternative and achievable training routine, which still allows the pursuit of the original purpose in a different way. For individuals with a compromised purpose in life, both part 2 and 3 would be important. For example, someone's purpose in life may have been to build up a business and (s)he has just opened three restaurants. However, due to the pandemic and the restrictive measures, nobody can visit the restaurants, and therefore, the person loses the company. This person would need to think about a new purpose in life during and after the crisis, for it might take a while before the economy is fully restored, and opening new restaurants may be unrealistic in the near future. This person may have been very passionate about the hospitality business, and since

purpose and significance in life are often intertwined, the sense of significance in life may also be compromised for this person. In such a case, it would be beneficial to take the full intervention, to discover new values and passions that lie within, and be able to find a new pathway to significance in life. This allows the person to discover other values and passions that exist besides the one that the person was focused on, and may help to find other directions in life that are also found worthy of pursuing.

DISCUSSION

Social and behavioral science research offers valuable insights into how the general population can be aided to cope better with the psychological effects of the COVID-19 pandemic and its restrictive measures (e.g., Schippers, 2020; Van Bavel et al., 2020). In this perspective paper, we argued that a life crafting intervention can be beneficial to rebuild meaning in life after it has been shattered by grief-like emotions over the loss of normalcy during the COVID-19 pandemic. A customized intervention is proposed based on the degree to which the sense of meaning has been affected.

An obvious advantage of the life-crafting intervention is that it is easily scalable. The expressive writing exercises can be done online, individually. This might be especially important during the COVID-19 pandemic, where many people struggle with psychological issues (e.g., Holmes et al., 2020), whereas demands on mental health care have increased, and are expected to maintain on a high level for the coming time. Some psychologists have argued that psychological help for the general population during this crisis has been largely overlooked (Van Hoof, 2020). Schippers (2020) has reviewed the combination of effects and ripple effects that the crisis and the measures that have been taken has in terms of economic, social, mental, and physical health, and presents a model of the interrelated effects. She also points to the fact that interventions are needed in order to counteract some of these effects. Fegert et al. (2020) expected that many young people will experience psychological problems not only during but also in the aftermath of the pandemic, and predict that the return to normality may take a long time.

The degree to which people suffer from psychological problems during the pandemic differs per individual and also depends on pre-existing psychological problems and vulnerabilities (e.g., Fegert et al., 2020). Therefore, there is even more need for customized, scalable interventions (see also Schippers, 2020). The large majority of the general population would likely not need extensive psychological care but could still benefit from interventions to rebuild their sense of meaning in life. For the more severe cases, more extensive psychological care would be needed. In a recent paper, it has been proposed that life-crafting can also be delivered using artificial intelligence, through a chatbot (Dekker et al., 2020). By using a chatbot, the intervention can be tailored to the individual's needs, and can also be extended with other online psychological interventions aimed at improving mental health, such as cognitive behavioral therapy. We expect that such online tailored interventions would be sufficient for the large majority of the general population and could also be of (temporary) help for individuals with more severe problems, awaiting further professional psychological care.

To conclude, we propose that a life crafting intervention can help individuals to rediscover meaning in life, defined as a sense of purpose and significance (Martela and Steger, 2016), after this has been shattered in a grief-like situation. We expect that a renewed sense of meaning can help people cope with this collective trauma and hopefully resolve their grief over the loss of normalcy.

AUTHOR CONTRIBUTIONS

EJ, NZ, and MS equally contributed to the conceptual conception of the manuscript. EJ and NZ have written the draft of the manuscript. MS provided important intellectual input at all stages and reviewed and revised the manuscript. All authors contributed to the article and approved the submitted version.

ACKNOWLEDGMENTS

The authors would like to thank Hatice Caglayan and Gabrielle Martins Van Jaarsveld for their assistance with the literature search and formatting of the manuscript. The authors would also like to thank them and Izaak Dekker for their helpful comments on earlier versions of this manuscript.

The outbreak of COVID-19 has spread to the entire world and is severely affecting social psychology. We conducted semi-structured interviews on 59 subjects from India to investigate the impact of information, misinfodemics (spread of wrong information), and isolation on their psychology. We perform qualitative analysis on the data. Our findings reveal that flow of information leads to anxiety, caution, and knowledge; while misinfodemics cause panic, distrust, and confusion; and isolation creates cognitive dissonance (the state of having inconsistent thoughts, beliefs, or attitudes) and adaptability among masses. The encouraging part of our findings is that, as of now, the situation is far from the state of depression. Practically, our research calls upon the government to support the masses in fighting through the crisis by focusing on pointed psychological counseling. We contribute theoretically to the body of knowledge in the field of social psychology, which is studying the psychological interventions to avoid panic amid pandemic. Future researchers in the area would do well by detailing the psychological interventions required to contain the negative impacts of the pandemic on social psychology.

Keywords: COVID-19, social psychology, semi-structured interviews, cognitive dissonance, depression

INTRODUCTION

The coronavirus disease (COVID-19), which emerged in Wuhan (China) in December 2019, has spread throughout the world, infecting 2.5 million people and causing 179,000 deaths (as on 21 April 2020) (Worldometers, 2020).[1] COVID-19, declared a pandemic by the World Health Organization in March 2020, is generating stress among masses across the world (World Health Organization, 2020). As it is a new virus, the mechanism of action of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is relatively novel and no cure is currently available.

[1] www.worldometers.info

COVID-19 is an ill-defined problem for the masses (Minda, 2015) and, therefore, people are likely to be influenced by fake news and myths, against which the WHO is actively coping. More than the disease itself, conventional media and social media channels are causing public stress (Depoux et al., 2020; Lima et al., 2020; World Health Organization, 2020). Given the highly contagious nature of the disease, patients are being quarantined or isolated immediately on being tested positive (Bobdey and Ray, 2020; Wang et al., 2020). Social relationships, interactions, and gatherings are integral to human life. However, due to the rapid spread of COVID-19, this critical component of human existence has been severely impacted and compromised, which has further increased stress and anxiety at the individual level. The absence of social interactions leads to overwhelming stress, depression, a state of panic, mental instability, and reluctance to work both at individual and community levels (Brooks et al., 2020). While medical and preventive interventions are of utmost importance at this stage, psychological interventions both at individual and social levels are incredibly critical as the human mind inevitably tries to bring structure to the sensory world (Minda, 2015).

Given the novelty of COVID-19 outbreak, the resultant responses, and actions needed to handle the crisis, this paper attempts to report the socio-psychological impact of the outbreak. The focus of this study is in line with Levin's ideas of focusing on the subjective perceptions of individuals (Fiske and Taylor, 2017) rather than performing an objective analysis.

India is the country with second largest population in the world. The outbreak of COVID-19 in India was rather late as compared to other countries, but it has picked up really fast and reached a critical stage as on date (**Figures 1**, **2**). Given the high density of population in the country, the spread of the virus may take a threatening position for the entire world.

The study aims at capturing and measuring the psychological impact of COVID-19 on individuals and their social environment. In addition to COVID-19 infection, the world at large is experiencing mental health crisis, to which India is no exception. The major stressors associated with COVID-19 are social isolation, job loss, threat of infection, etc. These stressors are observed to have an impact on mental well-being of individuals, which leads them to approach the psychologists. Therefore, for the purpose the study, we included psychologists as the prominent category, since they would be able to provide the information not only on their own behalf but also share the experiences of their clients. In India, service sector is one of the badly effected sectors due to COVID-19, as the overseas orders have fallen significantly leading to a threat of job losses (Dhama et al., 2020). Therefore, we have given fair representation to the service sector professionals, and software experts in our study. Businessmen faced the economic consequences of this pandemic and the prolonged lockdowns by incurring unprecedented losses, due to which we included businessmen as subjects in our study. The deep correction in stock markets was observed to cause panic among the financial investors in India. To include the viewpoint of financial investors, we recruited financial consultants. We also recorded the trauma of isolation by recruiting the quarantined people. Other essential services, which were working through this period included doctors, media persons, bankers, social workers, defense personnel, insurance agents, and housekeeping staff, leading us to recruit some participants from these services. We also recruited the professionals whose work suffered heavily during this period, and their jobs were put under risk. These included educationists, artists, and graphic designers. Since spiritual healing is extensively used in India for psychological counseling, we also recruited a spiritual healer.

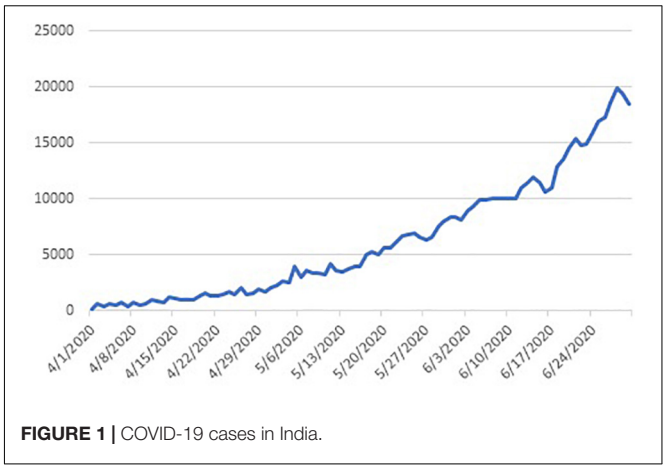

FIGURE 1 | COVID-19 cases in India.

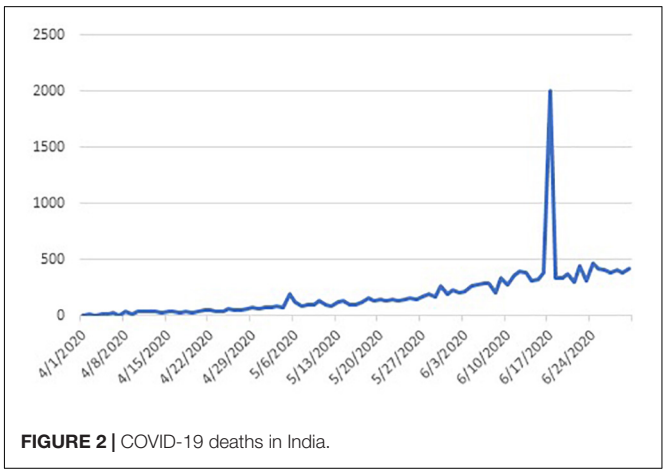

FIGURE 2 | COVID-19 deaths in India.

Based on the psychological challenges being reported by the above-mentioned classes of people, we attempt to address the following research questions.

> RQ 1: What is the impact of COVID-19 information presented by media on social psychology in India?
> RQ 2: What is the impact of misinfodemics (spread of an epidemic/disease through misinformation) on social psychology in India?
> RQ 3: What is the impact of quarantine and isolation on the psychology of Indians battling COVID-19?

We focused on the socio-psychological impact as the understanding of people's perception of COVID-19 is as important as the disease itself and accounts for the individuals' construction of the situation (Fiske and Taylor, 2017). By addressing the above research questions, we make a theoretical

contribution to the field of social psychology in line with the work of Levin. In addition, our findings are of practical relevance for the policymakers engaged in minimizing the negative impacts of the pandemic on social psychology in India and other nations.

Rest of the paper is organized as follows. The next section outlines the methodology of our study, the third section discusses our results, and the last section concludes.

MATERIALS AND METHODS

The methodology of our qualitative study is in line with the COnsolidated criteria for REporting Qualitative research (COREQ) guidelines. The COREQ checklist for the study is available as **Supplementary Annexure 2**.

Sampling

We used a qualitative design based on semi-structured interviews (on an organic schedule) using purposive sampling to carry out our research objectives. Using the data saturation strategy as suggested by Charmaz (2014), we stopped on learning (at 59 participant) that no new information or themes are emerging in the data (Guest et al., 2006, p. 59).

One of the authors of this paper is a clinical psychologist by profession, and had information about the psychological counsellors who were providing counseling services to the above categories of people during the pandemic. Through this network, key counsellors were identified and recruited for the study. Using the leads from these counsellors, as also some other relevant networks, professionals from other sectors were contacted through emails (as the physical interviewing was not possible due to lockdown). Our respondents included the following–

Psychologists	12
Service sector professionals	09
Software experts	09
Businesspersons	04
Financial consultants	03
COVID-19 positive and quarantined	02
COVID-19 negative but quarantined	04
Media professionals	03
Artists	02
Educationists	02
Social workers	02
Banker	01
Insurance advisor	01
Spiritual healer	01
Doctor	01
Graphic designer	01
Housekeeping staff	01
Defense personnel	01

Data Collection

The data were collected by a professional clinical psychologist (details available in **Supplementary Annexure 2**). As deductive qualitative approach allows the inclusion of many different kinds of data collection and analysis techniques, we used a thematic analysis to gain an in-depth understanding of the phenomenon of interest. The qualitative approach adopted was to delineate the psychological impact of isolation and COVID-19 information provided by media on social psychology in India.

Semi-structured interviews were conducted with 59 selected participants from India. The respondents were aware about SARS-CoV-2 and the COVID-19 pandemic and are under the state of lockdown since 26 March 2020. We interviewed the participants and asked open-ended questions expanded from the primary research questions. The participants expressed their experiences, views, and feelings about the impact of isolation as well as COVID-19 information presented by media. The interviews lasted for 30–45 min and were audio-recorded and transcribed verbatim.

Data Coding/Code Development

The unit of analysis was "interviews." The coding unit "sentences" was used throughout the coding phase. An attempt was made to establish relevance based on meaning rather than just frequency. The coding units were copied and pasted to the memo "coding process" and were read and checked for sense and contextuality. Following the five elements of a good thematic code, a code book was written to define each code using a label (name), definition of the theme, description that flags when the theme is likely to occur, inclusion and exclusion criteria, and examples of occurrences of the theme (refer to **Supplementary Annexure 1**) (Boyatzis, 1998). The coding scheme used was theory-driven.

Data Analysis

Deductive pattern seeking was used as a method of scientific reasoning. Within this context, we proposed that COVID-19 information presented by media leads to anxiety and knowledge enrichment among viewers, while isolation leads to cognitive dissonance and adaptability.

RESULTS AND DISCUSSION

Our study focused on examining the (a) impact of COVID-19 information presented by media on social psychology in India, (b) impact of misinfodemics (spread of an epidemic/disease through misinformation) on social psychology in India; and (c) impact of quarantine and isolation on the psychology of Indians battling COVID-19. We followed the stopping rule for qualitative investigations as advocated by Charmaz (2014). In line with Guest et al. (2006, p. 59), we continued to recruit the participants till new information or themes kept on emerging. From 57 participant, we started observing that the data saturation has arrived on all the themes other than cognitive dissonance. For the theme of cognitive dissonance (in response to the RQ3), the data saturation was observed at 59 participant, leading us to stop recruiting the participants.

In this section, we present the results and discuss them in accordance with the research questions. In addition, we present

the relevant quotes from the subjects with regard to the research questions and the themes in **Supplementary Annexure 1**. **Figures 3–5** are concept maps of the responses of subjects.

Impact of the Information About COVID-19 Presented by Media on Social Psychology in India

Based on the responses that were received from the subjects, the impact of COVID-19 information presented by media on the social psychology in India can be classified into three themes— (a) anxiety; (b) knowledge; and (c) neutral. These themes were identified based on the responses of the subjects in **Supplementary Annexure 1**.

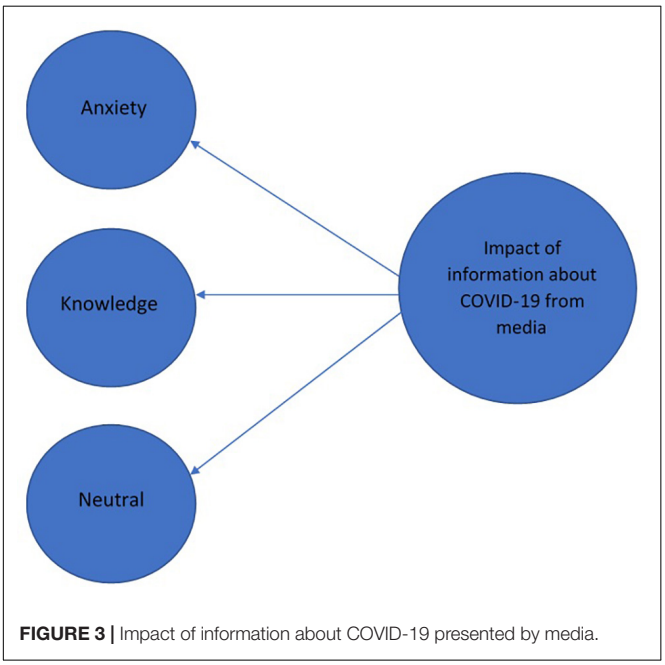

FIGURE 3 | Impact of information about COVID-19 presented by media.

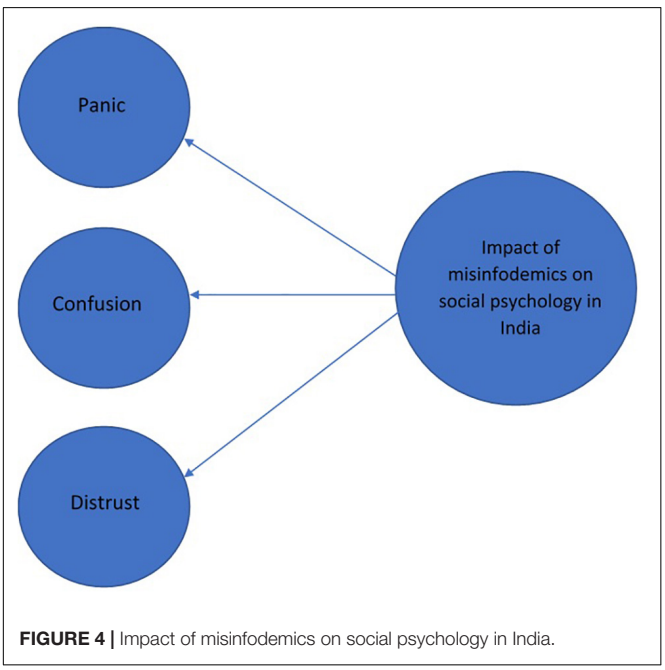

FIGURE 4 | Impact of misinfodemics on social psychology in India.

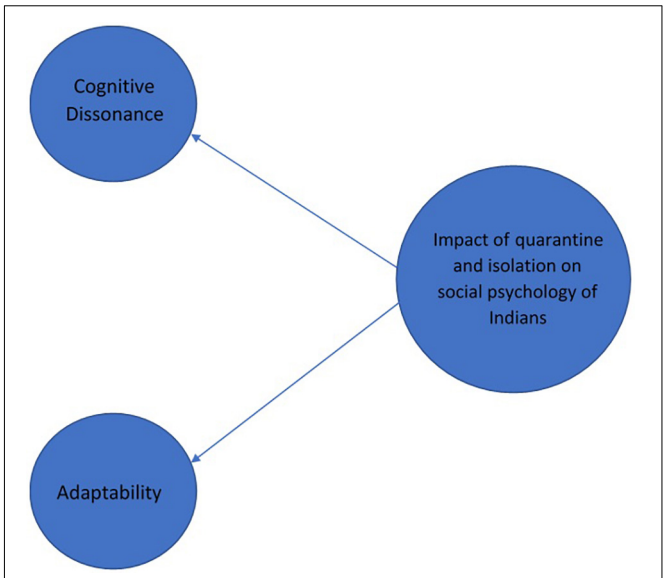

FIGURE 5 | Impact of quarantine and isolation on social psychology of Indians.

India is under lockdown (a 21-day lockdown, followed by an extension of 19 days) since 24 March 2020 (BBC News, 2020a,b), due to which the availability of physical sources of information are limited, underlining the role of media in sharing information regarding COVID-19 (Happer and Philo, 2013). Information shapes social psychology and public opinion, therefore, individuals having negative belief apropos media feel that misinformation causes anxiety and depression (Yuan et al., 2020). However, it is challenging to measure the myriad of misinformation (Nawrat, 2020). The disagreement among different sources of information leads to ambiguity in general public.

It appears that some of our respondents believe the information (**Supplementary Annexure 1**) and treat it as a significant contributor to their knowledge. According to them, information is a vehicle that helps masses sail through the crisis by serving as a liaison between people and the government. The information also cautions masses about the consequences of committing mistakes. Through experiential sharing, the media makes people appreciative of social distancing and makes them aware of the administrative and infrastructural arrangements. However, during these testing times, media needs to play a responsible role in creating public opinion, failing which, people may develop negative opinion toward this important pillar of society (World Health Organization, 2016).

India is broadly an informal economy filled with migrant labor (Chandrasekhar and Ghosh, 2020). The lockdown has resulted in job losses for thousands of migrant laborers, who were left with no option but to walk till their hometowns, leading to lockdown violations (Rising, 2020). Worries of the masses are

further aggravated by the fear of uncertainty regarding economic security resulting from the potential job losses due to lockdown and the long-term effects of COVID-19 (Chandrasekhar and Ghosh, 2020; Goyal, 2020).

Altogether, the impact of media on the social psychology of a majority of people was found to be negative (causing anxiety), while it was neutral (causing caution) and positive (causing knowledge enrichment) in a few cases. The role of media is immensely significant during these testing times as people need to be precisely informed about the do's and don'ts in order to be sufficiently prepared to deal with the pandemic. As a result, the negative and neutral feelings of anxiety and caution, respectively, may get transformed positively into knowledge enrichment (Fiske and Taylor, 2017). The policy interventions at the level of governmental and non-governmental bodies may be directed at ensuring the timeliness and precision of the information flow regarding COVID-19 (Roy, 2020).

Impact of Misinfodemics on Social Psychology in India

Misinfodemics refers to the spread of false information during a pandemic with or without any maleficent intention (Drexler, 2019). While the information is reliable for the most part, it can be inaccurate at times. The spread of misinformation worsens the impact of the pathogen and creates a feeling of uncertainty amongst individuals (Drexler, 2019; Banerjee, 2020). Furthermore, the uncertainty generates ambiguity and creates a situation of (a) panic, (b) confusion, or (c) distrust among masses.

In our study, we also observed that the respondents were agitated and frustrated, which is detrimental to their mental well-being. Concurrently, amidst the pandemic, conventional public health responses are not enough to supersede these contemporary digital sources. Online connectivity makes people xenophobic toward the infected ones, and they may take wrong medications that affect their physical as well as mental well-being. It is often found that the availability of precise and timely information plays a positive role in building a harmonious situation.

The lockdown of major economic activities in India has caused a steep fall in the agricultural, manufacturing, and service activities in the country (Bloomberg, 2020a; Business Today, 2020; BusinessLine, 2020; Goyal, 2020). The spread of unreliable information about lockdown and its impact on the national economy, the resultant job losses, and slowing down of the economy further affect social psychology in the country (Madhav et al., 2017; Bloomberg, 2020b; McKibbin and Fernando, 2020; Roy, 2020). This uncertainty adds fuel to the fire by causing chaos and confusion among masses, leading to irrational decision making. For instance, the misinformation regarding working of public transport in Mumbai led to a stampede at a train station (NDTV, 2020). All these factors are responsible for causing a feeling of distrust among masses, thus significantly hampering social psychology. Similarly, in the past also, misinfodemics have affected the treatment and renormalization of depression, even leading to suicides. Certain cases of suicide have also been reported in India as a result of the panic caused by COVID-19 (Ojha, 2020). It is indispensable for media to compile and publicize accurate information, and therefore, the masses need to exert some control over the information and forward it responsibly.

Impact of Quarantine and Isolation on the Social Psychology of Indians Battling COVID-19

Our findings reveal that quarantine and isolation are causing (a) cognitive dissonance or (b) adaptability in Indians. Amidst the pandemic, individuals are experiencing swelling of health, economic, and humanitarian crisis through every dimension of their social fabric. The way people bounce back from the state of cognitive dissonance to the state of adaptability as a result of the pandemic and restrictions resulting from the pandemic suggests that the society is moving toward a new normal Initially, the individuals were found to resist such a situation due to mobility constraints and the fear of no escape and losing their livelihood. However, in the course of time, it appears that they are willing to perform multiple tasks. Another fear among masses was the compulsion to stay together with their families without having any outlet to move out for long. This belief arouses the feeling of restlessness, confusion, frustration, and stress, due to which, people tend to lose trust in the system, leading to deterioration of their mental well-being.

On the positive side, these conditions have developed the idea of appreciative inquiry among masses, as they are able to appreciate that their captivation will effectively help in controlling the disease. Individuals, during self-quarantine, feel that social distancing has given them an opportunity for psychological explorations and developing their intelligence- and emotional-quotient. For instance, they have ample time to spend with themselves, their family, and in natural surroundings, and they are able to acknowledge the fact that psychological communication is the key to bonding. The masses are also able to admire the idea of achieving a work–life balance and look forward to innovative ways of working from home.

CONCLUSION

This paper contributes to the theoretical field of social psychology by addressing the subjective perceptions of our respondents, and holds practical significance by informing the policymakers on tackling the panic amid pandemic. The semi-structured interview-based qualitative analysis conducted through this study on a sample of 59 subjects revealed that information, misinfodemics and isolation emerge as three prominent factors impacting the social psychology of Indians during the COVID-19 outbreak. We found that flow of information leads to anxiety, knowledge, and neutral approach in India. The governments may address the flow of information in interest of transparency, so that the outcomes in the form of anxiety and neutral approach may shift toward knowledge, thereby leading to management of the pandemic in a more effective manner. The sources of information

in these critical times are limited, and the reliability of those is also questionable, which is reflected from the panic emerging from the misinfodemics. We suggest that to avoid panic in such critical times, the policymakers need to focus on misinfodemics, which are a result of fake news, in general. The encouraging fact of our study is that isolation is not observed to drive toward critical psychological patterns, such as depression. Rather, isolation drives Indians toward cognitive dissonance and adaptability, which is a sign of psychological strength. The governments need to plan the psychological interventions in such a way that the citizens can productively utilize the period of isolation.

Risk Factors and Mental Health Promotion Strategies in Children During COVID-19

Keywords: risk factors, COVID19, mental health, children, strategies

Since 5 March 2020, the Italian government has ordered a nationwide school closure as an emergency measure to prevent diffusion of the infection. The emergency home-schooling plan has been strictly implemented thanks to the hard work of schools and teachers to create online courses. Furthermore, in a first step, public activities were discouraged, and now, they are firmly forbidden. Researchers have established that such measures should have both negative psychological and physical effects on children. Stressors, such as prolonged duration; fears of infection; frustration and boredom; inadequate information; lack of in-person contact with classmates, friends, and teachers; lack of personal space at home; and family financial loss can have even more problematic and lasting effects on children and adolescents (1).

Evidence suggests that when children are out of school (e.g., weekends and summer holidays), they are physically less active, have much longer screen time, have irregular sleep patterns, and have less favorable diets. Such negative effects on mental health are expected to be much worse when children are confined to their homes without outdoor activities and interaction with friends of the same age (3), which are essential for their normal psychological development and well-being. The uncertainty about the personal and global effects of COVID-19 is creating great concern, in addition to the specific psychological effect of quarantine (2). Some children might be separated from their parents due to the infection. Parental separation pushes children into a state of crisis and might increase the risk of psychiatric disorders, as well as a higher risk of developing mood disorders, psychosis, and death by suicide in adulthood (2). The age of the initial separation is known to be relevant to psychological development disrupting the ongoing attachment processes with significant outcomes if this happens in the first year after birth (3). In this rapidly changing situation, children are experiencing substantial changes to their daily routine. At the same time, they are exposed to large amounts of information and high levels of stress and anxiety in the adults around them (2). Sprang et al. (4) reported that children who were isolated or quarantined during the influenza A (H1N1) pandemic in 2009 were more likely to develop acute stress disorder, adjustment disorder, and pain. Conversely, anxiety in children and adolescents can also manifest itself in challenging externalizing behaviors, such as acting or arguing (3). In Sprang's sample, 30% of children who were isolated or quarantined met the clinical criteria for posttraumatic stress disorder (PTSD) (4). Adult concern about the implications of COVID-19 could impair their ability to recognize and respond to children's ideas or distress (4).

It should be stressed that children may respond in a different way to an outbreak depending on their age. In this respect, the National Child Traumatic Stress Network (NCTSN) has suggested some reactions according to age group, assuming that preschoolers might manifest fear of staying alone, bad dreams, speech difficulties, loss of bladder/bowel control, constipation, bed-wetting, change in appetite, increased temper tantrums, whining, or clinging behaviors. School age children (ages 6–12) might be irritable, plaintive, or aggressive; have nightmares or sleep/appetite disturbance; and show physical symptoms (headaches, stomach aches), withdrawal from peers, loss

of interest, competition for the attention of parents, and forgetfulness of household chores and new information learned at school.

Lastly, adolescents (ages 13–18) may complain of physical symptoms (headaches, rashes, etc.), sleep/appetite disturbance, agitation, decrease in energy, or apathy, as well as ignore health promotion behaviors, isolate from peers and loved ones, be concerned about stigma and injustices or avoid/cut school. In this particular contingency, children are exposed to unexplained and unpredictable behavior, which can be perceived as a threat, resulting in a state of anxiety (3). Children are well-attuned to the emotional states of adults; indeed, a strong relationship was found between clinically significant levels of PTSD symptoms in parent respondents and their children; nearly 86% of responders had children who also met the clinical cut-off score (4).

Mental health responses to previous emergencies and disasters have included widespread psychological first aid, focusing on psychoeducation about normative reactions and coping strategies.

Promotional videos can be useful to motivate children to have a healthy lifestyle at home by increasing physical activities and having a balanced diet, regular sleep pattern, and good personal hygiene (1). These are expected to help maintain a daily routine and cope with this difficult moment. In the event of home confinement, parents are often the best and closest resource for children to ask for help; children need honest information about changes; when this information is absent, children try to make sense of the situation on their own (1, 2). They are constantly exposed to news related to the epidemic, so having direct conversations with children about these issues could mitigate their reactions, such as anxiety and panic. Close and open communication with children is also the way to identify any physical and psychological problems, comfort them, and resolve them (1). We agree with Liu and colleagues who propose that pediatric health professionals should receive training to facilitate early identification of children's mental health problems by learning to discern their normal and abnormal behaviors and to use rapid screening tools for mental health (3). Additionally, it is important to consider postpandemic surveillance of mental disorders among these children, remembering that the identification of PTSD or other mental health disorders in parents should trigger an investigation of behavioral health disorders in their family members.

Galli F, Pozzi G, Ruggiero F, Mameli F, Cavicchioli M, Barbieri S, Canevini MP, Priori A, Pravettoni G, Sani G and Ferrucci R (2020) A Systematic Review and Provisional Metanalysis on Psychopathologic Burden on Health Care Workers of Coronavirus Outbreaks. Front. Psychiatry 11:568664. doi: 10.3389/fpsyt.2020.568664

Background: The new coronavirus (SARS-CoV-2) shows several similarities with previous outbreaks of Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS). Aim of this systematic review and meta-analysis is to provide evidence of the psychopathologic burden on health care workers (HCWs) of the first two deadly coronavirus outbreaks to get lessons for managing the current burden of COVID-19 outbreak.

Method: According to Cochrane Collaboration guidelines and the PRISMA Statement, the study quantified the effects of frontline work on mental health of HCWs. Major databases — Pubmed, Scopus, Embase, Medline, and Web of Science — were searched for observational and case-control studies evaluating mental health indexes reported by front-line work. This study computed the percentage of sample that reported clinically significant levels of psychiatric symptoms. Cohen's *d* was used for comparing mental health outcomes of health care workers directly involved in addressing pandemic emergency with a control group that was not directly exposed to such conditions. Pooled effect sizes (d_w) were estimated whenever at least three independent studies yielded data. Heterogeneity of findings and bias of publication were estimated as well.

Findings: Fifteen studies have been selected for a total of 7,393 HCWs. From 9.6% to 51% of HCWs reported symptoms of Post-Traumatic Stress Disorder (PTSD) and from 20% to 75% reported psychiatric symptoms, with a prevalence of anxiety and depression. From one to the three years after outbreak, from 2% to 19% reported PTSD symptoms and from 5% to 90% psychiatric symptoms. Interestingly, HWCs who were directly involved in pandemic emergency showed significantly higher depressive and anxious

symptoms (d_w = .66 (.46–.85); p <.001) than ones who were not directly exposed. Similarly, the direct involvement significantly affected the severity of PTSD symptoms (d_w = .30 (.21–.39); p <.001).

Conclusion: Health care professionals in general and most of all frontline workers showed an association with a likely risk of developing psychiatric disorders following outbreaks and for at least three years later. Mental health interventions for professionals exposed to COVID-19 need to be immediately implemented. Further studies are warranted to investigate long-term consequences carefully, and to look for mediating and buffering factors as well. The role of clinical psychologists and psychiatrists in delivering adequate interventions is critically important.

Keywords: Post-Traumatic Stress Disorder, anxiety, depression, psychological distress, "health care worker"

INTRODUCTION

Several viral diseases have emerged and impacted healthcare systems worldwide. Apart from the pure medical response, a major issue in dealing with viral pandemic is the human aspect.

The novel coronavirus infection (SARS-CoV-2) and related syndrome (COVID-19) was first identified in Wuhan, China, in December 2019 (1), with a declaration of pandemic on March 11, 2020 (2). Previous coronavirus outbreaks resulted in a major global public crisis. In November 2002, in China's Guangdong, Severe Acute Respiratory Syndrome (SARS-CoV) was first detected. It lasted 80 days (from mid-March 2003 till 31 May 2003) when Singapore was removed from the World Health Organization (WHO) list of SARS (3). SARS was characterized by atypical pneumonia and droplet transmission.

The SARS outbreak had an important concentration in health care settings and a large number of health care workers who have been infected, with an estimate of more than 20% of those who contracted the disease (3). During the SARS outbreak, more than 8,000 individuals in 29 countries were infected over 7 months (4).

After the emergence of SARS, the Middle East Respiratory Syndrome (MERS-CoV) was the second coronavirus infection resulting in a major global public health crisis. It first emerged in 2012 in Saudi Arabia (5, 6), with an outbreak infection occurring in Korea from May to December 2015. The virus caused a total of 2,279 cases from 27 countries, till the end of February 2019 (7), with health care workers who continue to be at higher risk of being affected (1).

The COVID-19 showed several similarities with the SARS, and MERS, about the clinical presentations, which can vary from asymptomatic infection to severe or fatal disease and it is highly transmissible. The most common onset symptoms of the COVID-19 include fever, dry cough, muscle pains, lethargy and fatigue. However, the spread of COVID-19 infection is much broader than SARS or MERS and involves larger numbers of patients (8). From now, COVID-19 killed a higher number of people than MERS and SARS together, in spite of a fatality rate around 2%, compared to a case fatality rate of around 10% for SARS, with 34% of affected people killed by MERS between 2012 and 2019 (9).

All the physicians and nurses embedded in emergency care are under extreme psychological pressure and are at high risk of developing psychological diseases, with protracted working hours and unexpected changes in the sort of work (10). This situation may result in severe psychological distress and could lead to burnout (11). The analysis of the psychopathologic burden of previous outbreaks may help to understand the likely consequences for HCWs of the current pandemic of COVID-19, to plan psychological interventions and prevent future negative outcomes.

The objective of our study is to provide a systematic review of the psychological and psychopathological burden on HCWs of the two first deadly coronavirus outbreaks (SARS and MERS).

METHODS

The objective of this systematic review is to analyze all observational studies realized on the burden on mental health of caring for patients affected by MERS and SARS. The case-control study design, adequacy of sample size, comparison and outcome measures have been all carefully analyzed to guarantee the right inclusion of selected studies.

Search Strategy

Electronic searches were conducted on the major databases in the field of health and social sciences — Pubmed, Scopus, Embase, Medline, and Web of Science — in order to include the broadest range of relevant literature.

The selection of the search terms is based on the clinical experience and the topic literature on mental health (12). The search was performed using Mesh terms/Keywords (depending on the database) with the same search strategy: "Health Worker" AND "Epidemic" OR "MERS" OR "SARS" OR "Outbreak" AND "Depression" OR "Anxiety" OR "Burnout" OR "PTSD" OR "Suicide".

The search was limited to English-written publications, and to the period from 2002 to April 2020. When the full text was not retrievable, the study was excluded. Study selection was performed by independent reviewers with research expertise in clinical psychology who assessed the relevance of the study for the objectives of this review (**Figure 1**).

An additional analysis of the reference list was performed in each selected paper as well. When the full text was not retrievable, the study was excluded. It has been selected a final number of fifteen studies.

Inclusion Criteria:

- Studies should report data on mental health indexes linked to epidemic infections (SARS, MERS).
- Studies with an analytical study design as defined by Grimes and Schulz (13) (i.e., an observational study with a comparison or control group).
- Studies adopting standardized and validated instruments to assess psychological factors.
- Studies written in English.

Exclusion Criteria:

- Case reports, reviews, Letters to the Editor.
- Number of subjects per group ≤5.
- Qualitative studies.

Data Extraction

Study selection was performed by independent reviewers with research expertise in clinical psychology (FG, FM, RF) who assessed the relevance of the study for the objectives of this review. This first round of selection was based on the title, abstract, and keywords of each study. If the reviewers did not reach a consensus or the abstract did not contain sufficient information, the full text was reviewed.

In the second phase (screening), full-text reports have been evaluated to detect whether the studies met the inclusion criteria (**Figure 1**). In the phase of eligibility, full texts have been retrieved, and a final check was made to exclude papers not responding to inclusion/exclusion criteria, and reaching the final consensus to decide the final number of studies to be selected.

A standardized data extraction form was prepared; data was independently extracted by two of the authors (FG and RF) and inserted in a study database (Cohen's k = .85) (14).

A process of discussion/consensus moderated by a third reviewer (GP) (15) resolved discrepancies between reviewers (for three studies).

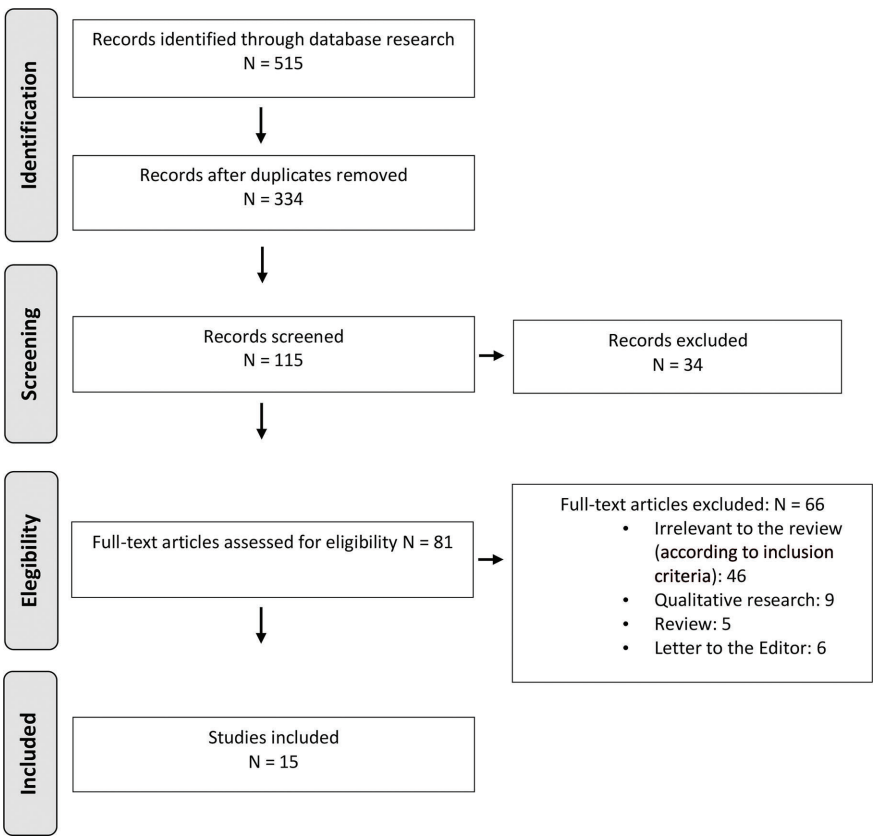

FIGURE 1 | PRISMA flow diagram of literature search and selection of publications.

Statistical Methods

A systematic analysis was conducted according to the Cochrane Collaboration guidelines (15) and the PRISMA Statement (16). The current review provided a quantitative approach for aggregating results of studies considering as the main outcomes the percentage of sample that reported clinically significant levels of overall and specific psychiatric symptoms (i.e., PTSD, depression and anxiety) (**Figures 2–4**) (for a description of cut-off scores see **Table 1**). Furthermore, this work aims at quantifying mental health consequences of the direct exposure to clinical management of pandemic emergency. Accordingly, meta-analytic procedures were conducted comparing levels of different mental health outcomes of health care workers directly involved in addressing pandemic emergency to a control group that was not directly exposed to such conditions. Cohen's *d* (32) was used as measure of effect size. Cohen's *d* was primarily calculated using descriptive statistics reported in the Results section of each study. Values of Cohen's *d* less than or equal to.20,.50, and.80 were interpreted as small, moderate, and large effect sizes, respectively (32). The overall pooled effect sizes (*dw*) for each mental health outcomes were estimated using the weighted mean of *d* value for each study (33, 34). The 95% confidence interval (CI) was computed, as was its significance according to the ratio of pooled effect size to the standard error (33, 34). Pooled effect sizes were estimated whenever at least three independent studies yielded data. Heterogeneity in effect sizes was computed using the *Q* statistic (34) and I^2 index (14, 35). Excel was used to compute these metrics.

Despite the small number of studies for each outcome, Egger's regression (i.e., the standard normal deviate [SND] is regressed against the estimate's precision, defined as the inverse of the standard error; SND = a + b × precision) (36) was performed to detect publication bias. These analyses were conducted using SPSS 22.

Risk of Bias

The current systematic review assessed quality of studies included using the rating scale developed by the National Institutes of Health for observational cohort and cross-sectional research designs (37). This scale is composed of 14 items rated on three levels (i.e., Yes; No; Cannot determine/Not applicable/Not reported [CD, NA, NR]) where a "no" or "undetermined" response indicates the presence of possible bias. The quality of each study was independently assessed by two authors (GP and FG), who reached a high inter-rater

reliability (Cohen's k = .89). At the end of the evaluation, ratings of each study were summed up within each item in order to provide a quantitative approach to the assessment of risk of bias. Given the number of studies included in this review, the total score (i.e., 210) was divided in three subscales capturing strengths (i.e., Yes responses), biases (No responses) and qualities not applicable (NA response). For a detailed description of results of these procedures, see **Table 4**.

RESULTS

A total of 7,393 HCWs has been scrutinized by the all studies (**Table 1**). Descriptive analysis of the all studies are reported in **Table 2**. Data are drawn from survey with voluntary and anonymous participation with a response rate ranging from 19.9% to 92%. Only one study (20) determined the clinical picture of participants by a diagnostic interview by DSM criteria (12). The most part of the studies (17–19, 22, 23, 26–29) measured the level of psychological distress during or immediately after the outbreak. From 9.6% to 51% of HCWs reported symptoms of PTSD and from 20% to 75% reported the prevalence of anxiety and depression, respectively. The other studies (20, 21, 24, 30) rated psychological distress from one to three years after outbreak. PTSD symptoms were detected from 2% to 19% and from 5% to 90% reported psychiatric symptoms at follow-up. One study (38) reported in 19%–30% of HCWs significant levels of burnout. Only one study (19) comparing HCWs and healthy subjects did not report significant findings on the self-rating of perceived stress level. Only few studies compared the psychological burden of the outbreak comparing doctors and nurses: three did not find any differences (17, 26, 29), two reported a higher occurrence in nurses (28, 37) and the last one (22) a trend for nurses (**Table 1**).

TABLE 2 | Summary of descriptive statistics of studies included (*N* = 15).

Variable	*N*	%
Total sample	7,766	
Doctors	577	7.4
Nurses	3,171	40.8
Other health care workers	1,306	16.8
Not specified	2,712	35.0
Singapore	3	20.0
Taiwan	2	13.3
Hong Kong	4	26.7
Canada	3	20.0
South Korea	1	6.7
Beijing	2	13.3
SARS	14	93.3
MERS	1	6.7
Cross-sectional and case-control	7	46.7
Cross-sectional	4	26.7
Case-control	4	26.7
General psychiatric symptoms	8	53.3
PTSD symptoms	10	66.6
Depression and anxiety symptoms	4	26.7
General psychological distress	4	26.7
Burnout	2	13.3
Mean of clinically relevant psychiatric symptoms	8	35.92 (19.17–52.67)
Mean of clinically relevant PTSD symptoms	8	17.24 (7.02–27.47)
Mean of clinically relevant depression and anxiety symptoms	2	6.4 (1.70–11.10)

Some studies (17, 20, 24, 26, 38) analyzed the buffering factors for the burden of outbreak on psychological distress. Protective factors were clear communication of directives/precautionary measures, support and training from supervisors/colleagues, years of health care experience and altruism; risk factors for depression were having been quarantined, high work exposure, current stressful job, high PTSD symptoms and pre-SARS trauma exposure.

Considering aggregated results, eight studies showed that up to 35% (95% CI: 19.17–52.67) of HCWs reported clinically significant levels of general psychiatric symptoms during and after pandemic emergency. Interestingly, pooled effect size (d_w = .07 [−.11–.26]) did not highlight significant differences between HCWs who were and were not directly involved in addressing medical emergency. This evidence was consistent across studies included ($Q_{(2)}$ = .16; *ns;* I^2 = .00%). With respect to PTSD symptoms, the analyses found that 17% (95% CI: 7.02–27.47) of HCWs developed clinically significant symptoms of this conditions. Furthermore, the direct involvement in the management of pandemic emergency significantly affected the severity of PTSD symptoms (d_w = .30 (.21–.39); p <.001), even though the heterogeneity across studies were large (I^2 = 72.05%) and significant ($Q_{(6)}$ = 27.41; p <.01). Overall, clinically significant depressive and anxious symptoms were reported by up to 6% (95% CI: 7.02–27.47) of HCWs. Nevertheless, the HWCs who were directly involved in addressing pandemic emergency showed significantly higher depressive and anxious symptoms (d_w = .66 (.46–.85); p <.001) than ones who were not directly exposed to the medical emergency. This finding was consistent across studies ($Q_{(2)}$ = 2.93; *ns;* I^2 = 31.78%).

Ultimately, Egger's regression coefficients did not detect bias of publication for the previous indexes (**Table 3**). **Table 4** reported the rating of the risk of bias. Overall, the reviewed studies showed specific weaknesses in the participation rate, definition and measurement of exposure, and control of confounding variables. Anyhow, we must bear in mind that these real-world studies were performed in emergency contexts, and therefore their quality is acceptable though just sufficient from a methodological point of view.

TABLE 3 | Pooled effect sizes concerning the effects of direct exposure to pandemic emergency.

Outcome	*N* direct exposure	*N* control subjects	*N* studies	d_w (95%CI)	*Q* (df)	I^2	Egger's coefficient(95% bootstrap CI)

TABLE 4 | Assessment of risk of bias (*N* = 15).

Criteria	Yes	No	NA/ NR
1. Was the research question or objective in this paper clearly stated?	14	0	1
2. Was the study population clearly specified and defined?	15	0	0
3. Was the participation rate of eligible persons at least 50%?	8	4	3
4. Were all the subjects selected or recruited from the same or similar populations (including the same time period)? Were inclusion and exclusion criteria for being in the study prespecified and applied uniformly to all participants?	15	0	0
5. Was a sample size justification, power description, or variance and effect estimates provided?	0	14	1
6. For the analyses in this paper, were the exposure(s) of interest measured prior to the outcome(s) being measured?	8	7	0
7. Was the timeframe sufficient so that one could reasonably expect to see an association between exposure and outcome if it existed?	15	0	0
8. For exposures that can vary in amount or level, did the study examine different levels of the exposure as related to the outcome (e.g., categories of exposure, or exposure measured as continuous variable)?	0	15	0
9. Were the exposure measures (independent variables) clearly defined, valid, reliable, and implemented consistently across all study participants?	5	10	0
10. Was the exposure(s) assessed more than once over time?	1	14	0
11. Were the outcome measures (dependent variables) clearly defined, valid, reliable, and implemented consistently across all study participants?	15	0	0
12. Were the outcome assessors blinded to the exposure status of participants?	1	0	14
13. Was loss to follow-up after baseline 20% or less?	0	1	14
14. Were key potential confounding variables measured and adjusted statistically for their impact on the relationship between exposure(s) and outcome(s)?	3	12	0
TOTAL SCORE	**100**	**77**	**33**

DISCUSSION

The COVID-19 pandemic presented as a significant challenge for healthcare services all over the world. The overload of healthcare systems for the burden of a new and unknown virus, the spread of diffusion, a significant lethality rate, and lack of definitive treatment protocols or vaccine represented some additional factors potentially influencing the psychological resources of HCWs.

Our findings evidence the likely link with mental problems of previous coronavirus outbreaks in terms of PTSD symptoms and other psychopathology (anxiety, depression, psychological distress) both in the acute phase and after a time interval in attenuated forms.

Unfortunately, almost all studies recruited convenience samples from well-defined, though small, populations reasonably due to this peculiar real-world research context. Beyond obvious problems of statistical power, sources of bias can be found in the insufficient measurement of the amount of exposure and in a poor evaluation of confounding variables (e.g. other sources of stress apart from working or not in high-risk settings, previous personal career, and so on). On the positive side, the reviewed studies highlight that evidence is not too dissimilar in various parts of the world, despite cultural and organizational differences. The most part of the studies adopted the Impact of Events Scale (IES) to detect PTDS symptoms, which have been diagnosed by a range of 20%–50% of health-care professionals. However, IES is a self-administered symptom scale to screen symptoms of PTSD. In addition, only one study (20) performed a vis-à-vis structured diagnostic interview and only 2% of subjects had a definite PTSD diagnosis after one year.

Possible psychopathological consequences of stress exposure include both specific sequelae (i.e. Adjustment Disorder, Acute Stress Disorder, Post-Traumatic Stress Disorder) and common mental disorders (e.g. Major Depressive Disorder, Generalized Anxiety Disorder, Substance-Related Disorders). Moreover, the emergence of a clinical condition among distressed individuals can be a new onset condition as well as a recurrence of previous disorders; finally, comorbid personality traits may play a role in the development of psychopathology among other predisposing factors (10). It is clear that a complete psychopathologic work-up should proceed with clinical interviews and psychometric tests, and self-administered tests on a voluntary basis may give only screening information. For this reason, we need studies assessing mental health of HCWs in a direct way, eventually adopting the cut-off of the screening tests to candidate people to the traditional procedure. Another critical point is the relevance of making follow-up study, because the cross-sectional design of most studies does not allow any prevision on the evolution of the clinical situation.

A rapid review on HCWs involved in COVID-19 pandemic (39) evidenced significant levels of distress, anxiety, depression and insomnia. Our study on previous coronavirus outbreaks adds a critical point, because we quantified the role of direct exposure to the risk of contagion (**Table 3**): if all HCWs showed a somewhat associated risk of developing psychiatric symptoms during outbreaks, only those in frontline showed a significant increased level of anxiety/depression and (then) PTSD. The wider study on HCWs involved in COVID-19 (40) had been performed in 34 hospitals of China and involved 1257 health care workers (68.7% response rate), with overall, 50.4%, 44.6%, 34.0%, and 71.5% of all participants reported symptoms of depression, anxiety, insomnia, and distress, respectively. The role of sleep disruption needs more studies, for the well-known link with psychopathology (41). Moreover, we need studies analyzing protective factors (both as institutional and personal ones) from the psychiatric outcome, to implement strategies of prevention.

A critical question is whether the health care workers who participated in these studies are representative of the entire

population of HCWs. Unfortunately, the psychological mechanism motivating an individual to participate or not to a voluntary survey is unknown. Response bias may be present if the nonrespondents were either too stressed/depressed and/or anxious to respond or not at all stressed/depressed and/or anxious and therefore not interested in this survey.

Lancee and coworkers (20) evaluated new-onset episodes of psychiatric disorders in a mixed sample of 139 HCWs by using the Structured Clinical Interview for DSM-IV and the Clinician-Administered PTSD Scale, one to two years after the SARS-1 outbreak in Ontario. They found rates of lifetime prevalence for any mental disorder before the coronavirus pandemic, which were comparable to the Canadian community samples, including a lifetime prevalence rate of PTSD even lower than that of civilian samples in North America. Only a few new-onset episodes of common psychiatric disorders were detected (5%) including just one case of PTSD specifically attributable to the SARS experience. This small investigation was performed on subjects who were still in service on a voluntary basis (roughly one in four agreed to participate), and a critical question is whether the HCWs who participated in this study are representative of their colleagues; so, it is not informative under an epidemiological perspective.

The current COVID-19 outbreak might represent a matchless opportunity to study the burden and buffering factors of pandemic virus for mental health. This, in the perspective of planning an intervention for future epidemic outbreaks, both from the side of public health services and for the implementation of education strategies also focused on working in emergencies (e.g. core curriculum in clinical/emergency psychology in school of medicine and nursing). We do not know how many of HCWs participating to the survey have had a specific training on psychological issues, but we know that a lot of them have been called to manage difficult clinical decisions with strong ethical meanings, to communicate bad news, to remain quarantined from their families and kids, while maintaining overloading rhythms of work. In Lombardy (the most part of the Authors work in Lombardy, the Italian region with the worst situation related to COVID-19) (42), some of HCWs had to face the emergency without being allowed to choice if work or not in COVID wards (sometimes with different sub-specialty expertise as the case of dermatologists or neurologists called to work in intensive care). In many cases, there was not any psychological training to work in emergency. It is clear that each factor may have had a role in predicting the level of psychological burden of the medical emergency on HCWs, and these factors should be controlled in future research. Providing psychological support to frontline workers takes over as a significant public mental health challenge over the coming weeks and months (43). Some evidence exists that altruistic acceptance of the own role (24) and institutional support and training (38) may have a role in buffering the psychopathologic outcomes. However, we need more studies on resilience factors in HCWs. Given the adverse impacts of experiencing burnout, psychological distress in the workplace, it is of great importance to investigate the potential factors and mechanisms that could enlighten the improvement of the mental health and maintenance of adequate proficiency of HCWs in the midst of the pandemic. The role of the spouses and/or familial support, capacity of self-help and using mindfulness techniques to cope with distressing situations, personality characteristics, institutional facilities (e.g. mental health support, availability of medical supplies) deserve further studies. Moreover, we need to address factors bolstering resilience. Among all the influential factors, social support is one of the protective factors for mental health for HCWs (44–46). A strong social support network can buffer feelings of isolation, strengthening resilience. Video calls and virtual meetings (or on-line group support) allow for maintenance of social relations while preserving physical distancing.

Other moderating interventions include delivery of general and medical supplies, limiting isolation to the shortest duration necessary, and emphasizing altruism as core value of the profession as much as a strong leadership with clear, honest and open communication to balance fears and uncertainties (47).

Proposals for delivering psychological support exist (48), with better chance of achieving psychological interventions when clinical psychology units are available within the hospitals (a rarity in Italy). Telemedicine may be an opportunity for offering supportive interventions intended to promote wellness and boost coping strategy (such as empathic listening, psychoeducation or supportive therapy) (47).

In synthesis, our review showed an association with a likely negative burden for mental health of HCWs in terms of PTSD symptoms and other psychopathology (anxiety, depression, psychological distress) both in the acute phase and, in some cases, after a time interval. Learning lessons from the current pandemic outbreak is imperative to prepare better strategies for new healthcare management models for the next generations of doctors, nurses and staff of health-care services.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

AUTHOR CONTRIBUTIONS

FG and RF ideated, wrote and called to collaborate the co-authors. GiP contributed to the theoretical building of the paper and wrote the parts on psychiatric issues, with a contribution in the selection of papers and quantification of the risk of bias. FR and FM made the bibliographic search. MC made the statistical analysis, giving some of the methodological indications. GaP, GS, MPC, AP supervised the all work, read and approved the manuscript. All authors contributed to the article and approved the submitted version.

Italians on the Age of COVID-19: The Self-Reported Depressive Symptoms Through Web-Based Survey

Michela Balsamo†* and *Leonardo Carlucci*†

Department of Psychological, Health and Territorial Sciences, University of Chieti, Chieti, Italy

The pandemic of coronavirus disease 2019 (COVID-19) has affected the Italian community. The widespread use of quarantine had the desired impact of controlling the epidemic, although it caused many psychological consequences. To date, compliance of the Italian public with voluntary home quarantine has been very high, but little is known about the impact of psychological health on sociodemographic categories during the quarantine. The purpose of this study was to assess the prevalence of depressive symptoms in specific sociodemographic categories during the COVID-19 quarantine lockdown and the potential factors that contribute to, or mitigate, these effects. In the very early stage of the nationwide lockdown, 3,672 quarantined Italian adult residents (65% females, ranging from 18 to 85 years) participated in a web-based cross-sectional survey, including measures of depressive symptoms, which were measured by the Teate depression inventory, and state anxiety levels. The overall prevalence was 27.8% for moderate and 9.3% for severe levels of depressive symptoms. A generalized logistic model was used to identify the factors associated with mental health problems. Among these factors, sociodemographic variables (e.g., sex, age, employment status) and adherence to quarantine guidelines were analyzed. Females, younger people, students, singles, residents in northern Italy, people who were reluctant to adhere to quarantine guidelines, and people less worried about being infected with COVID-19 were at high risk of developing depressive symptoms during the COVID-19 epidemic, also after controlling for state anxiety. These findings showed that public levels of depressive symptoms did not increase the greater likelihood of being infected. Our study suggested that the monitoring of psychological outcomes for outbreaks could identify groups at higher risk of psychological morbidities due to the current pandemic in order to target future psychological interventions for implementation.

INTRODUCTION

The pandemic of coronavirus disease 2019 (COVID-19), caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2, previously known as 2019-nCoV) has affected the Italian community since late January. According to the Imperial College COVID-19 Response Team (Ferguson et al., 2020), cumulatively, 5.9 (1.9–15.2) million people had been infected as of March 28, giving an infection rate of 9.8% (3.2–25%) of the Italian population.

To contain the rapid spread of this pandemic, the Italian Government ordered nationwide lockdown by March 11: all public places were closed (included educational, religious, and public/cultural institutions, such as schools, universities, museums, and law courts), all public events and any form of congregation were banned, and a distance of at least 1 m had to be maintained (Government of Italy, 2020). All Italian people were in quarantine at home (#iorestoacasa) until May 4: people had to stay at home apart from essential tasks. The slowing growth in daily reported deaths in Italy was consistent with the significant impact of these restrictions. The effective reproduction number, Rt, dropped to close to 1 around the start of the lockdown, with 38,000 (13,000–84,000) deaths averted. The widespread use of quarantine had the desired effect of controlling the epidemic, this was also due to the fact that the compliance of the Italian public with quarantine guidelines had been very high (Carlucci et al., 2020).

Yet, the pandemic created a breeding ground for direct psychological consequences, suddenly throwing many individuals into daily lives filled with health threats, existential depression, and generalized stress (Holmes et al., 2020). A recent review of the psychological impact of quarantine, due to earlier outbreaks, suggested that there were high rates of negative psychological effects among the public, including post-traumatic stress symptoms, persistent depression, substantial anger, panic attacks, and suicidality (Liu et al., 2003; Maunder et al., 2003; Brooks et al., 2020).

Social distancing and isolation exacerbate the burden of stress, and often cause effects on immune, cardiovascular, and mental health because these measures frustrate the deep-seated human instinct to connect with others. On this point, social connection helps people to regulate negative emotions, remain resilient during difficult times, and cope with stress (Rimé, 2009; Hawkley and Cacioppo, 2010; Haslam et al., 2012; Doré et al., 2017; Jetten et al., 2017).

Remarkably, the mental impact of quarantine can depend largely on the characteristics of participants and the quarantine variables selected. As documented by Reynolds et al. (2008), Taylor et al. (2008), and Brooks et al. (2020), while compliance with quarantine guidelines requirements are significant factors behind a higher level of post-traumatic stress disorder (PTSD), healthcare workers were more likely to be affected than the public.

In Italy, in the early phase of quarantine (7–10 days after the decree of nationwide lockdown), deleterious consequences on the population's psychological health were analyzed in a nationally representative survey of 3,452 participants (Barari et al., 2020). Different demographic groups were struggling with different aspects of quarantine. Older adults expressed worry or anxiety, while those who were likely working parents (40–49 years) cited consistent economic distress and struggles with home-schooling and smart-working, compared to other groups. Younger people were struggling with increased boredom, perceived immobility, and conflicts within family, while vulnerable groups, like the elderly and health-compromised people, cited consistent loneliness relative to others. Overall, the average level of anxiety surrounding the crisis in the Italian population was high: no respondents reported being completely without anxiety.

According to Barari et al. (2020), the negative psychological consequences of the quarantine were beginning to wear on people and seemed likely to become more serious over time.

Further findings derived from an online survey (Mazza C. et al., 2020) showed the prevalence of psychiatric symptoms in 2,766 participants drawn from the general population from March 18 to 22 2020. Female gender, negative affect, and detachment were associated with higher levels of stress, anxiety, and depression. Having an acquaintance infected was associated with increased levels of both depression and stress, whereas a history of stressful situations and medical problems was associated with higher levels of anxiety and depression. Finally, those with a family member infected and young people who had to work outside their domicile presented higher levels of anxiety and stress, respectively.

Thus, it is important that the potential advantages of home quarantine are weighed against the possible mental costs (Rubin and Wessely, 2020; Torales et al., 2020). Quarantine as an efficacious public health measure also needs to lower the psychological strain associated with it.

Aims of This Study

Research evidence aims of this study were to explore (1) the likely effects of quarantine on mental health (anxiety and depressive symptoms), immediately after the nationwide lockdown issued by the Italian Government, and (2) the factors that contribute to, or mitigate, these consequences.

Among these factors, sociodemographic variables (gender, age, employment status, marital status, education, geographic area, and income per year), worry about being affected by COVID-19, and adherence with quarantine guidelines were analyzed. Depression was the principal outcome, while anxiety was used as a covariate, given its close association with depression (Clark and Watson, 1991; Barlow and Campbell, 2000).

MATERIALS AND METHODS

Sample and Procedure

Respondents were Italian quarantined adults aged 18 and older with access to a networked computer. An online cross-sectional study was conducted from March 21 to 26, immediately after the nationwide lockdown issued by the Italian Government on March 11 (#iorestoacasa). A virtual snowball sample via social media was used within a wider web-based study including other psychological measures (Carlucci et al., 2020).

This study has been approved by the Department of Psychological Sciences, Health and Territory, University of Chieti, Italy Review Board. Written informed consent was obtained from all the participants included in the study.

Measures

Sociodemographic Variables

General information concerning sex, age, education, marital status, geographic area and region, employment status, yearly income, and health status including history

of psychiatric illnesses and medical problems (e.g., hospitalizations) were collected.

Depression

The 21-item Teate Depression Inventory (TDI; Balsamo et al., 2014, 2018b), developed via Rasch analysis (Rasch, 1960), was employed to evaluate depressive symptoms in participants in the past 2 weeks. Respondent answers were measured on a 5-point Likert scale ranging from "*never*" to "*always*." Cronbach's α coefficient in our study was 0.90.

Anxiety

The 21-item state scale of the State-Trait Inventory for Cognitive and Somatic Anxiety (STICSA) (Ree et al., 2008; Balsamo et al., 2016; Carlucci et al., 2018) was administered to evaluate cognitive (e.g., "I have trouble remembering things") and somatic (e.g., "My muscles are tense") symptoms of state anxiety. Individuals rated how often a statement was true in the past 2 weeks, from 1 "*not at all*" to 4 "*very much so*." Cronbach's α coefficient was 0.89.

Adherence to Quarantine Guidelines

Adherence to quarantine guidelines in response to the COVID-19 outbreak was measured by a global index composed of 11 items classified into preventive (i.e., handwashing with soapy water/alcohol-based solution) and avoidant (i.e., avoidance of gatherings in public or open to public places, handshaking) disease behaviors (Carlucci et al., 2020). Respondents were asked about the frequency of which they had carried out quarantine restrictions on a 5-point Likert scale from 0 "*never*" to 4 "*always*." Cronbach's α coefficient was 0.70.

Worry

Worry about being infected with COVID-19 was assessed by a single item drawn from a multidimensional questionnaire of risk perception for the COVID-19 infectious disease outbreak. Responses were classified according to three levels of worry severity: none ("*Not worried at all*"), moderate ("*Slightly worried*"), and quite a lot ("*Really worried*").

Data Analysis

Descriptive statistics were computed for sociodemographic characteristics, physical symptoms and health service utilization variables, knowledge and concern-related variables, precautionary measure variables, and additional health information variables. Prevalence of depressive and anxiety symptoms during the COVID-19 outbreak in the Italian population were also computed for sex and age. In line with similar studies (e.g., Giallonardo et al., 2020; Mazza C. et al., 2020; Wang et al., 2020), the TDI outcome score was categorized into "minimal," "mild," "moderate," and "severe" depression levels (Balsamo and Saggino, 2014). A STICSA-S score of 40 points or greater was indicated as the cut-off point for the presence of anxiety symptoms (Van Dam et al., 2013).

Sensitivity analysis was conducted using the Hmisc R package (Harrell and Dupont, 2006) in order to assess the power and sample size of ordinal outcomes under the proportional odds ordinal logistic model.

Next, generalized linear regression (GLMs) was applied to the explanatory model to analyze whether the severity of depression during the COVID-19 quarantine could be predicted by high levels of adherence to quarantine guidelines and worry about being infected with COVID-19, and by sociodemographic variables (Model 1), that resulted as significant in our previous study (Carlucci et al., 2020). Since depression was measured in terms of severity levels, we specified multinomial (ordinal) as the distribution and cumulative logit as the link function.

Predictors were selected according to a two-step process. Firstly, a potential set of considered variables were correlated with the outcome variable. All the potential variables that correlated significantly with the outcome were selected as predictors in the GLMs model. Hence, based on the test of model effects (Wald chi-square statistic and *p*-values), the predictors were compared (Guisan et al., 2002). Only the resulting significant predictors ($p < 0.05$) were retained in the model.

A Wald test (and its 95% confidence interval) based on robust estimates of the coefficients and covariance matrix were used to assess the models, and residual deviance as a goodness-of-fit statistic was applied to evaluate model overdispersion (McCullagh, 2018). The model with the deviance/df ratio closest to the unit was retained as the most parsimonious model (McCullagh, 2018).

In addition, due to the high comorbidity between depression and anxiety symptomatology (Clark and Watson, 1991; Barlow and Campbell, 2000), the model was re-estimated controlling for anxiety as the covariate (Model 2), in order to increase the ability to detect differences on dependent variables (depression severity levels) by an independent variable inserted as the covariate. Differences between the two models were interpreted in terms of unique contribution of any independent variable on depression severity symptoms. The data were statistically analyzed with SPSS for Windows 21.0 (IBM Corp, 2018). Statistical significance was set by *p*-values of less than 0.05.

RESULTS

Demographic Characteristics

The characteristics of the participants are shown in **Table 1**. Of the 3,672 respondents, 1,282 (34.9%) were male and 2,390 (65.1%) were female. The mean (±SD) age of the participants was 33.27 ± 14.29 years. A total of 45.2% of them were located in the south of Italy (N = 1660). Among these, 1,817 (49.5%) respondents held a high school diploma, while 1,535 (41.8%) held a higher education qualification (bachelor/master/doctorate). In terms of occupational status and income per year, 1,138 (31.20%) participants were students, 232 (6.3%) were healthcare workers, and 1,742 (47.4%) were employed. Concerning marital status, 2,249 (61.2%) participants were unmarried/single, 901 (24.5%) were married, 103 (2.8%) were divorced/separated, 366 (10%) were cohabiting, and 53 (1.4%) were widowed.

Most of the subjects had a high level of health: 2,616 (71.2%) were found to show no physical disease, while 24 (0.7%) were detected as "fragile," having more than three

**Missing values n = 90 (2.5%).*

diseases, and with a long history of chronic medical illness. A total of 967 (26.3%) participants had previously carried out psychotherapeutic treatment. Among these, 97.2% of respondents had carried out at least one psychotherapy treatment (individual, family/couple, and/or group treatment), 20.9% had undergone psycho-pharmacological treatment, and 0.6% had participated in other psychological treatments.

Most (84.2%) of the participants spent their quarantine period with family members. A total of 1,787 (48.7%) were found to be highly adherent to quarantine guidelines, and 2,326 (63.34%) reported that they were worried about being infected with COVID-19.

A sample size of 3,672 was used for the statistical power analyses, and a 1:2 odds ratio was used as a baseline. The alpha level used for this analysis was $p < 0.05$. The *post-hoc* analyses showed that the statistical power for this study was 0.859. Thus, there was an adequate power at the moderate to large effect size level. An N of approximately 4,182 would be needed to obtain statistical power at the recommended 0.90 level (Cohen, 1988).

Prevalence of Depressive Symptoms, and State Anxiety During the COVID-19 Outbreak Stratified by Sex and Age

The overall prevalence was 6.4% for severe, 24.2% for moderate, 39.7% for mild, and 29.7% for minimal depressive symptoms. The overall prevalence of anxiety symptoms was 13.6%, using the cut-off of >40. Taking together, the prevalence of depressive symptoms and state anxiety severity was significantly higher in female participants, and those younger than 30 years compared to participants aged 31 years or older ($p < 0.001$, as shown in **Tables 2**, **3**). In addition, those who received psychotherapeutic treatment in the past reported higher severity levels of depressive [$\chi^2 = 45.58$ (3), $p < 0.001$] and anxiety [$\chi^2 = 47.43$ (1), $p < 0.001$] symptoms relative to the general public.

Predictors of Depressive Symptoms During the COVID-19 Outbreak

Preliminarily, nonparametric correlations (*Spearman's rho*) were performed in order to select independent variables as predictors in the GLMs. As expected, all the sociodemographic variables, as well as worry were found to correlate negatively with the outcome variable (depressive symptom severity levels) ranging from *rho* = 0.298 (age, $p < 0.01$) to *rho* = −0.040 (education, $p < 0.05$), except for sex and worry (*rho* = 0.113, $p < 0.01$ and 0.037, $p < 0.05$, respectively).

Parameter estimates of the generalized linear model and the exponentiated values of the coefficients [the "Exp(B)" column] are displayed in **Table 4**. The first model resulted in an underestimation of the data with no statistical association for education [$W\chi^2(df) = 3.19$ (3), $p = 0.372$], and income per year [$W\chi^2(df) = 7.306$ (3), $p = 0.063$] as predictors of depressive symptoms. To improve model fit, we discharged them and re-estimated the model. The Omnibus test [$\chi^2(df) = 526.21$ (20); $p < 0.001$], and residual deviance/df ratio (deviance/df = 1.038) of the re-estimated models suggested that the refined model fit significantly better than the proposed model (McCullagh, 2018). Female participants showed significantly higher depression scores compared to male participants (β = 0.490; SE = 0.068; $p < 0.001$), with a greater risk of depressive symptoms (odds ratio, 1.632 [95% CI, 1.427–1.866]). Participants aged from 30 years and above reported significantly lower levels of depression scores compared to the younger respondents (β = −0.647/−0.344; SE = 0.186/.101; $p < 0.001$), with a decreased risk of depressive symptoms (odds ratio range: 0.524/0.709 [95% CI, 0.363–0.755/0.581–0.864]). Likewise, widowed, cohabiting, and married participants were less likely to experience depressive symptoms than single/unmarried participants, with a decreased risk of depressive symptoms (odds ratio: 0.521 [95% CI, 0.400–0.679]). Concerning geographic area, participants living in the south of Italy had significantly lower depression scores

TDI, Teate Depression Inventory; STICSA-S, State-Trait Inventory for Cognitive and Somatic Anxiety—State Scale. [a]STICSA-S was defined as individuals who scored ≥ 40 points (Van Dam et al., 2013).

(β = −0.176; SE = 0.080; $p < 0.05$) compared to residents in the north-west, with a decreased risk of depressive symptoms (odds ratio: 0.839 [95% CI, 0.717–1.981]). Students (β = 0.360; SE = 0.118; $p < 0.01$) and healthcare professionals (β = −0.510; SE = 0.160; $p < 0.001$) were slightly and/or not depressed compared to unemployed participants, respectively. The first group displayed a decreased risk of depressive symptom severity (odds ratio: 0.600 [95% CI, 0.438–0.822]), while the latter showed a higher risk of depression symptoms (odds ratio: 1.358 [95% CI, 1.077–1.713]) compared to the unemployed. Next, those who reported to adhere to the quarantine guidelines had significantly lower levels of depressive symptoms those who were not adherent (β = −0.502; SE = 0.067; $p < 0.001$), with a decreased risk of depressive symptoms (odds ratio: 0.606 [95% CI, 0.531–0.690]). Lastly, participants less worried about being infected with COVID-19 (β = −0.517; SE = 0.127; $p < 0.001$) had significantly lower level of depressive symptoms than those who reported to be quite worried, with a decreased risk of depressive symptoms (odds ratio: 0.596 [95% CI, 0.464–0.765]).

As expected, a preliminary analysis showed that depression and anxiety symptoms shared approximately 38% of the common variance, as derived by the Spearman rho coefficient (rho = 0.62, $p < 0.001$). Thus, state anxiety, as measured by the state STICSA, as the covariate was inserted in our model (Model 2).

Compared to the previous model, no statistical differences were found in sex, age, and adherence level to quarantine guidelines groups when predicting depression symptom severity, when controlling for anxiety (see **Appendix A**). Statistically significant differences were maintained in depression symptom severity for marital status, geographic area, and occupational status groups, after controlling for anxiety.

In detail, divorced/separated participants were less likely to experience depressive symptoms compared to single people, with a significant decreased risk of depressive symptoms (odds ratio: 0.654 [95% CI, 0.434–0.983]). On the other hand, no statistical differences on depressive symptom severity was found in cohabiting participants compared to unmarried participants in the second model.

Concerning geographic area, the participants living in central Italy were found less likely to experience severe depressive symptoms (odds ratio: 0.794 [95% CI, 0.641–0.984]) compared to those living in north-west Italy, after removing anxiety effects. Far from the previous model, the healthcare professionals' group were not found to differ from other occupational groups in predicting high levels of depressive symptoms compared to unemployed participants. Interestingly, participants "moderately" worried about being infected with COVID-19 were more prone to experience high levels of depressive symptoms (odds ratio: 1.252 [95% CI, 0.953–1.643]) compared to participants who were "quite a lot" worried, after controlling for the state anxiety effect.

Predictors of Depressive Symptoms During the COVID-19 Outbreak in Subsample of Participants With Psychotherapeutic Treatment History

We fitted both the GLMs models (without and with anxiety as the covariate) in the subsample of participants with

TABLE 4 | Results of GLMs model 1 (*N* = 3,672).

$^*p < 0.001$; $^{**}p < 0.05$. The Exp(β) or Odds ratio and β values (95%Wald CI) were derived from generalized linear regression (logistic ordinal) COVID-19, coronavirus disease 2019.

a psychotherapeutic treatment history. No substantial differences were found in both the model's goodness of fit (deviance/df = 1.048 vs. 0.911). However, differences in the estimates and standard errors of the two models were found for the model with anxiety as the covariate vs. the model without the covariate (see **Appendix B**).

In line with models tested on the entire sample, in Model 1, female participants showed significantly higher depressive symptoms scores compared to male participants (β = 0.310; SE = 0.151; $p < 0.05$), with a greater risk of depressive symptoms (odds ratio, 1.364 [95% CI, 1.014–1.834]). Participants aged from 30 to 39 and 50 to 59 years reported significantly lower levels of depressive symptoms scores compared to the younger participants (β = −0.543/−0.696; SE = 0.187/0.339; $p < 0.05$), with a decreased risk of depressive symptoms (odds ratio range: 0.581/0.449 [95% CI, 0.403–0.839/0.256–0.971]).

Likewise, cohabiting (β = −0.526; SE = 0.193; $p < 0.01$) and married (β = −0.446; SE = 0.195; $p < 0.05$) participants were less likely to have experienced depressive symptoms compared to single participants, with a decreased risk of depressive symptoms (odds ratio: 0.591/0.640 [95% CI, 0.404–0.863/0.433–0.946]). Healthcare professionals (β = −0.797; SE = 0.280; $p < 0.01$) were less depressed compared to unemployed participants, with a decreased risk of depressive symptom severity (odds ratio: 0.450 [95% CI, 0.260–0.780]). Next, those who reported to adhere to the quarantine guidelines had significantly lower levels of depressive symptoms compared to those who were not adherent (β = −0.475; SE = 0.133; $p < 0.001$), with

a decreased risk of depressive symptoms (odds ratio: 0.622 [95% CI, 0.479–0.809]).

No statistical association was found for worry about being infected with COVID-19 and geographic area.

Surprisingly, in Model 2, no statistically significant differences were maintained in depression symptoms for the sex, marital status, and occupational status groups, after controlling for anxiety. Participants aged from 30 to 39 years reported significantly lower levels of depression scores compared to the younger participants ($\beta = -0.5.04$; SE = 0.194; $p < 0.01$), with a decreased risk of depressive symptoms (odds ratio range: 0.604 [95% CI, 0.413–0.884]). Concerning geographic area, the participants living in south Italy were less likely to experience severe depressive symptoms (odds ratio: 0.688 [95% CI, 0.493–0.962]) compared to those living in north-west Italy, after removing anxiety effects. As expected, participants "moderately" and "none" worried about being infected with COVID-19 were more prone to experience high levels of depressive symptoms (odds ratio: 1.757/1.722 [95% CI, 1.292–2.391/1.063–2.791]) compared to participants who were "quite a lot" worried, after controlling for the state anxiety effect.

DISCUSSION

Quarantine has been used extensively in all countries of the world to lower the spread of the COVID-19 infection and to protect individuals' health, at different times (Sohrabi et al., 2020).

Quarantine includes the separation and restriction of movement of people who have potentially been exposed to a contagious disease to ascertain if they become unwell, so reducing the risk of them infecting others. It is an unpleasant experience for those affected (Hiremath et al., 2020). Imposed isolation and separation from loved ones, loss of mental health needs (freedom, social contacts, stimulation), uncertainty over disease status, family conflict, and boredom can, on occasion, contribute to the onset of psychological disorders (Brooks et al., 2020). Due to the fact that the psychological impact of quarantine depends largely on the characteristics of participants and the quarantine variables selected, several sociodemographic characteristics have been selected here, with depressive symptoms measured by the TDI as the outcome. In the second model, anxiety, as measured by the STICSA state scale, was inserted as the covariate, given the close relationship with depression (Brooks et al., 2020).

About gender, depressive symptoms were more likely to occur in female participants, with a risk of developing depressive symptoms higher 1.6 compared to male participants in our sample. This finding was in accordance with studies by Qiu et al. (2020) and Wang et al. (2020) among the Chinese general population in the first 2 weeks following the outbreak, as well as Broche-Pérez et al. (2020) among the Cuban population. Also, among the Italian general population higher levels of psychological distress were reported in the female gender compared to their male counterparts (Ho et al., 2020; Mazza C. et al., 2020; Rossi et al., 2020).

Sex differences in depression were not caused by a higher prevalence of COVID-19 infection in women because mortality and vulnerability to the COVID-19 disease indicated that more men are dying from COVID-19 (Lancet, 2020). Thus, these differences seem to be caused by the fact that women carry a different kind of burden from this epidemiological emergency. Gender inequities disproportionately affect the well-being and economic resilience during lockdown. Households are under strain, but children and elderly care, as well as housework generally fall on women (Cluver et al., 2020). By increasing caregiving needs, COVID-19 has intensified the pressure on women to uphold prescriptive feminine norms. Women have to bear more of the burdens of providing additional support for children's distance learning, and alleviating children's emotional tedium, isolation, and anxiety of shelter-in-place (Rosenfeld et al., 2020).

In addition, increased intimate partner violence has grown during the quarantine due to COVID-19 because women are required to stay uninterruptedly with their partners and away from those people who can give help or at least validate their experiences and, particularly if these women live in small houses (Bradbury-Jones and Isham, 2020; Mazza M. et al., 2020; van Gelder et al., 2020). Indeed, some studies suggest that sudden forced proximity with their immediate household members is a risk factor for domestic violence, and aggression (Taylor et al., 2008; Brooks et al., 2020). In Italy, since the beginning of the COVID-19 quarantine, three domestic homicides and 11 murder-suicides have been registered to date.

Furthermore, while COVID-19 has coincided with greater rises in unemployment for women than men, the rise in unemployment for men remains substantial (Bureau of Labor Statistics, 2020).

About the age groups, depressive symptoms were most likely to occur in younger people (aged 18–29 years). With increasing age, depressive symptoms were less prevalent during the Italian lockdown due to the COVID-19 outbreak. Our results were similar to those from previous studies, such as a study during the SARS outbreak in Taiwan (Su et al., 2007), a study of horse owners quarantined because of equine influenza (Taylor et al., 2008), and one recent study during the COVID-19 epidemic in China (Huang and Zhao, 2020). As well, like gender, for this sociodemographic variable, the prevalence of the depressive symptoms in different age groups and the probability of risk of developing depressive symptoms depending on age do not relate to the greater likelihood of being infected.

Being elderly has been reported to correlate with adverse clinical outcomes, including hospitalization and mortality (Applegate and Ouslander, 2020; Zhou et al., 2020). Indeed, in Italy the mean age of COVID-19 patients who died was 81 years (Remuzzi and Remuzzi, 2020) and the case fatality rate was 16% from 60 to 79 years, 19.7% from 80 to 89 years, and 16% for 90 years and older (Livingston and Bucher, 2020). Despite this, respondents older than 60 years had the lowest risk for developing depressive symptoms compared to the younger age groups. In a population where loneliness and isolation have already been described as an epidemic (Luo et al., 2012), the impact of even short-term social distancing measures and the resulting distress did not influence the vulnerability to mental health issues (Jeste et al., 2020; Vahia et al., 2020). This finding is

in accordance with part of the literature. Although mixed results derive across current and previous studies on the association between participants' age and depression as a psychological outcome of health-related emergency (Hawryluck et al., 2004; Qiu et al., 2020), some authors reported that only young age was found to be associated with increased distress as a psychological outcome of the COVID-19 quarantine (Barari et al., 2020; Mazza C. et al., 2020) and of the SARS quarantine (Hawryluck et al., 2004). The higher psychological distress reported by the younger population could be due to their greater and uncontrolled access to the amount of information ("*infodemic*") through social media, which can easily trigger distress (Cheng et al., 2014).

As regards marital status, unmarried/single people were the most depressed group with quarantine policies in the event of this outbreak. It is plausible that single people had greater difficulty in relying on or obtaining the assistance of others during the Italian lockdown, thus are at risk of depressive symptoms and lower self-confidence more than cohabiting and married participants. This datum is in line with part of previous literature reporting that being married was protective for depression or associated with a lower risk of depressive symptoms (Inaba et al., 2005; Yan et al., 2011; Bulloch et al., 2017), although other studies conducted during the SARS outbreak suggested that demographic factors such as marital status, as well as living with other adults, and having children were not associated with psychological outcomes (Hawryluck et al., 2004; Mihashi et al., 2009).

As to geographic area of residence, people living in the south of Italy showed the lowest risk of developing depressive symptoms among all the groups, followed by participants from regions of central Italy compared to residents from northern regions and the islands. As expected, residents in the most severely affected regions are at the highest risk of developing depressive symptoms. Southern and central regions recorded a smaller number of deaths and diagnosed cases (1,812 and 2,730 deaths, respectively), compared to the north-east and north-west regions (6,935 and 21,009 deaths, respectively), where the disease spread first on a large scale. To explain this datum, it should be considered that the authorities introduced control measures in the northern regions (the "Red Zone"), before any other region and carried out extraordinary efforts to restrict the movement of people (Carlucci et al., 2020). In addition, residents from northern Italy were found less adherent to restrictive measures compared to the those from the south of Italy. People who have shown more adherence were found less at risk of depressive symptoms compared to people with less adherence (see under).

As for occupational status, this study highlighted students as suffering from the highest level of psychological distress among all the other groups, including the unemployed group. Also, in this case, the public's level of depressive symptoms did not increase with an increased probability of contracting the disease. Since the physical spaces of universities were closed, students' mental well-being was affected by the sudden interruption of social interactions. However, the possibility of having online lessons and maintaining social contacts through social networks would not explain the onset of the depressive symptoms compared to other groups, for example employees who had been laid off or were retired.

The reason for students' greater risk of depressive symptoms, reported also by Wang et al. (2020) among the Chinese population, could lie in a sense of uncertainty toward the future that this emergency, not only in health, but also in economic, social, and political areas, is eliciting all over the world (Chong et al., 2004; Wenzel et al., 2005; Tan and Enderwick, 2006).

Compared with other professions and the general population, healthcare workers were associated with a lower risk of psychological outcomes compared to the unemployed in our sample. "Learned helplessness"(Seligman, 1972) could explain why health professionals were the least depressed group. After being exposed to inescapable difficult events, people become passive and stop trying after being exposed to events such as uncontrollable bursts of noise (Alloy et al., 1984) and as a result show greater levels of anxiety and depression. On the contrary, health professionals, considered the real heroes of this emergency, were associated with a lower risk of psychological outcomes compared to unemployed participants. Through the practice of their profession, they felt more useful to society, despite their increased risk for infection and transmission (Al-Rabiaah et al., 2020).

After students, the unemployed were at a higher risk of depressive symptoms compared to the other groups (Stuckler et al., 2009; Reeves et al., 2012). This datum is inserted within the context of the COVID-19-related risk unemployment and economic losses and insecurity with the closure of community services and the collapse of industries negatively impacting the national economy. It should be a critical public health priority to prevent suicide. Indeed, during the most recent economic recession, a 1% rise in unemployment was correlated with a rise in the suicide rate of 0.99% in the United States (95% CI: 0.60–1.38, $p < 0.001$) (Reeves et al., 2012). Similarly, each percentage point increase in unemployment was accompanied by 0.79% rise in suicide (95% CI: 0.16–1.42, p = 0.016) in Europeans aged 65 years or less.

As to adherence, people with low adherence were more likely to exhibited depressive symptoms relative to people with a great level of adherence to COVID-19 preventive measures. As expected, adherence has been found to be a protective factor against mental health problems (Hawryluck et al., 2004; Koenig and Schultz, 2010; Brooks et al., 2020). Adopting the preventive behaviors contribute to lower the uncertainty of the epidemic progression which would cause higher psychological pressure on the public. As to worry about being infected with COVID-19, people with more worry were more depressed than people with a low level of worry.

As for the whole sample, also in the subsample of participants with psychotherapeutic treatment history, the same sociodemographic factors and behaviors that contribute to, or mitigate mental effects of the quarantine in terms of depressive symptoms were reported. However, when anxiety symptoms or concomitant stressful events were present in comorbidity, these participants were found to experience higher levels of worry associated with increased depression symptomatology, compared to the whole sample. Current evidence showed similar results. A history of stressful situations and medical problems was associated with a greater degree of depression and anxiety during

the COVID-19 quarantine in the Italian population (Hao et al., 2020). Again, psychiatric patients were significantly more likely to experience a higher degree of the negative mental impact of the outbreak, including stress, anxiety, and depression, compared to the general public (Hao et al., 2020).

CONCLUSION

During the COVID-19 quarantine outbreak in Italy, female participants, younger people, single people, students, people living in northern regions, and who were less compliant with quarantine guidelines and less worried about being infected with COVID-19 were at a high risk of displaying psychological issues. These findings suggest public levels of depressive symptoms did not increase with the greater likelihood of being infected. For example, although female and younger people reported a lower risk of COVID-19 infection, they experienced higher levels of depressive symptoms during the COVID-19 quarantine in Italy.

Therefore, ongoing monitoring of the psychological strain associated with outbreaks of epidemic-potential, life-threatening diseases should become routine as part of preparedness efforts worldwide by establishing early targeted mental health interventions. In other words, more vulnerable groups, likes those cited above, should benefit from personalized "morale-boosting" interventions. Or, intervention research could be valuable to combat amplifications of gender inequalities, particularly to address the added challenges women are likely to face. This research can provide timely insights for government agencies toward improving and safeguarding the psychological well-being of women, younger people, and categories of subjects at a higher risk of suffering from psychological distress on the occasion of subsequent waves of the spread of COVID-19 or other epidemic diseases. This study has several limitations. Firstly, the analyses presented here were derived from a cross-sectional design, thus it is difficult to make causal inferences. Secondly, given that the research was conducted in close temporal proximity to the period of the COVID-19 quarantine, a web-based survey method was necessary to recruit a convenience sample by avoiding possible infections. This limited sampling in our study. As a consequence, a self-selection effect may have occurred and should be considered with those people who were experiencing the greatest or least levels of distress responding to the survey (Saggino et al., 2017). In addition, participants were required to access the internet and to be familiar with online devices to respond, which suggests that they might be more educated, younger or/and have a higher socioeconomic status than the overall surveyed quarantined population. Thirdly, due to the uncontrolled occurrence of this health-related emergency, an accurate picture of the individual's psychological conditions before the COVID-19 outbreak was not conducted. Although it would been interesting to conduct pre-post analyses, these data could provide a baseline for future research on the psychological consequences of quarantine in the Italian population throughout the rest of the current COVID-19 pandemic. Fourthly, depressive and state anxiety symptoms were measured by means self-report inventories that are notably biased by response set, such as social desirability (Innamorati et al., 2014; Carlucci et al., 2015; Balsamo et al., 2018a,b). Thus, future research should include methods, such as observational methods and psychophysiological or behavioral assessment, in order to objectively record the levels of these mood states (Campbell and Fiske, 1959). Fifthly, the assessment of state anxiety could be completed or replaced by adding the specific fear of COVID-19 scale (Ahorsu et al., 2020; Broche-Pérez et al., 2020; Soraci et al., 2020). In addition, it should be acknowledged that the study was carried out was not sufficiently heterogeneous for sex, with marked female preponderance, and age sample, with a prevalence of juveniles. Hence, these findings may not translate accurately to the public at large.

Finally, it could not evaluate whether the outcomes considered in this study will be long-lasting after the COVID-19 outbreak. However, follow-up with these participants will continue in order to facilitate our understanding about how long these outcomes will last. A deeper understanding of how the epidemic affects Italians' psychological health by identifying which groups were at a high risk of psychological morbidities due to the current pandemic can help to guide and target future psychological intervention implementations.

Taylor S, Landry CA, Paluszek MM, Groenewoud R, Rachor GS and Asmundson GJG (2020) A Proactive Approach for Managing COVID-19: The Importance of Understanding the Motivational Roots of Vaccination Hesitancy for SARS-CoV2. Front. Psychol. 11:575950. doi: 10.3389/fpsyg.2020.575950

Importance: Vaccination hesitancy—the reluctance or refusal to be vaccinated—is a leading global health threat (World Health Organization, 2019). It is imperative to identify the prevalence of vaccination hesitancy for SARS-CoV2 in order to understand the scope of the problem and to identify its motivational roots in order to proactively prepare to address the problem when a vaccine eventually becomes available.

Objective: To identify (1) the prevalence of vaccination hesitancy for a SARS-CoV2 vaccine, (2) the motivational roots of this hesitancy, and (3) the most promising incentives for improving the likelihood of vaccination uptake when a vaccine does become available.

Design, Setting, and Participants: A cross-sectional sample of 3,674 American and Canadian adults assessed during the COVID-19 pandemic in May 2020.

Main Outcomes: Measures of vaccination intention (i.e., "If a vaccine for COVID-19 was available, would you get vaccinated?"), attitudes toward vaccines in general and specific to SARS-CoV2 using the Vaccination Attitudes Examination Scale, and incentives for getting vaccinated for those who reported they would not get vaccinated.

Results: Many American (25%) and Canadian (20%) respondents said that they would not get vaccinated against SARS-CoV2 if a vaccine was available. Non-adherence rates of this magnitude would make it difficult or impossible to achieve herd immunity. Vaccine rejection was most strongly correlated with mistrust of vaccine benefit, and also correlated with worry about unforeseen future effects, concerns about commercial profiteering from pharmaceutical companies, and preferences for natural immunity. When asked about incentives for getting vaccinated, respondents were most likely to report that evidence for rigorous testing and safety of the vaccine were of greatest importance.

Conclusions and Relevance: Vaccination hesitancy is a major looming problem for COVID-19. To improve vaccine uptake, it is imperative that the vaccine is demonstrated to the public to be rigorously tested and not perceived as rushed or premature in its dissemination.

Keywords: COVID-19, SARSCoV2, pandemic, coronavirus, vaccination, vaccination hesitancy, vaccination attitudes

INTRODUCTION

Vaccination hesitancy—the reluctance or refusal to be vaccinated—is among the top ten global health threats (World Health Organization, 2019). It is a major problem for seasonal influenza (World Health Organization, 2019), was a significant problem during the 2009 H1N1 pandemic (Bangerter et al., 2012), and may be increasing in recent years (Yaqub et al., 2014). Vaccination hesitancy is also a growing problem among healthcare workers (Maltezou et al., 2018). In order to proactively manage the COVID-19 pandemic, it is important to identify the prevalence of vaccination hesitancy for SARS-CoV2. A review of 12 studies found that the mean R_0 for COVID-19 virus is 3.28 (Liu et al., 2020), suggesting that the threshold for achieving herd immunity ($1–1/R_0$) is 70% (Fine et al., 2011). Since people who refuse vaccination are not randomly dispersed (i.e., they tend to occur in clusters) (Fine et al., 2011), more than 70% of people in a community would need to be vaccinated in order to achieve herd immunity.

Mandatory vaccination is unlikely to be a viable option in individualistic societies due to increasing anti-vaccination sentiment (Taylor, 2019). If vaccination hesitancy for SARS-CoV2 is prevalent, then it is important to identify the motivational roots (i.e., attitudes or reasons) underlying the reluctance (Hornsey et al., 2018) and ways to address these. Public education programs (e.g., "do it for the herd") can be helpful to some extent (Taylor, 2019); but, identifying motivational factors for vaccination hesitancy and then proactively tailoring public health messaging and incentives to address these factors prior to beginning an immunization program may improve overall vaccine uptake (World Health Organization, 2020).

The purpose of this study was to assess a population-representative sample of adults from the United States and Canada in order to identify (1) the prevalence of vaccination hesitancy for a SARS-CoV2 vaccine when one does become available, (2) the motivational roots of this hesitancy, and (3) the most promising incentives for improving the likelihood of vaccination uptake when a vaccine does become available.

MATERIALS AND METHODS

Design

A cross-sectional design was used in which participants completed an internet-based battery of questionnaires, including demographic questions and measures of vaccination intention, attitudes, and incentives.

Sample and Data Collection Procedures

Data were collected from May 6–19, 2020, from 3,674 adults recruited from communities in the United States (n = 1,772) and Canada (n = 1,902) using an internet-based self-report survey delivered in English by Qualtrics, which is a commercial survey sampling and administration company. Qualtrics maintains a pool of potential participants who have agreed to be contacted in order to respond to surveys. For the present study, Qualtrics selected and contacted participants to meet sampling quotas based on age, gender, ethnicity, socioeconomic status, and geographic region within each country to obtain a representative sample. Filters were used to eliminate data from careless or incomplete responses. Respondents received credit points for participation, similar to points in a credit card rewards program, which could be converted into currency. For the present study, respondents received credit points equivalent to US$7.00 for participating in the online study. All respondents provided written informed consent prior to completing the survey. All procedures followed were in accordance with the standards of the Helsinki Declaration. The research described in this article was approved by the Research Ethics Board of the University of Regina (REB# 2020-043).

Measures

Vaccination attitudes were measured using two versions of the Vaccination Attitudes Examination Scale (Martin and Petrie, 2017), assessing general vaccination attitudes and attitudes specific to SARS-CoV2. Both versions contain four subscales, including mistrust of vaccine benefit, worries over unforeseen future effects of the vaccine, concerns about commercial profiteering from the vaccine, and preference for natural immunity.

Regarding the assessment of vaccine uptake, vaccination is a binary event (i.e., a person does or does not get vaccinated); accordingly, participants answered a forced-choice yes/no question to measure vaccination intention: "If a vaccine for COVID-19 was available, would you get vaccinated?" A "don't know" or "uncertain" response option was omitted because it simply defers endorsing a decision.

Incentives for getting vaccinated were assessed only for people who responded "no" to the measure of vaccination intention (incentives were not assessed for "yes" responders because they were not in need of additional vaccination incentives). "No" responders were presented a list of 21 incentives (**Table 1**) and asked to rate whether each would increase their chances of getting vaccinated using a 5-point scale (0 = definitely would not, 4 = definitely would). The relative efficacy of each incentive was

calculated by computing the percentage of respondents who gave a rating of 3 or 4 ("probably would" or "definitely would").

RESULTS

A total of 43% of the sample were female, most (92%) were employed full- or part-time, and most (82%) had completed full or partial college. Most (69%) were Caucasian, with the remainder being Asian (12%), African American/Black (9%), Latino/Hispanic (6%), or other (5%). Only 2% of the sample reported being diagnosed with COVID-19, and only 3% were healthcare workers who might come into contact with patients infected with SARS-CoV2. Sample mean age was 53 years (SD = 15 years, range 18–94 years). According to American and Canadian census records, the population mean age (including children and adults) is approximately 40 years (Statistics Canada, 2020; United States Census Bureau, 2020). The mean age of sample is what would be expected from a population representative sample consisting only of adults.

In response to the question of whether participants would get vaccinated against SARS-CoV2, if a vaccine was available, 25% of Americans and 20% of Canadians said "no." Significantly more Americans than Canadians said that they would not get vaccinated, $\chi^2(df = 1) = 12.41$, $p < 0.001$. **Table 1** shows the correlations between vaccination intention (1 = no, 0 = yes) and negative attitudes toward vaccination. All of the negative attitudes toward a SARS-CoV2 vaccination, and vaccinations in general, were significantly correlated ($p < 0.001$) with the decision to not get vaccinated against SARS-CoV2. The largest correlation was between "no" to vaccination and mistrust of the benefit of a SARS-CoV2 vaccine. This correlation was significantly larger than all of the other correlations in **Table 1** ($p < 0.001$). These correlations were moderate-to-large in magnitude (rs > 0.30), according to Cohen's classification (Cohen, 1988).

According to Cohen's classification, correlations of 0.20 are considered small. Given the sample size, trivially small correlations (<0.20) were statistically significant. This was the case concerning the correlation between vaccination refusal and demographic variables, which were statistically significant but trivial in magnitude: Female gender $r = 0.10$, $p < 0.001$; age $r = 0.11$, $p < 0.001$; completed full or partial college education (vs. did not complete) $r = 0.10$, $p < 0.001$, unemployed r = −0.050, $p < 0.005$, minority status (vs. Caucasian) $r = -0.04$, $p < 0.05$.

For respondents indicating they would not get vaccinated against SARS-CoV2, **Table 2** shows the percentage who probably would/definitely would get vaccinated if incentives were provided. Consistent with the finding that the strongest correlate of vaccination refusal was concern about the benefit of the vaccine, the most efficacious incentives were those providing evidence that the vaccine was safe and efficacious. In other words, the most efficacious incentives were those that matched the motivational roots of vaccination hesitancy for a SARS-CoV2 vaccine. The least efficacious incentives involved promotions for vaccine uptake from social media, news media, or from community leaders.

TABLE 1 | Point-biserial correlations between the decision to not get vaccinated against SARS-CoV2 and negative attitudes about a SARS-CoV2 vaccine and vaccines in general.

Type of negative attitude	Concerning SARS-CoV2 vaccine	Concerning vaccines in general
Mistrust of vaccine benefit	0.64*	0.42*
Worry about unforeseen future negative effects	0.33*	0.33*
Concerns about commercial profiteering	0.43*	0.37*
Preference for natural immunity	0.43*	0.30*

*$p < 0.001$.

DISCUSSION

Anticipating and preparing for problems concerning vaccination adherence when a vaccine for SARS-CoV2 becomes available is

TABLE 2 | Respondents stating that they would *not* get vaccinated against SARS-CoV2 (n = 812): Percentage reporting that the following incentives would probably or definitely induce them to get vaccinated.

Incentive	% Probably or definitely would get vaccinated
If I was convinced that the vaccine had been rigorously tested	38
If I saw that enough people were safely vaccinated without negative side effects	36
If I saw that enough people who got the vaccine didn't get sick with COVID-19	34
If I saw that my friends and family didn't have negative side effects from the vaccine	34
If getting vaccinated was a requirement for my job	31
If I thought the health authorities were trustworthy	29
If I was convinced that getting vaccinated helped protect vulnerable members of my community	25
If getting vaccinated was required by my government	25
If a trusted health care worker told me to get vaccinated	22
If I knew that I was not being exploited by the pharmaceutical industry	19
If getting vaccinated was required for me to attend social or sporting events	19
If someone I knew died from COVID-19	18
I received a financial incentive	18
If I was assured that the government wasn't controlling the vaccine	17
If someone I knew got sick with COVID-19	16
If someone I knew was hospitalized because of COVID-19	16
If I received some other incentive (e.g., discount coupon)	8
If a news source that I trust promoted vaccination	8
If religious leaders in my community said I should get vaccinated	6
If my President or Prime Minister promoted the vaccine	6
If vaccination was promoted in my social media network	4

a critical step in managing the COVID-19 pandemic. Research suggests that greater than 70% of the population will need to be vaccinated against SARS-CoV2 to achieve herd immunity (Fine et al., 2011). Our research suggests that 25% of Americans and 20% of Canadians would reject a SARS-CoV2 vaccine, raising concerns that herd immunity might not be attained when a vaccine becomes available.

The degree of vaccination hesitancy found in the present study is broadly consistent with other studies that were published after our study had been completed. Studies conducted during March–April 2020, which was somewhat earlier than the present study (May, 2020), reported findings broadly similar to ours in terms of percentages of people who stated that they would not get vaccinated against SARS-CoV2: Italy (14%) (Barello et al., 2020), France (26%) (COCONEL Group, 2020), and Australia (14%) (Dodd et al., 2020). In a European survey in June, 2020, 24% of respondents stated that they were either unwilling or unsure about getting vaccinated (Neumann-Böhme et al., 2020). More recent surveys (August–September, 2020) in the United States and Britain suggest that upward of 50% of people would not get vaccinated (Bracken, 2020; McKie, 2020). Thus, vaccination hesitancy is an important and possibly growing problem.

Another concerning finding from the present study is that rejection of a SARS-CoV2 vaccine was associated with negative attitudes toward vaccination in general. If SARS-CoV2 persists during the forthcoming influenza season, then people might need to be vaccinated against both SARS-CoV2 and seasonal influenza. There could be devastating consequences, with widespread seasonal infection of both viruses, if people with negative attitudes about vaccination reject both vaccines. In our study, rejection of vaccination against SARS-CoV2 was correlated with a range of negative attitudes about a SARS-CoV2 vaccine, and vaccines in general, with the strongest correlation regarding mistrust about the benefits of a SARS-CoV2 vaccine. The public has been exposed to false hopes about COVID-19 treatments, such as the use of hydroxychloroquine (U.S. Food & Drug Administration, 2020), undermining confidence in the recommendations of community leaders. Our research suggests that exposure to authoritative information is a stronger incentive for vaccination than mere endorsements from community leaders or social media influencers.

Consistent with the present study, other studies appearing after our study had been completed have found that vaccination hesitancy is associated with negative attitudes toward a SARSCoV2 vaccine, including concerns about safety and efficacy (Fisher et al., 2020; Neumann-Böhme et al., 2020; Palamenghi et al., 2020), and doubts about the necessity for vaccination (Dodd et al., 2020). Findings from the present study, along with results from previous studies, have important implications for public policy. In order to maximize the uptake of a SARSCoV2 vaccine, when such vaccine becomes available, it is important to address the various anti-vaccination beliefs identified in the present study and in other recent investigations. Across studies, a commonly identified concern is that the risks might outweigh the benefits. Our research found that participants would be more likely to get vaccinated if they were persuaded that the vaccine had been rigorously tested (**Table 2**). In order to maximize vaccine uptake, health authorities need to reassure the public that vaccine development has followed all the preestablished guidelines and that the process of developing a vaccine has not been rushed. If the public perceives that health authorities are hastily rushing a SARS-CoV2 vaccine into production, then this would undermine public confidence and exacerbate vaccination refusal. Our findings suggest that the most important way of ensuring vaccine uptake is to provide the public with convincing evidence that a SARS-CoV2 vaccine has been rigorously tested, shown to be effective, and is not perceived as being rushed into production. Unfortunately, the vaccine production program by the U.S. Department of Health and Human Services is called "Operation Warp Speed"[1]. For people in the community who are worried that the vaccine production process has been excessively rushed, the name "Operation Warp Speed" sends a disturbing message; it suggests that due diligence has not been followed and that there has not been sufficient evaluation of the comparative risks and benefits. Mistrust of health authorities is an important deterrent to vaccination uptake (Taylor, 2019). Vaccination development and dissemination programs with more reassuring titles would be more likely to engage the public trust (e.g., calling the program "Operation Due Diligence" instead of "Operation Warp Speed").

The present study has various strengths and limitations. In terms of strengths, the sample was large and the study provides new information on barriers and incentives for people to get vaccinated against SARSCoV2. A limitation of the study is the cross-sectional nature of the design. It is possible that COVID-19-related vaccination attitudes may change over time, especially if governments or health authorities launch pro-vaccination public education programs. This remains to be investigated in future research. The question of whether vaccination attitudes differ across different ethnic or cultural groups also remains to be investigated. Additional research is also needed to investigate whether variables other than those investigated in the present study are association with vaccination hesitancy. Such variables might include health literacy and other individual difference variables. The question of whether the findings of the present study can be generalized across different countries and cultures also remains to be investigated.

Another limitation of this study is that political affiliation was not measured. Other surveys suggest that people who oppose a SARS-CoV2 vaccine are more likely have Conservative or Republican political affiliations than Liberal or Democrat affiliations in both the United States and Canada (Angus Reid Institute, 2020; Gallup, 2020). A further limitation is that we assessed vaccinations intentions rather than actual vaccination behaviors. This was unavoidable as a vaccine for SARS-CoV2 was not available at the time of this study. The study was conducted under the premise that it is more important to be proactive in addressing forthcoming vaccination problems than to be reactive in an attempt to deal with problems as they arise.

Psychotherapy During COVID-19: How the Clinical Practice of Italian Psychotherapists Changed During the Pandemic

Tommaso Boldrini[1], Arianna Schiano Lomoriello[1,2], Franco Del Corno[3], Vittorio Lingiardi[4] and Silvia Salcuni[1]*

[1]Department of Developmental Psychology and Socialization, University of Padova, Padova, Italy, [2]Department of Cognitive System, Denmark Technical University (DTU), Copenhagen, Denmark, [3]Association for Research in Clinical Psychology (ARP), Milan, Italy, [4]Department of Dynamic and Clinic Psychology, Faculty of Medicine and Psychology, Sapienza University of Rome, Rome, Italy

Aims: Italy was one of the first countries to be significantly affected by the coronavirus disease 2019 (COVID-19) pandemic, determining a unique scenario for Italian psychotherapists to consider changing the modality in which they deliver treatment. The present study aimed at studying which factors related to psychotherapists and their clinical practice had a major role in predicting two main outcomes: (1) the rate of interrupted treatments during lockdown and (2) psychotherapists' satisfaction with the telepsychotherapy modality.

Methods: An online survey was administered to licensed psychotherapists (n = 306), who worked mainly as private practitioners, between April 5 and May 10, 2020 (i.e., the peak of the pandemic in Italy).

Results: Psychotherapists reported that 42.1% (SD = 28.9) of their treatments had been interrupted, suggesting that Italy faced an important undersupply of psychotherapy during the lockdown. Using the Akaike information criterion (AIC) model selection, we identified three predictors of the rate of interrupted treatments: (1) psychotherapists' lack of experience with telepsychotherapy prior to the lockdown, (2) their theoretical orientation (with cognitive behavioral psychotherapists reporting a higher rate of interrupted treatments), and (3) patients' lack of privacy at home, as reported to the psychotherapists. Furthermore, we found four predictors of psychotherapists' satisfaction with the telepsychotherapy modality: (1) the rate of interrupted treatments, (2) psychotherapists' previous experience with telepsychotherapy, (3) their beliefs about the compatibility of telepsychotherapy with their theoretical orientation, and (4) their use of a video-conferencing modality, rather than telephone.

Conclusion: The following recommendations can help policy makers, professional associations, and practitioners in promoting the continuity of psychotherapy treatments during the COVID-19 outbreak and in future emergencies: (i) disseminating training programs for practitioners on telepsychotherapy, (ii) supporting patients to pragmatically access a private space at home, (iii) encouraging practitioners to use video-conferencing (instead of telephone) to deliver remote therapy, and (iv) increasing the acceptance of telepsychotherapy among both clinicians and the general public.

INTRODUCTION

Italy was one of the first countries to be severely affected by the coronavirus disease 2019 (COVID-19). Beginning on February 23, 2020, the Italian government took strong actions to restrict residents' freedom, aimed at reducing the contagion. The most severe of these restrictions was the imposition of a nationwide lockdown in early March. This lockdown caused unprecedented changes in daily personal and professional activities, forcing Italian residents to avoid unnecessary face-to-face interactions and social gatherings, as well as limiting their movement to the strictly necessary.

Along with other healthcare treatments, psychotherapy was not subject to the full government restrictions, with the exception of general precautions (i.e., as outlined in the Italian Ministerial Decree of March 8, 2020). However, while it remained possible to maintain in-person psychotherapy sessions, doing so was practically challenged in private clinics and public health systems, considering that face-to-face meetings could increase the risk of infection for both therapists and patients; thus, the National Council of Psychologists CNOP) explicitly invited psychologists and psychotherapists, as far as possible, to provide their professional services *via* digital devices to guarantee the continuation of previously active therapeutic treatments and to ensure the mental health support for diseases linked to pandemic and quarantine. Guidance and regulation for telepsychology in Italy was provided in a document on recommendations for telepsychology [National Council of Psychologists (CNOP), 2017], which did not forbid any online psychological practices, and provided specific guidelines regarding deontological norms, informed consent, privacy and correct identification of users, and emergency situations management (i.e., recommending therapist to obtain emergency numbers and contact details of places offering support that are close by the place where a patient logs in or telephones). The natural consequence of this extraordinary situation was that a primary element of psychotherapy – the setting – was subject to renewed reflection. Specifically, the crossroad at which psychotherapists found themselves was defined by a choice between using telepsychotherapy – which offered the possibility of continuing therapy – or temporarily interrupting treatment.

At this historical time, the continuity of care for psychological treatment is pivotal. A recent study by Brooks et al. (2020) documented an increase in mental health disorders due to the COVID-19 pandemic, including self-reported symptoms of anxiety and depression (16–28%), and stress (8%), frequently in association with a sleep disorder (Rajkumar, 2020).[1] Evidence suggests that telepsychotherapy could represent a safe and efficacious alternative to physical treatment during the pandemic (Swartz, 2020; Wind et al., 2020). Poletti et al. (2020) reviewed the results of 18 empirical studies in which psychotherapy was provided *via* synchronous web technology. Interestingly, the authors reported that telepsychotherapy was substantially equivalent to face-to-face psychotherapy in its efficacy for treating common mental health disorders (Poletti et al., 2020). In particular, research has found telepsychotherapy to be effective in treating anxiety (Catarino et al., 2018), depressive (Egede et al., 2015; Catarino et al., 2018), and posttraumatic symptoms (Wierwille et al., 2016). Of note, patients who attend telepsychotherapy treatments report similar perceived quality of life, satisfaction, and treatment credibility as those enrolled in face-to-face psychotherapy (Egede et al., 2015).

Conversely, despite the evidence for its effectiveness, negative attitudes about telepsychotherapy are prevalent (see also Varker et al., 2018). Survey studies have reported that approximately half of all respondent psychotherapists perceive telepsychotherapy as less effective than face-to-face psychotherapy (Gordon et al., 2015, 2016; Schulze et al., 2018). Indeed, there are ethical arguments against the seamless implementation of online therapy, including (1) privacy, confidentiality, and security issues, (2) therapist competence and need for special training, (3) communication issues specific to technology, (4) research gaps, and (5) emergency issues (Stoll et al., 2020).

Moreover, patients have been found to express a low willingness to use telepsychotherapy (Apolinário-Hagen et al., 2017; Hantsoo et al., 2017), especially when they have already experienced face-to-face psychotherapy (Hantsoo et al., 2017). General skepticism toward telepsychotherapy is also present and is particularly strong among practitioners. In a sample of 1,791 US psychotherapists, nearly 80% reported that they did not use telepsychotherapy within their own practice (Pierce et al., 2019). Overall, learning curves in the adoption of new e-mental health technologies by both patients and psychologists have progressed far more slowly than initially expected, thus tallying with the estimate that it takes, on average, 16 years for a healthcare innovation to be implemented (Rogers et al., 2017). However, this prevision has been dramatically disproved by the COVID-19 lockdown, which has led to significant and swift changes in clinical practice. This, in turn, has given rise to a unique opportunity to study the consequences of a sudden, large-scale, massive setting transition towards telepsychotherapy.

As Italy was one of the first countries to experience forced changes in clinical activities due to the COVID-19 pandemic, the aim of the present investigation was to provide a picture of the scenario and to delineate which factors played a pivotal role in promoting better telepsychotherapy interventions at this time. In doing so, the investigation sought to generate knowledge to guide other countries struggling with the pandemic. For this purpose, we focused on two outcomes: (1) the rate of interrupted treatments (i.e., failure in the implementation of telepsychotherapy treatments) and (2) psychotherapists' satisfaction with the telepsychotherapy modality. In particular, we collected information related to the psychotherapists (e.g., sociodemographic characteristics, theoretical orientation, and treatment modality), their clinical practice (e.g., their selected

[1]A growing body of literature found out the potential consequences of the COVID-19 pandemic scenario also in people with pre-existing mental health disorders (e.g., Moreno et al., 2020). For example, people with anxiety-related or mood disorders resulted in being significantly affected than others, reporting greater fear about the danger of contamination, socioeconomic consequences, xeno-phobia, and traumatic stress symptoms (Asmundson et al., 2020). Similarly, individuals at high clinical risk for psychosis may be prone to exacerbate psychological distress (DeLuca et al., 2020), as a result of heightened stress sensitivity and comorbid mental health problems (Boldrini et al., 2019).

modality for delivering remote psychotherapy sessions, previous experience with telepsychotherapy), and their general beliefs about telepsychotherapy (e.g., their perception of the compatibility of their theoretical orientation to the online modality), as these factors were thought to play a role in determining the selected outcomes.

MATERIALS AND METHODS

Study Design

An online survey designed in Qualtrics was administered to licensed psychotherapists in Italy, using snowball sampling techniques. Data were collected from April 5 to May 10, 2020 – during the peak of the pandemic in Italy, approximately 5 weeks from the beginning of the lockdown and just before the second phase of restrictions easement (e.g., to allow access to church services, weddings, salon services, and short-term hospitality without boarding).

Participation in the research was voluntary, and no incentives were provided. All participants provided informed consent by agreeing to the data protection declaration prior to starting the survey. The principles outlined in the Declaration of Helsinki were followed, ensuring anonymous participation through the administration of the informed consent format of the ethics committee of the University of Padua (GDPR EU 2016, pd. 196/03).

Description of Study Participants

A sample of 308 psychotherapists [84% female; mean age = 45.1 (SD = 10.2)] completed the survey. The geographical provenance of the respondents was pretty homogeneous (Northern Italy = 37%, Central Italy = 35%, Southern Italy = 28%). Participants had been registered psychotherapists in Italy for mean = 12.9 (SD = 8.5) years, and they typically (i.e., before the COVID-19 lockdown) treated an average of 21.8 patients (SD = 16.3) per month. Their psychotherapeutic orientations were as follows: psychodynamic (60.8%), cognitive behavioral (16.1%), systemic (8.6%), humanistic (11.7%), and integrated (2.27%). Individual psychotherapy was the preferred treatment modality of 49.1% of the clinicians; 32% saw mostly families and couples; and the rest (18%) specialized in group therapy. The enrolled psychotherapists performed their work mainly as private practitioners (58.4%), with most of the rest (32%) working in hospitals or mental health services in addition to private practice (see also **Figure 1**). Finally, the majority of the enrolled psychotherapists, under ordinary circumstances (i.e., before the COVID-19 lockdown), received clinical supervision: 38% received one supervision session per month, 36.3% received two to four sessions per month, and 5.34% received more than four sessions each month. The remaining psychotherapists (20.3%) received no supervisions. Information about the therapists' clinical practice is summarized in **Figure 1**.

Measures

The survey comprised 45 items in total, and it took respondents approximately 8 min to complete. Given the aim of the present study, we analyzed only a portion of all the items of the survey. In addition to collecting sociodemographic characteristics and information about the psychotherapists' working practices (as reported above), the survey also asked respondents to report the proportion of their interrupted treatments since the COVID-19 lockdown, as well as the relative proportions of their patients whom they currently treated face-to-face, *via* telephone, and *via* video-conferencing. Respondents were also asked to rate their personal beliefs about telepsychotherapy, in terms of its compatibility with their therapeutic orientation, and their personal satisfaction with it. Additional items evaluated respondents' previous experience with video psychotherapy and if their patients reported a lack of access to private space at home.

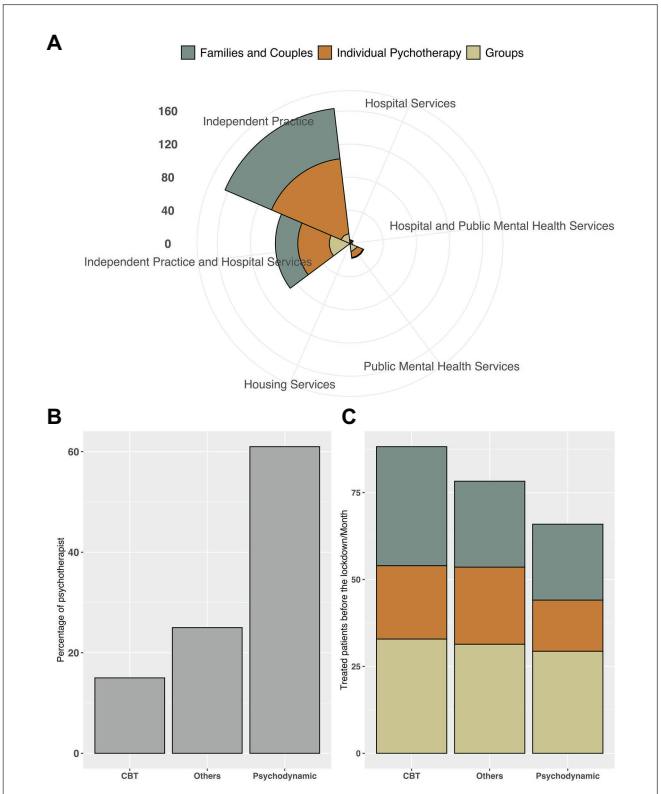

FIGURE 1 | The respective plots depict **(A)** the number of patients in treatment during the month prior to lockdown as a function of psychotherapists' work settings (i.e., independent practices, hospitals, public mental health, and housing services) and patient orientation (i.e., family and couples, individual, and group); **(B)** psychotherapists' theoretical orientations [i.e., psychodynamic, cognitive behavioral therapy (CBT), and "other"]; and **(C)** the proportion of patients in treatment in the month prior to lockdown, as a function of clinicians' theoretical orientation (i.e., psychodynamic, CBT, and "other") and patient orientation (i.e., family and couples, individual, and group).

Statistical Analysis

In the following analyses, we adopted a model selection strategy based on the Akaike information criterion (AIC; Wagenmakers and Farrell, 2004). The AIC (Akaike, 1973) is a powerful metric derived from information theory that identifies the relative quality of each model within a set of candidate models

(i.e., the lower the AIC, the higher the model quality, after controlling for model complexity).

Each full model was compared with simpler versions by removing predictors until an intercept-only model was reached. After identifying the best model (with the lowest AIC), we regressed participants' responses on the same set of regressors. Significant effects were explored with *post hoc* pairwise contrast using the Wald test, corrected for multiple comparisons using the false discovery rate (Benjamini and Hochberg, 1995).

The analyses were performed using the software R (2.13) with the lm function from the car package (Fox and Weisberg, 2019).

RESULTS

Changes in the Provision of Psychotherapy During the COVID-19 Lockdown

With respect to psychotherapists' changes in clinical practice during the COVID-19 lockdown, respondents reported that 42.1% (SD = 28.9) of their psychotherapy treatments were interrupted during the lockdown.[2] The remainder of their treatments was primarily delivered *via* online video [63.7% (SD = 38.3)] or telephone [29.1% (SD = 25.3)]. Only 7.2% (SD = 15.1) of their treatments were delivered face-to-face, while taking precautionary measures (e.g., wearing masks and gloves).

Predictors of a Higher Rate of Interrupted Treatments

The rate of interrupted treatments was estimated *via* a linear model. Data were fit to one model, which included respondents' therapeutic modality (individual vs. couples and families vs. groups), theoretical orientation [psychodynamic vs. cognitive behavioral therapy (CBT) vs. "other"], clinical experience (in years), previous experience with telepsychotherapy (frequent vs. rare vs. none), beliefs about the compatibility of telepsychotherapy with their own theoretical orientation (yes vs. no), and frequency of supervisions received before the outbreak (none vs. once vs. one to four vs. more than four per month), as well as patient's reported lack of privacy at home (yes vs. no) as predictive variables, as well as the interactions between these variables.[3]

Model comparisons showed that the best model for explaining the data observed for the rate of interrupted treatments included clinicians' previous experience with telepsychotherapy, clinicians' theoretical orientation, and patient's reported lack of privacy at home as predictive variables (AIC = 2,656.3, logL = −1,320.12, ΔAIC = 35.02).[4]

We regressed participants' responses to these sets of regressors and found a significant difference predicted by clinicians' previous experience with telepsychotherapy (b = −11.53, SE = 3.47, p = 0.001), suggesting that the rate of interrupted treatments was significantly lower when psychotherapists reported having frequently used telepsychotherapy prior to the COVID-19 outbreak (μ = 22.3; SD = 21.75); the opposite was true when psychotherapists reported having never used this modality (μ = 50.50; SD = 29.94). Notably, a significant difference was also present for psychotherapists who reported having used this modality rarely (μ = 39.54; SD = 26.40), compared to those who reported either frequent or no previous experience with telepsychotherapy. Furthermore, the model showed a significant difference depending on respondents' theoretical orientation (b = −12.04, SE = 4.75, p = 0.01), whereby those with a psychodynamic approach reported a lower rate of interrupted treatments (μ = 39.82; SD = 28.86), compared to those practicing CBT (μ = 48.6; SD = 31.11). However, this difference was not significant with those characterized as having an "other" clinical orientation. Finally, we found a significant effect of patients' reported lack of privacy at home (b = 10.37, SE = 3.77, p = 0.006), suggesting that psychotherapists with patients lacking private space at home (μ = 48.31; SD = 31.45) experienced a significantly higher rate of interrupted treatments compared to those who did not report the same issue (μ = 39.86; SD = 27.74; **Figure 2** and **Supplementary Table S1**).

Predictors of Therapists' Satisfaction With Telepsychotherapy

Participants' satisfaction was estimated *via* a generalized linear effect binomial model because the outcome variable (yes vs. no) was dichotomous. Data were fit in a model that included respondents' theoretical orientation (psychodynamic vs. CBT vs. other), clinical experience (in years), previous experience with telepsychotherapy (frequent vs. rare vs. none), beliefs about the compatibility of telepsychotherapy with their own theoretical orientation (yes vs. no), rate of interrupted treatments, dropped clinical supervisions (none vs. half vs. more than the half vs. all), use of the telephone, use of video-conferencing, and therapeutic modality (individual vs. couples and families vs. groups) as predictive variables, as well as the interactions between these variables.[5]

Model comparison showed that the model that best explained the data observed for perceived satisfaction included the rate of interrupted treatments, previous experience with

[2]Therapists were asked to consider the all number of patients treated before the lockdown and to report (on different sliders, which could vary between 0 and 100%) the percentages of (i) interrupted treatments, (ii) treatments currently delivered by video call, (iii) by telephone, and (vi) face-to-face. Thus, all the distributions reported in *Changes in the Provision of Psychotherapy During the COVID-19 Lockdown* should be interpreted as the means and standard deviations of the percentages reported by enrolled therapists to the number of patients treated before the lockdown.

[3]The full model for the rate of interrupted treatments was as follows: rate ~ theoretical orientation × clinical experience × experience with online × theoretical compatibility × supervision + patient's privacy (in Wilkinson notation).

[4]The ΔAIC was computed as the difference in AIC between the best ranked model and the null model, representing the difference in quality between the models.

[5]The full model for satisfaction was as follows: satisfaction ~ theoretical orientation + experience with online + theoretical compatibility + rate of interrupted treatments + dropped of supervision + telephone modality × clinical experience + video call modality × clinical experience + therapeutic modality (in Wilkinson notation).

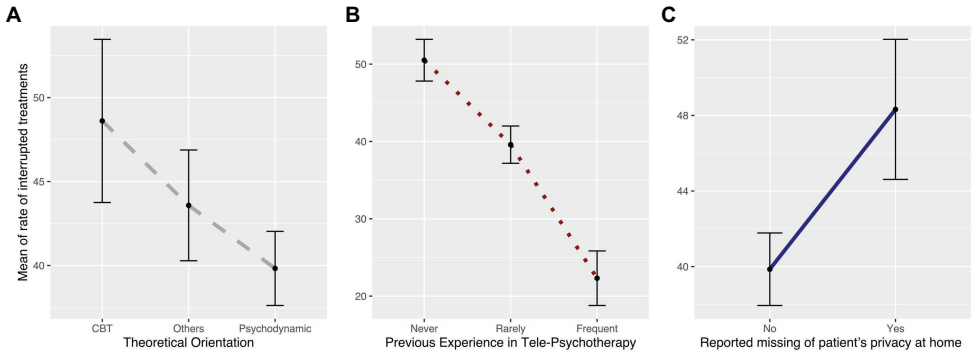

FIGURE 2 | The plots depict the parameters selected as the best predictors of the rate of interrupted treatments. In particular, they represent differences between **(A)** theoretical orientations (i.e., psychodynamic, CBT, and "other"); **(B)** psychotherapists' use of telepsychotherapy prior to the lockdown (i.e., none, rare, and frequent); and **(C)** patients' lack of privacy at home, as reported to psychotherapists (i.e., yes, no).

telepsychotherapy, theoretical compatibility, and use of video-conferencing as predictive variables (AIC = 305.5, logL = −146.618, ΔAIC = 2,386.01).

We regressed participants' responses to these sets of regressors and found a significant difference in satisfaction determined by psychotherapists' rate of interrupted treatments (b = −0.01, SE = 0.005, p = 0.02), whereby the more satisfaction they declared, the less dropout they reported. We also found a significant effect of previous experience with telepsychotherapy (b = 2.43, SE = 1.05, p = 0.02), indicating that psychotherapists who reported having frequently used telepsychotherapy prior to the COVID-19 lockdown had significantly higher satisfaction (μ = 0.97; SD = 0.16) than those who reported having never used this modality (μ = 59.35; SD = 29.94). Notably, a significant difference was also found for psychotherapists who reported having rarely used this modality (μ = 0.51; SD = 0.50), compared to those who had either frequent or no previous experience with telepsychotherapy. Furthermore, the model showed a significant effect of theoretical compatibility (b = 1.62, SE = 0.38, p < 0.001), suggesting that psychotherapists who perceived their theoretical orientation as compatible with the telepsychotherapy modality (μ = 0.69; SD = 0.46) were more satisfied than those who perceived their orientation as incompatible (μ = 0.26; SD = 0.44). The model also revealed a significant effect of the number of video-conference calls (b = 0.01, SE = 0.004, p = 0.01), showing that the more psychotherapists provided sessions *via* video-conferencing, the more satisfaction they reported (**Figure 3**; **Supplementary Table S2**).

DISCUSSION

The present study aimed at identifying the most significant factors in delivering psychotherapy during the COVID-19 lockdown in Italy. In this vein, we sought to both describe the situation for psychotherapy during the peak of the pandemic in Italy and provide guidance for countries still facing (or likely to face) a similar situation as that experienced in Italy.

The first outcome of the present study considered the rate of interrupted treatments (as reported by psychotherapists), suggesting the degree of failure in implementing telepsychotherapy. Psychotherapists reported that 42.1% of their treatments had been interrupted, suggesting that, during the COVID-19 lockdown, there was an important undersupply of psychotherapy. These data are even more surprising, because the majority of participants worked exclusively (58.4%) or mainly (32%) as private practitioner, so they could potentially quickly rethink their clinical practice without having to conform to the slower reorganization that impacted on public mental health services and hospitals. A similar reduction in psychotherapy was observed in Austria, where a decline in face-to-face sessions was compensated by a reported increase in telepsychotherapy in the early weeks of the COVID-19 lockdown – even though the increase was not sufficient to cover the full proportion of interrupted treatments (Probst et al., 2020). On the contrary, a survey study conducted in the Czech Republic, Germany, and Slovakia did not observe psychotherapy dropout during the pandemic (Humer et al., 2020). Notably, the present study was conducted during the peak of the pandemic, after the Italian government imposed strong limitations on personal movement; in contrast, no curfews existed in the aforementioned survey study at the time of data collection (Humer et al., 2020). This mismatch in the study conditions substantially limits our ability to compare findings.

The present analyses focused on identifying the predictive factors of treatment interruption, emphasizing that both therapists and patients play a role in this outcome. In particular, the model of best fit suggested that psychotherapists' lack of experience with telepsychotherapy prior to the lockdown was an essential factor in predicting the rate of interrupted treatments. It is reasonable to assume that a lack of experience with telepsychotherapy may have threatened clinicians' professional self-confidence (Poletti et al., 2020). Further, a lack of familiarity with using technology to provide video-conferencing psychotherapy (present in 43.8% of our sample) could have represented a barrier to providing remote treatment,

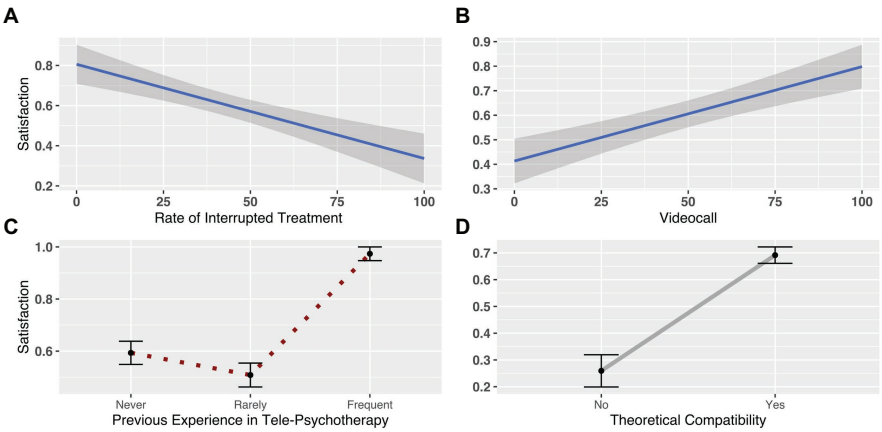

FIGURE 3 | The plots depict the parameters selected as the best predictors of differences in psychotherapists' satisfaction with telepsychotherapy. In particular, the respective plots represent the variation in perceived satisfaction according to **(A)** the rate of interrupted treatments; **(B)** the use of video-conferencing to deliver sessions; **(C)** psychotherapists' use of telepsychotherapy prior to the lockdown (i.e., none, rare, and frequent); and **(D)** psychotherapists' beliefs about the compatibility of telepsychotherapy with their theoretical orientation (i.e., yes, no).

as suggested by previous research (Rössler et al., 2011; Cipolletta et al., 2017; Etzelmueller et al., 2018). This finding is corroborated by evidence that therapists who have received specific training in delivering telepsychotherapy are more likely to adopt this treatment modality (Pierce et al., 2020). Given that COVID-19 may impact nearly everyone in the world, the need for psychological support is fundamental (Duan and Zhu, 2020). Thus, the dissemination of training programs on telepsychotherapy and video-conferencing technology by professional associations may be crucial for countries affected by the pandemic, in order to prevent an undersupply of psychotherapy treatment.

A secondary relevant aspect shown in our analyses related to patients. Although the information we obtained on patients' conditions was derived from psychotherapists, the data suggested that patients' reported lack of private space at home presented a significant barrier to the implementation of telepsychotherapy. According to this finding, the continuation of therapeutic work may require therapists to pragmatically discuss with their patients the incidental difficulties in achieving an intimate, reassuring, and safeguarded setting in which to participate in telepsychotherapy sessions.

Moreover, we found a significant effect of theoretical orientation on the rate of interrupted treatments, with psychodynamic therapists reporting a lower rate than CBT therapists. This result is unexpected, since previous studies have found CBT clinicians to be more accepting of telehealth interventions than psychodynamic therapists (e.g., Perle et al., 2012), and similar evidence is deducible from the higher number of studies on CBT delivered remotely (e.g., Egede et al., 2015; Zerwas et al., 2017; Catarino et al., 2018; Etzelmueller et al., 2018).

The second focus of the present investigation was psychotherapists' satisfaction with telepsychotherapy. As expected, the rate of interrupted treatments represented a negative predictor, as it implied a withdrawal of therapists' professional duties and consequent financial damage. Importantly, among the two different modalities for delivering remote sessions (i.e., telephone vs. video-conferencing), only the video-conferencing modality predicted therapists' satisfaction, suggesting that – although telephonic communication may provide a fast and easy method of providing remote care – whenever possible, therapists should choose video-conferencing technology over the telephone. Indeed, previous studies have reported the efficacy of this modality, explaining that it enables psychotherapists and patients in separate locations to see each other and interact in real time (i.e., "synchronously"; see Fletcher et al., 2018; Norwood et al., 2018, for reviews). This finding is also supported by experimental studies showing that the perceived distance between two interacting individuals modulates the empathic reaction between them (Schiano Lomoriello et al., 2018), which is a key ingredient of all psychotherapeutic interventions.[6]

Finally, therapists' attitudes and beliefs about telepsychotherapy played a significant role in qualitatively shaping their experiences of online sessions. In particular, we found that therapists who considered the online modality as incompatible with their theoretical orientation reported less satisfaction. Overall, there are no valid reasons to believe that a specific therapeutic orientation is more or less suitable for telepsychotherapy (Varker et al., 2018; Poletti et al., 2020). In fact, preliminary research has pointed to the efficacy of both CBT and diverse psychotherapeutic approaches, as delivered over an online modality (e.g., Dennis et al., 2020). Moreover, as brilliantly discussed by Swartz (2020), strategies for supporting patients during the COVID-19 pandemic can be found in virtually all psychotherapeutic disciplines. In this vein, therapists' reluctance

[6]As pointed out by Racine et al. (2020), another therapeutic concern is the assessment of patients' emotional states via telematic modality, especially about dissociation. Dissociative symptoms, which are challenging to assess even in natural therapeutic circumstances (e.g., Fagioli et al., 2015), could be more challenging to be identified using a video call, and barely impossible to identify via telephone.

to use technology for psychotherapy may be related to uninformed attitudes, rather than fundamental issues relating to this modality (Van Daele et al., 2020). National and international institutions hold the responsibility for increasing the acceptance of telepsychotherapy among both clinicians and the general public, especially in the current context, given that a surge in the demand for mental health resources is expected in the months following isolation (Gao et al., 2020).

Surprisingly, we did not find any effect of psychotherapists' clinical experience in predicting either the rate of interrupted treatments or therapists' satisfaction with the online treatment modality. We hypothesize that, given the high correlation between psychotherapists' age and clinical experience in our sample, this lack of evidence could represent a compensatory effect of the sample characteristics. Indeed, previous studies on psychotherapy treatments delivered *via* video-conferencing have shown that psychotherapists' familiarity with Internet technology promotes patients' compliance by limiting technical difficulties (e.g., brief interruptions or breakdowns in online communications; Etzelmueller et al., 2018) and that older age is associated with a lower dropout rate and better clinical outcomes (Catarino et al., 2018). In other words, younger therapists may encounter fewer technological barriers when delivering online sessions, whereas older therapists may benefit from their greater clinical experience, which allows them to better manage their patients during this potentially destabilizing transition in setting.

It is necessary to recognize the limitations of the present study. Notably, the enrolled psychotherapists performed their work mainly as private practitioners; thus, the generalizability of the present results should be limited to the changes in psychotherapy activities in the private practice. A further limitation relates to the cross-sectional design. Multiple measurement points in a longitudinal design would have the advantage of monitoring the provision of psychotherapy in Italy as the government restrictions eased. It should also be noted that the snowball technique used for recruitment may have produced a biased sample (e.g., the higher proportion of psychodynamic therapists may have been due to the therapeutic orientation of the authors). Finally, the study only analyzed psychotherapists' self-reports, and no objective data (e.g., health insurance information) were considered.

To conclude, **Table 1** reports key messages that can provide insight for countries struggling with the pandemic and offer specific guidance for policy makers, mental health institutions, professional organizations, and psychotherapists in promoting the continuity of psychotherapy treatment during the COVID-19 outbreak and in future pandemics.

TABLE 1 | Key message for practitioners.

During the peak of the lockdown in Italy, 42.1% of psychotherapy treatments were interrupted.

The following points are the factors we observed to limit the implementation of telepsychotherapy, followed by suggestions to help countries that are affected by the pandemic:

I. Therapists' lack of experience with telepsychotherapy.

→Disseminate training programs on telepsychotherapy.

II. Patient's lack of a private space to access telepsychotherapy sessions.

→Help and support patients to pragmatically access a private space.

III. Not using video-conferencing to administer telepsychotherapy (video-conferencing was the only remote modality found to predict therapists' higher satisfaction).

→Therapists should use video-conferencing to deliver remote therapy, where possible.

IV. Therapists' consideration of teletherapy as compatible with their theoretical orientation (those who did not report less satisfaction).

→Relevant associations should seek to increase the acceptance of telepsychotherapy among both clinicians and the general public.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Ethics committee of the University of Padua. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

TB and AS developed the survey and wrote the first draft of the manuscript. AS analyzed the data. SS conceived the research study and contributed to the development of the survey. SS, VL, and FC contributed to the interpretation of the results and critically reviewed the final draft of the manuscript. All authors contributed to the article and approved the submitted version.

ACKNOWLEDGMENTS

We would like to thank all of the psychotherapists who patiently responded to our survey during this critical and frightening time.

Demographic and Attitudinal Factors of Adherence to Quarantine Guidelines During COVID-19: The Italian Model

Leonardo Carlucci, Ines D'Ambrosio and Michela Balsamo*

School of Medicine and Health Sciences, University of Studies "G. d'Annunzio" Chieti–Pescara, Chieti, Italy

In Italy, a large outbreak of coronavirus disease 2019 (COVID-19) occurred from 2020 January 30, before the World Health Organization has stated that it is a pandemic. The nationwide quarantine had the desired impact of controlling the epidemic, although had presented many challenges, given its large economic and social costs. Complete adherence to recommendations can potentially decelerate and reduce infectious disease outbreaks. To date, it is not clear how compliant the Italian public has been with voluntary home quarantine, neither which factors have influenced an individual's decision to comply with a quarantine order. The purposes of this study were to investigate the degree of the adherence to quarantine restrictions and the factors associated with the self-reported adherence. During the third week of the national lockdown, 3,672 Italian quarantined adult residents (65% females; range, 18–85 years) participated in an online cross-sectional survey focused on the risk perception of contracting COVID-19 and their reported adherence to quarantine protocols. Analysis of variance showed significant differences among demographic groups in tendency to comply with quarantine orders, with women, most educated people, residents of Southern Italy, middle-aged individuals, and health workers more likely to adhere to quarantine guidelines. As well, participants exhibiting the perception, anxiety, and susceptibility of risk of contracting COVID-19 disease were found significantly more likely to adhere to quarantine guidelines. The results of this study can help public health policy makers to recognize target populations for COVID-19 prevention and health education and to understand how inform communication strategies aimed at minimizing the impact and spread of the disease.

INTRODUCTION

The novel coronavirus disease 2019 (COVID-19) had gained intense attention globally and continues to spread, posing a serious human pandemic threat (World Health Organization, 2020b). Given the lack of the proven vaccine, or efficacious treatments for infected people, the "killer" virus is arousing the sense of danger and uncertainty of its future course among health workers and the public.

After China, Italy has the second largest number of confirmed cases and was the first Western Republic affected by the COVID-19 spread (Saglietto et al., 2020). The Italian National Institute

of Health reported that between December 2019 and April 16, 2020, approximately 22,170 deaths occurred, 40,164 people were discharged or healed, and 168,941 million people were infected with COVID-19 on 1,046,910 tampons performed. In response to the rising numbers of suspected and diagnosed cases and deaths and to maintain the capacity of health systems to treat as many severe cases as possible, in Italy and in the world, a range of control measures had urgently adopted or are in the process of implementing, such as "isolation" and "quarantine," as non-pharmaceutical interventions tools to slow or prevent spread (Schabas, 2004; Bensimon and Upshur, 2007). The Italian government declared the national lockdown status, by March 11 to May 3: all public places were closed, and people have to stay at home apart from exercise, serious health issues, and other essential tasks (Government of Italy, 2020b). All the Italian people were in quarantine (#iorestoacasa).

Punitive legislation for travelers who make false health declarations and/or ignore these recommendations was established. Similar to pharmaceutical interventions, the effectiveness of quarantine interventions should be evaluated and monitored over time.

According to the Imperial College COVID-19 Response Team (Ferguson et al., 2020), the slowing growth in daily reported deaths was consistent with a significant impact of the containment and quarantine measure implemented several weeks earlier. The effective reproduction number, Rt, was dropped to close to 1 around the time of lockdown (March 11). This meant that 38,000 (13,000–84,000) deaths were averted.

At the time of writing, these measures had been extensively followed in public health of most nations, with a substantial impact in reducing transmission in countries with more advanced epidemics (Ferguson et al., 2020).

Successful use of these major non-pharmaceutical interventions requires a good organization of health services and mostly a good adherence to protocols by citizens. As Webster et al. (2020) stated, "Quarantine does not work if people do not adhere to it" (p. 3). However, little is known about which factors can increase the likelihood of general population adhering to quarantine orders in a Western republic, like the Italian one (Gernhart, 1999).

During major epidemics, social variables (gender, age, ethnicity, education level, marital status, working status) were found associated to self-quarantine guidelines (Bish and Michie, 2010; Webster et al., 2020). In addition, a psychological factor affecting the adherence to quarantine was identified in beliefs about potential health-specific harm, such as "risk perception." Risk perceptions are placed as core concepts in most theories of health behavior, including the Protection Motivation Theory (Rogers, 1975), the Health Belief model (Rosenstock, 1974), Theory of Planned Behavior (Ajzen, 1991), and the Extended Parallel Process model (Witte, 1992; for reviews, see Sutton, 1987; Weinstein, 1993, 2000).

Indeed, perceived likelihood, susceptibility, or severity has been found to shape or predict many health behaviors. In many studies, these dimensions of risk perception were associated with the compliance with physician-prescribed medical regimens, such as the vaccination behavior [for a meta-analysis, see (Brewer et al., 2007)], adherence to measures for preventing transmission of microorganisms in primary healthcare (Maroldi et al., 2017), adherence to effective measures in preventing HIV infection (Storholm et al., 2017), and adherence to mammography guidelines as screening for women at risk of breast cancer (Graves et al., 2008). Also, during past epidemics, such as Ebola, perceived risk has been found to both positively and negatively influence health behaviors (Bish and Michie, 2010; Ajilore et al., 2017).

In addition, according to the literature on risk perception (Adams, 1995), public concerns about risk are higher with novel threats and, when individuals do not feel in control of the risk, both factors relevant to an influenza pandemic. There is also evidence from this review that perceiving the disease to be more severe is associated with taking preventive and avoidant behaviors. This is the case of the COVID-19 emergency.

All the aforementioned theories highlighted the importance of perceptions of threat in determining a behavioral response and provide a framework to understand the findings of these studies.

In light of this literature and the advent of this current influenza pandemic, the purpose of this study was to investigate (1) the degree of the adherence to quarantine restrictions and recommendations in a large sample of quarantined Italian participants during the COVID-19 pandemic and (2) the factors associated with the self-reported adherence to these measures (or protective behaviors).

Based on the previous literature (Bish and Michie, 2010; Webster et al., 2020), sociodemographic variables, such as gender, age, education, health, and marital status, employment status and characteristics, and the risk perception (perceived risk of contracting COVID-19) were selected as factors that could influence the self-reported compliance with the quarantine guidelines.

In addition to sociodemographic variables, geographical region of residence was examined (North-east, North-west, Center, South, Islands). The regional structure of the Italian National Health Service translated into very diverse responses to the emergency from the regions, which have differentiated, by spread of the epidemic, the number of diagnosed cases and deaths (Remuzzi and Remuzzi, 2020; Spina et al., 2020). Participants from different countries are hypothesized to show different values in perceived risk of contracting COVID-19 and adherence to quarantine guidelines.

MATERIALS AND METHODS

Sample and Procedure

Respondents selected for this study were quarantined Italian adults 18 years or older with access to a networked computer. An online cross-sectional study was conducted using a virtual snowball sample through social media. The study has been recorded to the Ministry of Education, University and Research and approved by the Department of Psychological Sciences, Health and Territory, University of Studies "G. d'Annunzio" Chieti–Pescara, Italy, review board. Written informed consent was obtained from all individual participants included in the

study. This cross-sectional survey was conducted between March 21 and 26, 2020, the 2 weeks immediately after the lockdown was decreed by the Italian Government on March 9 (#iorestoacasa) (Government of Italy, 2020a). We received responses from 3,964 respondents. Of these, 292 respondents did not complete the questionnaires (>50% of the missing values).

Measures

Sociodemographic Variables

General information, sociodemographic variables (such as age, education, marital status, geographic area and region, employment status, and year income) including history of psychiatric illnesses and medical problems (e.g., physical/mental pathologies; hospitalizations), and diagnosis or suspect of COVID-19, as well as living environment during quarantine, were asked (e.g., household type and size). In addition, participants were asked to rate their physical symptoms during quarantine (e.g., fever, cough, difficulty in breathing). Participants' physical health status index was derived from history of chronic medical illness and number of pathologies (none = excellent, 1 pathology = good, 2 pathologies = poor, ≥3 pathologies = fragile). Questions about religious practices and religiousness were also included in the survey.

Primary Outcome

Adherence to quarantine guidelines carried out in response to COVID-19 infection was measured by 12 items classified into three categories: preventive, avoidant, and management of disease behaviors (Bish and Michie, 2010). The preventive behavior category was composed of six items, which include hygiene behaviors such as handwashing with soapy water or an alcohol-based solution, coughing or sneezing into a handkerchief (preventing the hands from coming into contact with respiratory secretion), cleaning surfaces with chlorine or alcohol disinfectant, wearing protective mask, keeping at least 1 m (or 3 feet) of distance. The avoidant behaviors category included five questions about the avoidance of gatherings in public or open-to-public places, handshaking and hugging, touching eyes/nose/mouth with hands, sharing of promiscuous use of glasses and bottles, doing and outdoor sport, and/or physical activities alone in public areas (**Appendix A**). Respondents were asked about the frequency whether they had carried out quarantine guidelines on a 5-point Likert scale (from 0 "never" to 4 "always"), respectively, for the preventive and avoidant categories. A global index of adherence to quarantine guidelines has been developed, by summing the answers to the items below. These behaviors are all decreed by law (Government of Italy, 2020a). In the present sample, Cronbach α was 0.696 [95% confidence interval (CI), 0.681–0.710].

Finally, a single item about the "taking antiviral drugs" has been included in the questionnaire as a management of disease behaviors category.

Risk Perception

A multidimensional questionnaire on risk perception of COVID-19 infectious disease outbreak has been implemented following the "Effective Communication in Outbreak Management" guidelines and using a standardized and revised version of the Ebola risk perception surveys (Richardus et al., 2015; see **Appendix A**). The risk perception questionnaire contains the following dimensions: (A) perception (eight items); (B) anxiety and susceptibility to the COVID-19 (three items); (C) intention to carry out the preventive measures (one item); (D) perception of seriousness (one item); and (H) motivating/hindering factors that determine the willingness to carry out preventive measures (one item). Risk questions were responded to on a 5-point Likert scale for the dimensions A to D, whereas for H, response options were in a multiple-choice format. In addition, perception (A) risk dimension was classified into four groups according to quantiles (very low, low, high, and very high). In the present sample, Cronbach α for the risk perception dimension was 0.808 (95% CI, 0.798–0.817).

Data Analysis

Descriptive statistics were calculated for sociodemographic characteristics, physical symptoms and health service utilization variables, contact history variables, knowledge and concern-related variables, precautionary measure variables, and additional health information variables. A series of independent-samples *t* test and analyses of variance (ANOVAs) were carried out to determine whether there is a statistically significant difference ($p < 0.05$) in the adherence to quarantine guidelines scores between levels of risk perception and demographic factors. Statistical analysis was performed using SPSS Statistic 21.0 (IBM SPSS Statistics). Effect sizes (ESs) for independent *t* test was calculated using the Hedges *g*, in order to provide a measure of ES weighted according to the relative size of each sample. The Hedges *g* ES was interpreted using Cohen (1988) convention as small (0.2), medium (0.5), and large (0.8). ESs for the ANOVAs were computed using the partial ω^2 (ωp^2). Partial ω^2 represented an unbiased alternative to partial η^2 (Olejnik and Algina, 2003). ωp^2 was interpreted according to Murphy et al. (2014) convention as small (0.01), medium (0.06), and large (>0.15).

RESULTS

Sociodemographic Data

Sociodemographic variables and levels of risk perception are shown in **Table 1**. More than half of the participants were females (65.1%), with an average age of 33.27 (SD = 14.29) years and with a high level of education (49.5% upper secondary school, 41.8% bachelor's degree), single (61.2%), Roman Catholic (73.2%), and located in the South of Italy (45.2%). The 31.20% were students, and the 47.4% of the participants were employed, with a yearly income of 10,000–30,000 €. Among these, 5.2% declared they had moved from one to another city in the previous weeks, due to pandemic. The 6.3% of our sample declared to be employed as healthcare professionals: 20.3% were physicians, 14.7% were nurses, and 4.7% were pharmacists.

Most participants were in quarantine with family (84.2%), 6.5% alone, and the remaining with colleagues/roommate/other familiars. Participants lived in apartments with balcony (74.2%), approximately within 80–150 mq (52.5%).

TABLE 1 | Descriptive and differences among sociodemographic variables and risk in adherence to quarantine Guidelines (n = 3,672).

Group	Descriptive		Adherence to quarantine guidelines		
Sex Variables	**Frequency**	**%**	**Mean**	**SD**

Missing	1,698	46.2		
				$F(3;1970) = 1.970$, $p = 0.116$

North-West (Piemonte, Lombardia, Liguria, Valle d'Aosta). North-East (Veneto, Friuli Venezia Giulia, Emilia Romagna, Trentino). Center (Toscana, Umbria, Marche, Lazio). South (Abruzzo, Molise, Campania, Puglia, Basilicata, Calabria). Islands (Sicilia, Sardegna). Post hoc test = Tukey HSD. Not significant differences have been found between No Antiviral Drugs and Sociodemographic Variables, except for health status (Kruskal–Wallis = 13.347(3); p = 0.004).

Subjects were mostly healthy: 71.2% reported no physical pathologies, whereas 7% were detected as fragile and with a long history of chronic medical illness and several number of pathologies (e.g., diabetes or cancer, etc.). During this period of quarantine, 64.95% of the participants had reported no symptoms likely related to the COVID-19 infection, while the remaining has reported the following symptoms: cold (9.59%), feeling of weakness (8.22%), cough (7.5%), difficulty in breathing (1.44%), fever higher than 37.5°C (0.68%), and changes in taste/smell (0.14%).

Risk Perception and Adherence to Quarantine Guidelines

Participants exhibited an average perception of risk (Risk A), with a mean of 26.05 (SD = 5.89; range of scores, 8–40). In details, the perception of risk of contracting COVID-19 disease (Risk A) was homogeneously distributed across the four risk levels, from 30.8% of the participants perceiving very low risk to 20.6% of those perceiving very high risk (**Table 2**). As regards *anxiety* and *susceptibility* risk dimension (Risk B), 92.4% of the participants was found worried about getting COVID-19, from slightly to really worried; 95.6% perceived the *chances of getting COVID-19* from average to very high, *if* they did not *follow preventive measures adopted*; 91.5% of the respondents reported a medium to very high probability of getting COVID-19 within the next year, if they did not get vaccinated.

As regards the intention, 95.1% of the subjects expressed the willingness to carry out to follow the preventive measures without any doubt (Risk C), mostly driven from the following motivation factors (Risk H), from preventing the spread of COVID-19 (79.8%), avoiding to transmit COVID-19 to people close to me (75.7%), to considering the government actions helpful (30.6%) (**Table 2**). As for the perception of seriousness, 98.5% of the respondents perceived "The coronavirus emergency was quite and very serious threat on global health" (Risk D).

Information about COVID-19 emergency were sought by our respondents from the following media: 78.8% by radio or television newscasts, 69% from official channels (press releases, bulletins), 55.7% from social networks, 36.8% from newspapers (including its digital editions), and 12.8% from relatives and friends.

Adherence to Quarantine Guidelines

Respondents exhibited medium to high scores of adherence to quarantine guidelines as measured by a single interval index, with a mean of 32.59 (SD = 5.22; range, 0–44), with an average of quarantine duration of 15 days (SD = 6.64). A weak but significant positive association ($r = 0.035$, $p = 0.034$) was found between the adherence and the length of quarantine.

Within the preventive behaviors' category, covering the mouth or nose (when sneezing and/or coughing) and keeping at least 1 m of distance (also named social distancing measure) were the behaviors most always adopted by participants (78.5% and 70.6%, respectively), and then the use of handkerchief (54.5%), handwashing using soapy water or alcohol-based solution (40.8%), and wearing face mask (35.7%). Instead, the cleaning of surfaces represented the less frequent protective behavior (26.2% of "always" responses) of our respondents.

As avoidant behaviors, avoidance of gatherings (92.8%), of handshake/hug (76.8%), to do outdoor sports alone in public area (77.3%), and sharing of glasses and bottles (61.3%) were the most protective behaviors always adopted by our participants. Less importantly, avoidance to touch eyes/mouth with hands was adopted by 18% of the participants.

Finally, within the management of disease behaviors, only 0.9% of the participants take antiviral drugs even if not medically prescribed, and 5.4% with a medical prescription.

Reasons for going out declared by our respondents were as follows: 8.5% for working demands, 23.9% for receiving medical

TABLE 2 | Descriptive of risk perception dimensions (n = 3,672).

Group	Risk dimensions	Descriptive		Adherence to quarantine guidelines		
		Frequency	%	Mean	SD	*Post hoc*
Risk A) Perception						
(1) Very low		1,132	30.8	32.70	5.37	4 vs. 2, 3
(2) Low		888	24.2	32.08	5.17	
(3) High		897	24.4	32.37	5.36	
(4) Very high		755	20.6	33.31	4.98	
				$F(3;3668) = 8.337$, $p < 0.001$, $\omega p^2 = 0.006$		
Risk B) Anxiety and Susceptibility						
H*ow worried are you about getting COVID-19?* (Risk B1)						
(1) Not worried at all		44	1.2	28.41	8.38	5 vs. all
(2) Not worried		234	6.4	30.53	6.04	
(3) Slightly worried		1,068	29.1	31.35	5.19	
(4) Worried		1,540	41.9	33.03	4.90	
(5) Really worried		786	21.4	34.27	4.81	
				$F(4;3667) = 56.888$, $p < 0.001$, $\omega p^2 = 0.057$		
What are your chances of getting COVID-19 if you do not follow preventive measures adopted? (Risk B2)						
(1) Very low		45	1.2	32.64	5.39	5 vs. all
(2) Low		117	3.2	31.59	6.14	
(3) Average		451	12.3	31.03	5.99	
(4) High		1,399	38.1	32.13	5.03	
(5) Very high		1,660	45.2	33.48	5.00	
				$F(4;3667) = 26.358$, $p < 0.001$, $\omega p^2 = 0.026$		
If you don't get vaccinated. what are your chances of getting COVID-19 within this year?(Risk B3)						
(1) Very low		87	2.4	32.94	5.66	5 vs. all
(2) Low		226	6.2	32.21	5.60	
(3) Average		1,488	40.5	32.30	5.29	
(4) High		1,355	36.9	32.66	5.11	
(5) Very high		516	14.1	33.37	5.23	
				$F(4;3667) = 4.511$, $p < 0.001$, $\omega p^2 = 0.003$		
Risk C) Intention						
Do you intend to follow the preventive measures?						
	Absolutely not	5	0.1	27.20	11.30	
	Probably not	4	0.1	23.00	9.27	
	Probably yes	170	4.6	29.75	6.01	
	Absolutely yes	3,493	95.1	32.75	5.15	
Risk D) Perception of seriousness						
How severe do you think the coronavirus emergency on global health is?						
	Not serious at all	1	0.1	31.00	—	
	Not very serious	53	1.4	28.28	8.08	
	Quite serious	1,087	29.6	31.25	5.57	
	Very serious	2,531	68.9	33.26	4.88	
Risk H) Motivating/hindering factors						
*Why are you taking protective behaviors?**						
	I want to prevent the spread of COVID-19	2,930	79.8			
	I don't want to transmit COVID-19 to people close to me	2,779	75.7			
	COVID-19 can be dangerous	2,160	58.8			
	I feel responsible for my health	1,647	44.9			
	I trust the preventive measures are helpful	1,122	30.6			
	Authorities recommend them	370	10.1			
	I might regret it later if I don't take them.	357	9.7			
	I think I'm at risk COVID-19	161	4.4			
	Other people at home or at work are following them already	85	2.3			
	I'm often sick	75	2			
	I don't want problems with the law	6	0.2			
	Desire to return to normal	2	0.1			
	Civil responsibility	2	0.1			

**More than one options is possible. Post hoc test = Tukey HSD. No significant differences have been found between No Antiviral Drugs and Risk dimensions. Risk c-d-h dimensions contains zero/few cases in one or more category response and then discharged from mean/frequency analysis.*

treatments or for going to the pharmacy, 9.7% for essential necessities (to procure groceries), 1% for assisting families, and 5% for physiological needs of own domestic animal.

Differences in Adherence to Quarantine Guidelines

Differences among sociodemographic variables, as well as in risk perception dimensions, were found in adherence to protective measures scores. Means and standard deviations, group F/t tests, p values, and Tukey *post hoc* analysis were provided for each independent variable in **Tables 1**, **2**. Pairwise deletion techniques were applied to handling missing data.

As regards sex, women exhibited significantly higher levels of adherence to quarantine guidelines [$t(3670) = -11.145$, $p < 0.001$, Hedges $g = 0.401$] compared to the men.

A statistically significant difference was found between age groups as determined by one-way ANOVA [$F(4;3667) = 54.334$, $p < 0.001$, $\omega p^2 = 0.054$]. A *post hoc* test revealed that the 18- to 29-year age group scored statistically significantly lower ($p < 0.001$) compared to other age groups. Equally, the 50- to 59-year age group was statistically significantly higher ($p < 0.001$) in adherence scores compared to the 30- to 39-year group.

Participants with a high education showed the highest scores of adherences among the other levels of education [$F(3;3668) = 10.228$, $p < 0.001$, $\omega p^2 = 0.007$].

Significant differences in adherence within the marital status [$F(4;3667) = 36.097$, $p < 0.001$, $\omega p^2 = 0.036$] revealed that singles' ($p < 0.001$) adherence mean was statistically significantly lower than married, divorced/separated, and cohabiting status means. In addition, divorced/separated and married groups equally exhibited significant higher adherence ($p < 0.01$) compared to cohabiting people.

Differences of geographic area in adherence to quarantine guidelines [$F(4;3577) = 13.96$, $p < 0.001$, $\omega p^2 = 0.014$] revealed that participants from the Southern Italy showed statistically significantly higher level of adherence ($p < 0.01$) compared to the Central and North West/East areas, except for the Islands. Residents from Central Italy ($p < 0.05$) were statistically significantly higher in adherence levels compared to the North-East.

A slight but significant difference among adherence levels was found across health status variables ($p < 0.01$), where the fragile group ($p < 0.05$) showed the lowest mean, which was significantly lower compared to poor group.

Next, a statistically significant difference was found among the employment status [$F(4;3667) = 38.073$, $p < 0.001$, $\omega p^2 = 0.038$]; in details, students' mean ($p < 0.001$) was statistically lower compared to the other status. As expected, healthcare professional adherence mean ($p < 0.001$) was significantly higher compared the unemployed and employed. Because the healthcare professions category was quite broad, and not all categories are employed on the frontlines, a statistically significant difference among healthcare professionals was found [$F(4;215) = 4.551$, $p < 0.001$, $\omega p^2 = 0.060$]. A *post hoc* test revealed that rehabilitation therapists' adherence mean ($p < 0.01$) was statistically significantly lower than that of doctors and nurses. No statistically significant difference was found in adherence to quarantine guidelines for income for year groups.

A statistically significant difference between levels of risk perception A [$F(3;3668) = 8.337$, $p < 0.001$, $\omega p^2 = 0.006$] was found. A *post hoc* test revealed that the very high level of risk perceived ($p < 0.001$) was statistically significant compared to the high and low levels of risk perceived. The same trends in differences were found among risk anxiety [$F(4;3667) = 56.888$, $p < 0.001$, $\omega p^2 = 0.057$] and susceptibility levels [Risk B2, $F(4;3667) = 26.358$, $p < 0.001$, $\omega p^2 = 0.026$; and Risk B3, $F(4;3667) = 4.511$, $p < 0.001$, $\omega p^2 = 0.003$]. A *post hoc* test revealed that the last category was statistically higher compared to the previous ($p < 0.01$).

No statistical differences were found between the sociodemographic variables and antiviral drugs' protective behavior [except for health status, Kruskal–Wallis = 13.347(3); $p < 0.01$].

DISCUSSION

Italy was the first Western Republic affected by the COVID-19 spread (Saglietto et al., 2020). Despite the criticism about the lack of its scientific basis (Schabas, 2004; Bensimon and Upshur, 2007; Greenberger, 2018), the slowing growth in daily reported deaths in Italy was consistent with a significant impact of quarantine implemented several weeks earlier. Successful use of quarantine as a public health measure in a democratic society requires increasing the likelihood of people adhering to protocols.

A large sample of Italian quarantined adults showed very high rates of adherence to quarantine restrictions and recommendations, after 15 days of the national lockdown, due to COVID-19 pandemic.

Differences among sociodemographic variables indicated that women were more likely to carry out protective behaviors compared to men. Sex differences in mortality and vulnerability to the COVID-19 disease, observed also in Italy (China, 2019; Chen et al., 2020; Wenham et al., 2020), could be associated to different degrees of adherence to quarantine restrictions for gender, with women being more likely vigilant about preventive and avoidant behaviors.

As suggested by findings from previous studies regarding age and gender patterns of risk-taking behaviors (Pawlowski et al., 2008; Cobey et al., 2013), men are more likely to engage in risk-taking behaviors.

The pattern of findings for age is not straightforward. Italian youngest individuals (18–29 years) tended to be least adherent among all the age groups. Subjects aged 30–39 years had significantly lower levels of adherence compared to people aged 50–59 years. People older than 60 years had levels of adherence lower than those of the other age groups, except for the 18- to 29-year age group. Adherence seems to heighten with increasing of age until 59 years, after which the trend surprisingly reversed, with the over-60s reporting to adhere less to the quarantine guidelines, similarly to the 30- to 39-year group. The two extremes of the life span (very young: from 18 to 39 years

and seniors: 60+ years) have been found more reluctant to comply with the quarantine guidelines. If this is not a great problem for youngest people, it certainly is for the elderly, who are most particularly at risk of contracting the COVID-19 with fatal consequences. Older age has been reported associated with adverse clinical outcomes, including hospitalization and mortality (Applegate and Ouslander, 2020; Chen et al., 2020). Indeed, in Italy the mean age of the COVID-19 patients who died was 81 years (Remuzzi and Remuzzi, 2020), and case fatality rate was 16% from 60 to 79 years, 19.7% from 80 to 89 years, and 16% for 90 years or older (Livingston and Bucher, 2020). Reasons of this unexpected behavior (Lau et al., 2003; Leung et al., 2004, 2005; Quah and Hin-Peng, 2004; Tang and Wong, 2004) were, in elderly subjects of our sample, the loss of freedom to movement (57.4%) and renouncing to important habits, such as to going to the recreational club (47.4%). It seems that the management of daily time, the loss of real social contacts, and the difficulty accessing to "virtual" interactions via social networks can easily undermine compliance in this age group (Yip et al., 2010; Zhong et al., 2017). In a population where loneliness and isolation have already been described as an epidemic, the impact of even short-term social distancing measures merits careful and urgent study. As regards educational attainment, our findings indicated that increasing education was associated with adherence to quarantine restrictions, with people with high education showing highest scores of adherences among all the groups, in accordance with previous studies (Webster et al., 2020).

As regards marital status, single and widowed people are the least adherent group with quarantine policies in the event of this outbreak. This datum was in line with part of previous literature reporting that ever-married people had more compliance with quarantine policies compared to never-married people (Tang and Wong, 2004; Lau et al., 2007). It is plausible that these people had greater difficulty in relying on or obtaining the assistance of others.

As geographical area of residence, South of Italy showed the highest levels of adherence among all the groups, except for the Islands. Regions of Center of Italy were more likely to adhere with guidelines compared to North-East regions.

This datum is very interesting because Southern and Central regions had recorded minor number of deaths and diagnosed cases (938 and 10,452, 1,720, and 19,059, respectively), compared to North-East and North-West regions (4,582 deaths and 10,452 cases, and 14,652 deaths and 83,971 cases, respectively), which are the most severely affected areas, despite two considerations. First, the Italian Government implemented control measures in the Northern regions, before any other region, and carried out extraordinary efforts to restrict the movement of people at the expense of the Italian economy. Second, a huge number of people – mainly students attending universities in Northern Italy – came back from Po Valley to their families in the South just in the middle of the outbreak, representing potential factor able to accelerate the spreading of the viral infection.

Despite this, the greater spread of contagion was recorded in the North of Italy. Among other factors, the reason may lie also in less adherence of its residents toward the strict self- and forced-quarantine measure, compared to the rest of Italy.

The attitude of greater adherence of the respondents from Southern Italy could challenge cultural stereotypes about the alleged poor civic sense that southerners would have compared to northerners (Viesti, 2013).

As employment status, students showed the significantly lowest mean of adherence among all the other groups, consistent with findings of a previous study (Soud et al., 2009). Consistently with the data collected during this pandemic in China (Zhong et al., 2020), these differences could be ascribed to younger age.

Among occupational groups, healthcare workers showed significantly higher means of adherence compared to students and employed and unemployed people.

The adherence of healthcare workers to all the stringent occupational guidelines in the event of COVID-19 outbreaks is very critical because they are the occupational categories most at risk of contracting the virus during the COVID-19 epidemic (World Health Organization, 2020a). In Italy, because they have not been equipped promptly with self-protective equipment (PPE, such as gown, gloves, N95 masks, goggles, etc.), neither adequate nor sufficient IPC (infection prevention and control) training for respiratory pathogens had worked in life-threatening healthcare settings, with longer duty hours since February 20.

High fatality rates may occur in these health settings if widespread non-adherence to safety measures occurs, also for the risk of contagion and spreading the virus to their families, friends, or colleagues. At time of writing, in Italy around 10% (n = 16,050) of health care professionals have become infected, and 121 doctors have died (FNOMCeO, 2020).

Thus, as Remuzzi stated, "Our doctors and nurses are modern heroes in an unexpected war against a difficult enemy" (p.4) (Remuzzi and Remuzzi, 2020). Among healthcare professionals, physicians, nurses, and pharmacists exhibited significantly higher means of adherence to protocols compared with non-frontline health care workers, such as psychologists and rehabilitation therapists. This is also in line with previous experiences from severe acute respiratory syndrome/Middle East respiratory syndrome, showing frontline health professionals constitute a unique risk group compared with professionals working in second-line positions (Gardner and Moallef, 2015; Lee et al., 2018).

A weak but significant positive association was found between the self-reported adherence and the length of quarantine. This datum appears to be in line with the mixed evidences in literature on how the length of prescribed quarantine affects adherence to quarantine protocol (Webster et al., 2020).

People accounted for their compliance with the quarantine order on personal, ethical, social, or legal grounds. The most important reasons for complying were to prevent the spread of COVID-19 (79.8%) and to reduce the risk of transmission to others (75.7%). Also, the trust in government action to control the pandemic (e.g., "I trust the measurements to protect us from contracting COVID-19 are useful," "the authorities recommend them") is a crucial factor (40.2%). Importantly, even if the trust in the government is below average, the adherence of our participants to its recommendations is very high.

Differently to previous studies on past epidemics (Webster et al., 2020), ethical reasons were most uncommon with

our participants: only the 0.1% say that they complied with quarantine to be "good citizens" or to do their "civic duty." As well as, only 2.3% of the participants take protective behaviors for social norms toward COVID-19 prevention (e.g., agreement on the statement "other people at home or at work already follow measures to prevent against COVID-19") or for legal reasons were also cited ("I don't want problems with the law") (0.2%).

The reasons for not adhering to quarantine and negative aspects of adhering to quarantine were examined. Obstacles to compliance were in having in biased risk perception ("I don't think I'm at risk of contagion," "coronavirus is not so serious") (0.06% totally), or in attitude to general self-neglect ("I don't care about my health," "I never got sick") (0.06% totally).

Another kind of service needed by those in quarantine is psychosocial support to fight boredom and mute the stigma that could easily undermine compliance (DiGiovanni et al., 2004).

The most common negative experiences associated with the staying home were identified in the boredom deriving from being closed in the house (43.7%); renouncing to important habits (shopping, going to the gym, to the hairdresser/beautician, the recreational clubs, etc.) (74.3%); lacking of being free to movement, such as traveling for leisure or business (71.4%); the lack of a working environment (colleagues, routines, etc.) (29.7%); not being able to do something useful (26.8%); the inability to manage own daily time (25.8%); greater conflict in the family (14.8%); uncertainty about the future consequences (7.5%); forced and prolonged coexistence with unwelcome people (3.2%); and the imposition of such stringent rules (2.5%).

Lengthy confinement of people in their homes could also produce tensions within households that could become dangerous (Bish and Michie, 2010). Microsocial effects, such as ostracism within the family, questioning of the professional activity, and conflicts following selective sharing of information with relatives about risk exposure, can have an impact on intrafamilial relationships, when power relationships or preexisting conflicts put some members at a disadvantage (DiGiovanni et al., 2004; Johal, 2009).

The strength of this study lies in its large sample recruited during a critical period, the early stage of the COVID-19 outbreak in Italy. Nevertheless, the predominance of women and undergraduate students (who are generally young and perhaps have fewer responsibilities than adults who are employed full-time) and the small number of healthcare workers limit our ability to generalize these findings to a wider population. In addition, the sample recruitment approach through social media channels, due to the exceptional pandemic conditions, can have permitted the participation of only those who had a computer and computer literacy (probably excluding middle–old/old–old participants). However, features of our sample are similar to the others reported in already available studies carried out in the Italian context during the COVID-19 emergency (Barari et al., 2020; Mazza et al., 2020; Moccia et al., 2020). Another limitation of our study is related to the adoption of self-reported and not already validated questionnaires. Moreover, this survey has been translated into different languages with the aim of evaluating the impact of pandemic in other countries. It should also be noted that, given the public salience of these measures, it is likely that social desirability biased the self-reporting behaviors. Future studies should validate the compliance rates shown here for real-world observational data. For example, the registration in the questionnaire of possible arrests or sanctions in case of skipping the quarantine could provide objective measures of the adherence, as well as an implicit degree of responsibility of the population. Similarly, future research to understand how social (Saggino et al., 2017), religious (Carlucci et al., 2015), and economic factors, as well as personality factors (Innamorati et al., 2014), affect compliance with quarantine will be helpful in planning for future public health emergencies. Because there are likely to be cultural and societal differences in responses to a pandemic, some broad conclusions can be drawn from the evidence identified, but their applicability is likely to vary across country. Thus, caution should be given when generalizing the results of this study to other countries. International comparisons are therefore also greatly warranted.

CONCLUSION

Findings from previous researches suggested that some countries with quarantine still had problems with compliance, as evidenced by increasing fines and arrest penalties (Blendon et al., 2006). To increase compliance, public health authorities need to plan in advance. They should prepare trusted spokespeople to explain to the public the steps that need to be taken to halt the spread of the disease and stress the need for compliance and take the Italian model as example. With full population compliance with quarantine policies, the critical battlefront of the COVID-19 epidemic would shift to effective hospital infection control. As Saglietto stated, "We urge all countries to acknowledge the Italian lesson and to immediately adopt very restrictive measures to limit viral diffusion, ensure appropriate health system response, and reduce mortality, which appears to be higher than previously estimated, with a crude case-fatality rate of almost 4%" (p.1110) (Saglietto et al., 2020).

In this study, the perception of risk about contracting or spreading disease, associated with adherence to quarantine guidelines in Italian community, was also analyzed. To date, there are no studies on risk perception of infectious diseases COVID-19 in Europe. Therefore, this study makes an important contribution to the field and could be helpful for these countries that are hesitant to apply the quarantine protocols or which nowadays are evaluating its effects, due to a later spread of the contagion.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Department of Psychological Sciences, Health

and Territory, University of Studies "G. d'Annunzio" Chieti–Pescara, Italy, Review Board. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

MB and LC designed the study and drafted the manuscript. LC conducted the statistical analyses. ID'A collected the data. MB, ID'A, and LC interpreted the data. All authors contributed toward revising the manuscript and agreed to be accountable for all aspects of the work.

APPENDIX A

PERCEZIONE DEL RISCHIO
RISK PERCEPTION

(A) Percezione del Rischio/ Risk Perception (8-item);

- Penso che contrarrò il COVID-19 se entro in contatto con un paziente affetto da COVID-19.
  I think that I will contract COVID-19 if I come into contact with a COVID-19 patient.
- Penso che potrei contrarre il COVID-19 anche se non entro in contatto con un paziente affetto da COVID-19.
  I think that I might contract COVID-19 even if I do not come into contact with a COVID-19 patient.
- La mia salute sarà gravemente compromessa se contraggo il COVID-19.
  My health will be severely damaged if I contract COVID-19.
- Penso che il COVID-19 è molto più grave rispetto alle altre malattie respiratorie.
  I think that COVID-19 in more severe than any other respiratory diseases.
- Anche se mi ammalassi di un'altra malattia, non mi recherei in ospedale a causa del COVID-19.
  Even if I fall ill with another disease, I will not go to hospital because of COVID-19.
- Il COVID-19 causerà seri danni alla mia comunità.
  COVID-19 will inflict serious damage to my community.
- Il COVID-19 si diffonderà nuovamente in Italia un giorno o l'altro.
  COVID-19 may spread in Italy again someday.
- Penso che potrei contrarre il COVID-19 anche se non entro in contatto con una persona affetta da COVID-19 perché potrebbe essere asintomatica e ignara.
  I think I will contact COVID-19 even if I do not come into contact with a COVID-19 patient because he/she might be lack of symptoms or suspect nothing of them.

(B) Ansia e Suscettibilità/Anxiety and Susceptibility (3 item);

- Quanto sei preoccupato di contrarre il COVID-19?
  How worried are you about getting COVID-19?
- Che probabilità hai di contrarre il COVID-19 se non segui le misure preventive?
  What are your chances of getting COVID-19 if you do not follow preventive measures adopted?
- Se non dovessi essere vaccinato che probabilità avrai nel contrarre il COVID-19 entro questo anno?
  If you don't get vaccinated, what are your chances of getting COVID-19 within this year?

(C) Intenzione nel seguire le misure preventive/ Intention to carry out the quarantine guidelines (1 item);

- Hai intenzione di seguire le misure preventive?
  Do you intend to follow the preventive measures?

(D) Perception of seriousness (1 item);

- Quanto pensi che sia grave l'emergenza da coronavirus sulla salute mondiale?
  How severe do you think the coronavirus emergency on global health is?

(E) Fattori motivanti / ostacolanti che determinano la volontà di attuare le misure preventive
Motivating/hindering factors that determine the willingness to carry out preventive measures (1 item).

- Perchè esegui le misure preventive?
  Why are you taking preventive measures?
  - Sono spesso malato.
    I'm often sick.
  - Il COVID-19 può essere pericoloso.
    COVID-19 can be dangerous.
  - Mi sento responsabile della mia salute.
    I feel responsible for my health.
  - Penso di essere a rischio COVID-19.
    I think I'm at risk COVID-19.
  - Voglio prevenire il diffondersi del COVID-19.
    I want to prevent the spread of COVID-19.

- Non voglio trasmettere il COVID-19 alle persone a me vicine.
  I don't want to transmit COVID-19 to people close to me.
- Confido che le misure siano utili.
  I trust the preventive measures are helpful.
- Le autorità le raccomandano.
  authorities recommend them.
- Potrei pentirmene dopo, se non le eseguo.
  I might regret it later if I don't take them.
- Altre persone in casa o al lavoro, le seguono già.
  Other people at home or at work are following them already.
- Altro. . .
  Other. . .

ADERENZA
ADHERENCE

- Lavi le mani con acqua e sapone o con gel a base alcolica?
  Did you wash your hands using soapy water or an alcohol-based solution?
- Nei contatti sociali, mantieni una distanza di almeno un metro?
  When you had a social interaction, did you keep a distance no closer than six feet from the others?
- Starnutisci e/o tossisci in un fazzoletto evitando il contatto delle mani con le secrezioni respiratorie?
  Did you sneeze and/or cough in a tissue or elbow, preventing the hands from coming into contact with respiratory secretion?
- Eviti l'uso promiscuo di bottiglie e bicchieri?
  Did you avoid sharing bottles and cups for drinking?
- Eviti di toccare occhi, naso e bocca con le mani?
  Did you avoid touching your face, nose and mouth with your hands?
- Copri la bocca e il naso, se starnutisci e/o tossisci?
  Did you cover your mouth or nose when you sneeze and/or cough?
- Eviti strette di mano e abbracci?
  Did you avoid handshaking and hugging?
- Pulisci le superfici di casa o ufficio con disinfettante a base di cloro o alcol?
  Did you clean your home or office surfaces with disinfectant wipes or spray?
- Eviti assembramenti in luoghi pubblici o aperti al pubblico?
  Did you avoid gatherings in public places and avoid hosting gatherings in your home?
- Svolgi sport e/o attività motorie all'aperto da solo?
  Did you participate in outdoor sport and/or physical activities alone?
- Usi la mascherina?
  Did you wear a protective mask?
- Prendi farmaci antivirali e antibiotici?
  Did you take antiviral drugs or antibiotics?

Clinical observations suggest that during times of COVID-19 pandemic lockdown university students exhibit stress-related responses to fear of contagion and to limitations of personal and relational life. The study aims to describe the development and validation of the 7-item COVID-19 Student Stress Questionnaire (CSSQ), a measurement tool to assess COVID-19-related sources of stress among university students. The CSSQ was developed and validated with 514 Italian university students. Exploratory Factor Analysis (EFA) was conducted with one split-half sub-sample to investigate the underlining dimensional structure, suggesting a three-component solution, which was confirmed by the Confirmatory Factor Analysis (CFA) with the second one split-half sub-sample (CFI = 0.95; TLI = 0.95; RMSEA = 0.06). The CSSQ three subscales measure COVID-19 students' stressors related to (1) Relationships and Academic Life (i.e., relationships with relatives, colleagues, professors, and academic studying); (2) Isolation (i.e., social isolation and couple's relationship, intimacy and sexual life); (3) Fear of Contagion. A Global Stress score was also provided. The questionnaire revealed a satisfactory internal consistency (Cronbach's alpha = 0.71; McDonald's omega = 0.71). Evidence was also provided for convergent and discriminant validity. The study provided a brief, valid and reliable measure to assess perceived stress to be used for understanding the impact of the COVID-19 pandemic lockdown among university students and for developing tailored interventions fostering their wellbeing.

Keywords: COVID-19, health psychology, pandemic lockdown, university students, validation

INTRODUCTION

The Coronavirus Disease 2019 (COVID-19) has been defined as an extreme health, economic and social emergency and it was declared a global pandemic by the World Health Organization on March 2020 (World Health Organization, 2020), resulting in lockdown and life restrictions in Italy as worldwide in the attempt to prevent and slow the spread of the virus.

Comparable previous emergencies, such as the SARS outbreak, were strongly demonstrated as spreading stress and inducing psychological disease in terms of depression, anxiety but also panic attacks, and even psychotic symptoms, delirium, and increased rates of suicidal (Xiang et al., 2020). These results have been recently confirmed with respect to the current COVID-19 pandemic (Brooks et al., 2020; Zandifar and Badrfam, 2020), particularly in terms of high levels of psychological distress (Qiu et al., 2020), depression (Wang et al., 2020), anxiety (Horesh and Brown, 2020; Lima et al., 2020; Rajkumar, 2020), fear and panic behaviors (Shigemura et al., 2020).

In this perspective, a review conducted by Brooks et al. (2020) on the psychological impact of quarantine periods and outbreak confinements in last decades (e.g., the SARS outbreak, the 2009 and 2010 H1N1 influenza pandemic) identified specific common experiences such as fear of contagion, fear and frustration related to inadequate supplies (e.g., basic necessities and medical supplies), sense of confusion due to inadequate quality of information from public health authorities, sense of isolation, frustration and boredom due to loss of usual routine and to reduced social contacts (Brooks et al., 2020).

Furthermore, the COVID-19-related containment measures imposed massive work and school closures, segregation and social distancing, deeply impacting on personal and relational life and exposing people to experience uncertainty, feelings of isolation, and sense of "losses" in terms of motivation, meaning, and self-worth (Williams et al., 2020).

In view of that, research made several efforts to better explore the psychological impact of the ongoing Coronavirus global outbreak, developing and validating specific tools.

In particular, the Fear of COVID-19 Scale (FCV-19S; Ahorsu et al., 2020; Soraci et al., 2020) and the Coronavirus Anxiety Scale (CAS; Lee, 2020a) were developed to assess, respectively, perceived COVID-related fear and anxiety. Moreover, the COVID-19 Peritraumatic Distress Index (CPDI; Costantini and Mazzotti, 2020; Qiu et al., 2020) was developed to assess the frequency of anxiety, depression, specific phobias, cognitive change, avoidance and compulsive behavior, physical symptoms and loss of social functioning.

Finally, the COVID-19 Stress Scales (CSS; Taylor et al., 2020) was developed to measure the psychological impact of COVID-19 in terms of danger and contamination fears, fears about economic consequences, xenophobia, compulsive checking and reassurance seeking, and traumatic stress symptoms.

Overall, the instruments reported above specifically addressed the impact of the COVID-19 outbreak in terms of psychological outcomes, without addressing and identifying specific sources of stress related to relational and daily life changes induced by the COVID-19 pandemic lockdown. Indeed, the COVID-19 pandemic-related experiences induced not only fears of contagion and social isolation but also significant modifications in several aspects of daily routine, mainly influencing (hindering or intensifying) all relationships, such as those with relatives, with the partner, with friends, with colleagues. Consequently, it emerged the need to develop instruments able to address not only the potential effects of isolation and fear of contagion but also of modifications of all significant relationships in daily life, so considering all potentially perceived sources of stress featuring the experience of pandemic lockdown.

Furthermore, in line with the transactional perspective (Lazarus and Folkman, 1984), stress is considered a dynamic relational process, which depends on the constant interplay between individual factors (e.g., age, gender) and situational factors, so requiring to take into account specificities of target populations when defining tools to evaluate perceived sources of pressure.

From this perspective, the academic context was deeply affected by the lockdown restrictions worldwide. Indeed, due to the massive closure of colleges and universities (United Nations Educational, Scientific and Cultural Organization, 2020), all the scheduled activities and events were postponed/annulled, campuses and students' accommodations were forced to evacuations, all the formal and informal interactions were shifted to online platforms, leading to a substantial change in students' customary life.

Different studies exploring factors associated to COVID-19 outbreak among university students highlighted high levels of anxiety and worries about academic delays and influence of the epidemic on daily life, due to the disruption in students' daily routine, in terms of activities, objectives and social relationships (Cao et al., 2020; Chen et al., 2020; Lee, 2020b; Sahu, 2020). Indeed, the quarantine hindered the possibility to experience the university life, impacting on academic studying (i.e., uncertainties related to annulment/delays of activities, difficulties in employment of online platforms for the distance learning), but also impairing the possibility to benefit from the relationships that may represent anchor in students' life, such as those with peers, colleagues, and professors (Lee, 2020b; Sahu, 2020). In addition, also considering the increasingly key role played by romantic relationships in the young population (Anniko et al., 2019), research also outlined the potential changes in couple' relationship, intimacy, and sexual life due to the COVID-19 pandemic (Li et al., 2020; Rosenberg et al., 2020).

Moreover, whether, on the one hand, the abovementioned relationships with partner, friends, peers, colleagues, and professors were subject to a radical reduction and standstill, on the one other hand, in most of the cases, relationships with relatives were deeply intensified. Indeed, the majority of students were forced to return back home, also resulting from the campus dormitory evacuations, inducing an increased exclusivity of interaction with relatives, potentially exacerbating frustration and conflicts. This particularly when considering students living in already disadvantaged conditions and/or suffering from abusive home experiences (Lee, 2020b).

Overall, whether it's clear that university students' life was subject to broad modifications, up to date, there are no specific tools to understand, comprehensively identify and assess specific sources of stress featuring university students' COVID-19-related experiences. This, however, could help in early recognize those students at higher risk for developing a significant psychological disease related to the pandemic lockdown, and, accordingly, provide timely and tailored interventions fostering their wellbeing.

Responding to this need, the present study aimed at proposing and validating a newly developed measurement tool to specifically assess sources of stress related to the COVID-19 pandemic lockdown among university students, namely the COVID-19 Student Stress Questionnaire (CSSQ).

Seven potential sources of stress have been hypothesized and operationalized. These sources have been defined as connected not only to fear of contagion and to experience of isolation but also to the potential abovementioned changes in students' daily life and routine. In particular, it was hypothesized that induced changes in academic studying and relationships with friends, partner, university colleagues, professors and relatives could constitute significant perceived COVID-19 pandemic lockdown-related sources of stress among university students.

Hypotheses and research questions to rigorously check the validity and reliability of the COVID-19 Student Stress Questionnaire (CSSQ) are listed in **Table 1**.

MATERIALS AND METHODS

Participants and Sampling

Online survey data were collected from 15 April to 15 May 2020 with students from the University of Naples Federico II. This period fully corresponded to the pandemic lockdown due to COVID-19 in Italy, and students were experiencing the consequences of university closures, with massive social restrictions. The participants were recruited through Microsoft Teams. Students were contacted and given all the information about the study, and they were asked their participation on a voluntary basis. All the participants were fully informed about the aims of the study and about the confidentiality of the data, and they were also assured that the data would be used only for the purpose of the research and refusal to participate would not affect their current and future course of study in any way. The study was approved by the Ethical Committee of Psychological Research of the University where the study took place (IRB:12/2020). Research was performed in accordance with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. Informed consent was obtained from each student prior to participating in the study. Every precaution was taken to protect the privacy of research subjects and the confidentiality of their personal information. Overall, 514 university students voluntarily enrolled in the study and completed online Microsoft Teams forms.

Measures

The questionnaire included a section dealing with background information (i.e., Gender, Age, Degree Program, Year of study), the proposed 7-item COVID-19 Student Stress Questionnaire, and a measure for psychophysical health conditions.

TABLE 1 | Research questions and hypotheses of the validation study.

Level of evidence and reliability	Number of research questions (R) or hypothesis (H)	Research question or hypothesis
Evidence based on construct validity		
	R1	Are all the items of the proposed COVID-19 Student Stress Questionnaire (CSSQ) relevant and appropriate in terms of the construct of COVID-19-related perceived stress among university students?
	R2	Is the CSSQ a uni-dimensional or multidimensional measure?
	H1	The data from this study reveal correlations, so that significant and coherent factors can be identified.
	H2	A factorial structure of the CSSQ can be confirmed.
Evidence based on convergent validity		
	H3	The standardized factor loadings, and the values of Composite Reliability and Average Variance Extracted of all factors are adequate.
	H4	There are moderate to strong correlations between the scales scores of the CSSQ and the standardized scales scores of the SCL-90-R.
Evidence based on discriminant validity		
	H5	The square root of the Average Variance Extracted of factors is above the correlations among the factors of the CSSQ.
	H6	There are moderate correlations among the CSSQ subscales scores, and strong correlations between the CSSQ subscales scores and the Global Stress score.
Reliability: internal consistency		
	H7	The CSSQ shows satisfactory internal consistency.

COVID-19 Related Sources of Stress Among University Students

The COVID-19 Student Stress Questionnaire (CSSQ) was specifically developed to assess university students' perceived stress during the COVID-19 pandemic lockdown. It consists of 7 items on a 5-point Likert scale ranging from zero ("Not at all stressful") to four ("Extremely stressful"). For the purpose of instrument design, perceived stress was operationalized based on transactional models of stress (Lazarus and Folkman, 1984). Each item was developed to cover different domains that could have been subject to variations due to the COVID-19 pandemic lockdown, and, therefore, that may be potentially perceived as sources of stress (i.e., risk of contagion; social isolation; relationship with relatives; relationship with colleagues; relationship with professors; academic studying; couple's relationship, intimacy and sexual life). The scale provides a Global Stress score ranging from 0 to 28.

Psychophysical Health Conditions

The Symptom Checklist-90-Revised (SCL-90-R; Derogatis, 1994; Prunas et al., 2010) was used to assess self-reported psychophysical health conditions. The scale comprises 90 items on a 5-point Likert scale ranging from zero ("Not at all") to four ("Extremely") and divided into nine subscales: Anxiety (10 items, Cronbach's $\alpha = 0.84$), Depression (13 items, Cronbach's $\alpha = 0.87$), Somatization (12 items, Cronbach's $\alpha = 0.83$), Interpersonal Sensitivity (9 items, Cronbach's $\alpha = 0.83$), Hostility (6 items, Cronbach's $\alpha = 0.80$), Obsessive-Compulsive (10 items, Cronbach's $\alpha = 0.82$), Phobic Anxiety (7 items, Cronbach's $\alpha = 0.68$), Psychoticism (10 items, Cronbach's $\alpha = 0.77$), and Paranoid Ideation (6 items, Cronbach's $\alpha = 0.76$). Participants were asked to indicate how much these problems have affected them during the past 4 weeks (e.g., Anxiety subscale: "Tense or keyed up", "Fearful"; Depression subscale: "Hopeless about future", "No interest in things"). The scale also provides a global index, namely the Global Severity Index (GSI). GSI is the sum of all responses divided by 90, and it indicates both the number of symptoms and the intensity of the disease (GSI Cronbach's $\alpha = 0.97$).

Data Analysis

For the validity testing of the CSSQ we used the European Federation of Psychologists' Association's (EFPA) standards and guidelines (Evers et al., 2013), which describe the standard method for validity testing by the following levels of evidence: 1) Construct validity; 2) Criterion validity: (a) Post-dictive or retrospective validity; (b) Convergent validity; (c) Discriminant validity. In the present study, validity evidence was examined in relation to Construct validity, Convergent validity, and Discriminant validity.

Evidence Based on Construct Validity

Evidence based on construct validity was examined to answer research questions 1 and 2 and to test hypotheses 1 and 2 (**Table 1**). To examine the validity of the COVID-19 Student Stress Questionnaire (CSSQ) we used a two-step analytic strategy. First, the entire study sample ($N = 514$) was split using a computer-generated random seed. According to the rules of thumb for sample size in factor analysis, the sample size for each sub-sample ($n = 257$) was considered adequate to explore the structure of the 7-item CSSQ (Comrey and Lee, 1992; Costello and Osborne, 2005; DeVellis, 2017). Construct validity was analyzed using Exploratory Factor Analysis (EFA) and Confirmatory Factor Analysis (CFA).

EFA was performed in the first split-half (Sub-sample A, $n = 257$) to explore the latent dimensional structure (R1 and R2) and to identify significant and coherent factors (H1). Principal Components Analysis (PCA) with oblique promax rotation was used. The choice of non-orthogonal rotation was justified on the hypothesis that the factors would be correlated. The factorability of the correlation matrix of the scale was evaluated by Kaiser–Meyer–Olkin (KMO) measure and Barlett test of sphericity. Criteria for extraction and interpretation of factors were as follows: eigenvalues > 1.0, Cattell's scree test and inspection of scree plot, communality ≥ 0.30 for each item and factor loading > 0.32 for each item loading on each factor (Costello and Osborne, 2005).

CFA was performed in the second split-half sub-sample (Sub-sample B, $n = 257$) to determine the goodness-of-fit of the extracted factor model (H2). Standard goodness-of-fit indices were selected *a priori* to assess the measurement models: χ^2 non-significant ($p > 0.05$), Tucker-Lewis Index (TLI > 0.95), Root Mean Square Error of Approximation (RMSEA < 0.08) and Comparative Fit Index (CFI > 0.95) (Hu and Bentler, 1998).

Evidence Based on Convergent Validity

Evidence based on convergent validity was explored to test hypotheses 3 and 4 (**Table 1**). Convergent validity was tested, first, by calculating standardized factor loadings, composite reliability (CR), and average variance extracted (AVE) of factors (H3). If the standardized factor loadings of a questionnaire are > 0.5 and statistically significant, and the values of CR and AVE of each factor are higher than 0.7 and 0.5, respectively, the questionnaire is considered as having a satisfactory convergent validity (Fornell and Larcker, 1981; Hair et al., 2010). Moreover, convergent validity was assessed by correlational analyses (Pearson's correlation coefficient) between the scales scores of the newly developed COVID-19 Student Stress Questionnaire and the standardized scales scores of the SCL-90-R (nine subscales and Global Severity Index) (H4). The effects size were interpreted following Cohen's thresholds ($r < 0.30$ represents a weak or small correlation; $0.30 < r < 0.50$ represents a moderate or medium correlation; $r > 0.50$ represents a strong or large correlation) (Cohen, 1988).

Evidence Based on Discriminant Validity

Evidence based on discriminant validity was explored to test hypotheses 5 and 6 (**Table 1**). Discriminant validity was evaluated by comparing the square root of the average variance extracted (SQRT AVE) with the correlations between latent constructs (H5). When the SQRT AVE is above the correlations among factors, a questionnaire is considered as having an acceptable discriminant validity (Fornell and Larcker, 1981). Furthermore, discriminant validity was also tested basing on the correlations

between the CSSQ subscales and the Global Stress scores using the Pearson's correlation coefficient (H6).

Evidence Based on Internal Consistency

Evidence based on internal consistency was explored to test hypothesis 7 (**Table 1**). Item means, standard deviations, and mean inter-item correlation (between 0.15 and 0.50) were evaluated (Clark and Watson, 1995). Moreover, for the reliability test, Cronbach's Alpha (Cronbach, 1951) and McDonald's Omega (McDonald, 1999) were used to assess the internal consistency of the questionnaire, considering $\alpha \geq 0.70$ (Santos, 1999) and $\omega \geq 0.70$ (McDonald, 1999) as indices of satisfactory internal consistency reliability (H7).

Finally, means, standard deviations, and ranges of the newly developed COVID-19 Student Stress Questionnaire (CSSQ) scales were calculated.

RESULTS

Characteristics of Participants

Characteristics of the total sample ($N = 514$) as well as of each sub-sample (A and B) are shown in **Table 2**. The total sample consisted of 372 women and 142 men, with a combined mean age of 19.92 ($SD = 1.50$) years. The sample was composed of students enrolled in Philosophy ($n = 10$, 1.9%), Modern Languages and Literature ($n = 44$, 8.6%) and Psychology ($n = 460$, 89.5%) degree programs; the majority of them were 1st year students (1st year $n = 400$, 77.8%; 2nd year $n = 46$, 8.9%; 3rd year $n = 68$, 13.3%).

Construct Validity

Construct validity (research question 1) was examined by conducting EFA and CFA.

Exploratory Factor Analysis

Exploratory Factor Analysis (EFA) using Principal Components Analysis (PCA) with oblique promax rotation was carried out to investigate the underlining dimensional structure of the CSSQ. The assessment of factorability showed that the Kaiser–Meyer–Olkin measure was 0.73 and Bartlett's test of sphericity was significant ($\chi^2 = 332.26$, df = 21, $p < 0.001$) indicating that the data were adequate for the factor analysis, supporting hypothesis 1. The examination of the scree plot produced a departure from linearity corresponding to a three-component result; the scree-test also confirmed that our data should be analyzed for three components, responding to research question two. The first three eigenvalues were 2.61, 1.20, and 1.00. The three-component solution explained a variance of 67.09% from a total of 7 items.

The first component (4 items, explained variance = 37.23%) was loaded by items referred to perceived stress related to relationships with relatives, relationships with colleagues, relationships with professors, and academic studying. We labeled this scale Relationships and Academic Life.

The second component (2 items, explained variance = 17.20%) was loaded by items referred to perceived stress related to social isolation and changes in couples' relationship, intimacy and sexual life due to the social isolation. We labeled this scale Isolation.

The third component (1 item, explained variance = 12.66%) was loaded by a single item referred to perceived stress related to the risk of infection, hence it was labeled as Fear of Contagion (**Table 3**).

Confirmatory Factor Analysis

Confirmatory Factors Analysis (CFA) was run to test hypothesis 2. The results supported the PCA findings (**Figure 1**) by demonstrating that the three-factors model ($\chi^2 = 4.52$,

Factors and Items	1	2	3	h^2
Factor 1: Relationships and Academic Life				
4. How do you perceive the relationships with your university colleagues during this period of COVID-19 pandemic?	**0.904**	−0.419	0.109	0.732
5. How do you perceive the relationships with your university professors during this period of COVID-19 pandemic?	**0.687**	0.240	−0.136	0.646
6. How do you perceive your academic studying experience during this period of COVID-19 pandemic?	**0.560**	0.381	−0.207	0.621
3. How do you perceive the relationships with your relatives during this period of COVID-19 pandemic?	**0.491**	0.180	0.271	0.441
Factor 2: Isolation				
7. How do you perceive the changes in your sexual life due to the social isolation during this period of COVID-19 pandemic?	−0.139	**0.838**	0.048	0.650
2. How do you perceive the condition of social isolation imposed during this period of COVID-19 pandemic?	0.088	**0.788**	0.128	0.722
Factor 3: Fear of Contagion				
1. How do you perceive the risk of contagion during this period of COVID-19 pandemic?	−0.003	0.122	**0.917**	0.885
Eigenvalue	2.61	1.20	1.00	
Percentage of variance	37.23	17.20	12.66	

Total variance explained = 67.09%. Cronbach's α = 0.71. Values in bold indicate major loadings. h^2 is item communality.

p = 0.79), comprising all the 7 items proposed, yielded good fit for all of indices (χ^2/df ratio = 0.56; CFI = 0.95; TLI = 0.95; RMSEA = 0.06).

Convergent and Discriminant Validity

Concerning Convergent validity, the standardized factor loadings of CSSQ items were all > 0.5 (see **Figure 1**) and statistically significant ($p < 0.001$). Moreover, the CR values were all > 0.7 (i.e., Relationships and Academic Life CR = 0.924; Isolation CR = 0.809; Fear of Contagion CR = 0.769). The values of AVE of all factors were > 0.5 (i.e., Relationships and Academic Life AVE = 0.637; Isolation AVE = 0.549; Fear of Contagion AVE = 0.649). Therefore, the standardized factor loadings, CR and AVE of factors were united to suggest that the CSSQ had strong convergent validity, confirming hypothesis 3.

Moreover, correlations with measures of psychophysical disease (SCL-90-R subscales and GSI) were carried out to further test convergent validity, showing that COVID-19 Student Stress Questionnaire scales and Global Stress scores revealed moderate to strong correlations with the SCL-90-R scales scores in the expected directions, and confirming hypothesis 4 (**Table 4**).

Concerning Discriminant validity, the square root of AVE values were compared with the correlations among factors. All the square root of AVE values (i.e., Relationships and Academic Life, SQRT AVE = 0.798; Isolation SQRT AVE = 0.741; Fear of Contagion SQRT AVE = 0.805) were above the correlation values (i.e., correlation between Relationships and Academic Life and Isolation, r = 0.645; correlation between Relationships and Academic Life and Fear of Contagion, r = 0.621; correlation between Isolation and Fear of Contagion, r = 0.660; see **Figure 1**), indicating suitable discriminant validity, and supporting hypothesis 5.

Furthermore, still concerning discriminant validity, intercorrelations between the three COVID-19 Student Stress Questionnaire scales and the Global Stress scores were also calculated. Intercorrelations ranged from 0.30 to 0.42, showing medium levels of correlation, while correlations of

*$p < 0.05$; **$p < 0.01$.

all COVID-19 Student Stress Questionnaire scales with Global Stress scores were high in size and significant, indicating that the questionnaire assessed different but related dimensions, and confirming hypothesis 6 (**Table 5**).

Item Analysis and Reliability

Mean scores for the single items varied from a maximum score of 2.01 (Item 2: "How do you perceive the condition of social isolation imposed during this period of COVID-19 pandemic?") to a minimum of 0.44 (Item 4: "How do you perceive the relationships with your university colleagues during this period of COVID-19 pandemic?"). SDs for the single items varied from 1.36 (Item 7: "How do you perceive the changes in your sexual life due to the social isolation during this period of COVID-19 pandemic?") to 0.75 (Item 4: "How do you perceive the relationships with your university colleagues during this period of COVID-19 pandemic?"). The mean inter-item correlation was 0.26, therefore it was satisfactory. Cronbach's alpha of the total scale was 0.71, while McDonald's omega coefficient was 0.71, confirming that the CSSQ had satisfactory internal consistency (hypothesis 7).

All the items of the CSSQ were presented in **Table 6**.

Table 7 displays items, means, standard deviations, and ranges of the CSSQ scales (Relationships and Academic Life, Isolation, Fear of Contagion) and the total score (Global Stress). Considering that high levels of COVID-19-related stress can be indicated by scores that are 1 SD above the mean (e.g., the 84th percentile) and low levels of stress can be indicated by scores that are 1 SD below the mean (e.g., the 16th percentile) of the distribution of the CSSQ scores, we can affirm that scores of 6 or below indicate low levels of perceived COVID-19-related Global stress, scores of 7–15 indicate average levels of perceived COVID-19-related Global stress, and scores of 16 or more indicate high levels of perceived COVID-19-related Global stress among university students.

DISCUSSION

The aim of the present study was to develop, validate and evaluate the psychometric properties of the 7-item COVID-19 Student Stress Questionnaire (CSSQ), a brief measure to assess sources of stress related to the COVID-19 pandemic lockdown among university students. Indeed, addressing specific sources of stress tailored to target populations foster efficacy in preventive efforts and interventions (Zurlo et al., 2013, 2017; Anniko et al., 2019).

Accordingly, responding to the widespread need for developing specific tools to understand the impact of the COVID-19 global pandemic among students (Cao et al., 2020; Lee, 2020b; Sahu, 2020), it was hoped this instrument could foster a timely identification of those students at higher risk for developing a significant disease related to the ongoing unique situation, and to deliver evidence-based and tailored interventions to promote their adjustment and wellbeing.

Findings highlighted that the proposed CSSQ possessed adequate factor validity, tapping three meaningful factors.

The first factor, labeled Relationships and Academic Life, comprised four items covering perceived stress related to relationships with relatives, relationships with colleagues, relationships with professors, and academic studying. Indeed, considering that students' daily routine have been subject to specific changes (Cao et al., 2020; Chen et al., 2020; Lee, 2020b), this first factor fostered a greater understanding of the dimensions characterizing these modifications among university students in terms of relationships and academic life.

From this perspective, the relationships with relatives should be carefully focused, considering the forced full-time cohabitation, with almost exclusive sharing time and spaces throughout all days. This also as a consequence of the closures of the campus and students accommodations, which forced several students to return back home, but also considering the great number of students already living with their parents, however under completely changed conditions.

In the same direction, since restrictions drastically impaired the possibilities to benefit from living the university life, university students may report growing disease connected to changes in relationships with colleagues and professors (that, during the COVID-19 pandemic, are only allowed through online platforms), but also increased suffering related to the

TABLE 6 | The COVID-19 Student Stress Questionnaire.

	Not at all Stressful	Somewhat stressful	Moderately Stressful	Very Stressful	Extremely Stressful
1. How do you perceive the risk of contagion during this period of COVID-19 pandemic? (Come vive il rischio di contagio durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4
2. How do you perceive the condition of social isolation imposed during this period of COVID-19 pandemic? (Come vive la condizione di isolamento sociale imposta durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4
3. How do you perceive the relatioships with your relatives during this period of COVID-19 pandemic? (Come vive le relazioni con i suoi familiari durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4
4. How do you perceive the relationships with your university colleagues during this period of COVID-19 pandemic? (Come vive il suo rapporto con i colleghi universitari durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4
5. How do you perceive the relationships with your university professors during this period of COVID-19 pandemic? (Come vive il suo rapporto con i docenti universitari durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4
6. How do you perceive your academic studying experience during this period of COVID-19 pandemic? (Come vive la sua esperienza di studio universitario durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4
7. How do you perceive the changes in your sexual life due to the social isolation during this period of COVID-19 pandemic? (Come vive i cambiamenti nella sua vita sessuale causati dall'isolamento durante l'attuale periodo di pandemia COVID-19?)	0	1	2	3	4

The Italian version is provided in brackets.

academic studying (e.g., fear of delays, difficulties in finding appropriate spaces to concentrate) (Cao et al., 2020; Lee, 2020b; Sahu, 2020).

The second factor, labeled Isolation, comprised two items exploring perceived stress related to social isolation and changes in sexual life due to the containment measures. From this perspective, in line with research emphasizing the strong weight of containment measures such as quarantine and social distancing on individuals' psychological health and wellbeing (Brooks et al., 2020; Horesh and Brown, 2020; Lee, 2020a; Williams et al., 2020), the second factor also captured the perceived disease and sense of loneliness derived from living this condition, often far from the loved ones (Sahu, 2020; Zhai and Du, 2020).

From this perspective, considering the specificity of the target population, it's not surprising that the confinement in itself and sexual life belonged to the same factor. Indeed, since students were more likely to still live with their families or they returned back home due to the pandemic, it's more probable that their couple' relationship, intimacy and sexual life were subject to significant restrictions due to the lockdown. However, these findings may be also due to the specific European context, considering that the average age of young people leaving the parental house is 25.9 (Eurostat, 2020), while in several other countries students use to leave home around 18 years for starting the college (Aassve et al., 2002; Crocetti and Meeus, 2014).

The third factor, labeled Fear of Contagion, comprised one item assessing perceived stress related to the risk of infection. The relevance of the latter dimension is, indeed, in line with previous studies on the key role played by the fear to be infected, the fear for others (e.g., relatives, friends) to become ill, as well as the fear to be a source of contagion for the others (Ahorsu et al., 2020; Brooks et al., 2020; Taylor et al., 2020).

TABLE 7 | Items, mean, SD and range scores of the COVID-19 Student Stress Questionnaire scales.

CSSQ Scales	Items	Mean ± SD	Range
Relationships and Academic Life	3, 4, 5, 6	4.95 ± 2.74	0–13
Isolation	2, 7	3.51 ± 2.05	0–8
Fear of Contagion	1	1.61 ± 1.12	0–4
Global Stress	All items	10.07 ± 4.52	1–22

Concerning convergent validity, the standardized factor loadings, and the values of AVE and CR were well above the threshold suggested by Hair et al. (2010), indicating that the variances were more explained by each factor and all of the items of each factor were consistent for measuring the same latent construct.

Furthermore, data revealed significant associations of all CSSQ scales scores with all the SCL-90-R standardized scales scores as well as with the Global Severity Index. This revealed how the specific sources of stress we have identified, covering changes in Relationships and Academic Life, perceived Isolation and Fear of Contagion, could have significant negative effects on perceived psychophysical health conditions among students. These results suggested the meaningfulness to adopt the proposed instrument also to foster the development of early interventions supporting students' adjustment and promoting their psychophysical health during and after the COVID-19 pandemic lockdown.

Concerning discriminant validity, the square root of AVE values were greater than the correlations coefficients between the factors, indicating that the three factors could extract more variance than the sharing among factors, so revealing a satisfactory discriminant validity. Moreover, intercorrelations between COVID-19 Student Stress Questionnaire scales (moderate in size) and correlations between the three scales and the Global Stress score (high in size) confirmed that the CSSQ assessed different but connected dimensions, so giving further support about the validity of the proposed tool to evaluate both perceived Global Stress and different sources of stress related to the COVID-19 pandemic. Therefore, both perceived levels of Global Stress and specific stressors should be carefully considered when defining interventions fostering students' wellbeing during the current COVID-19 crisis.

Finally, the evaluation of mean inter-item correlation, Cronbach's alpha and McDonald's omega confirmed that the CSSQ had satisfactory internal consistency.

In conclusion, this study demonstrated that the COVID-19 Student Stress Questionnaire is a 7-item multidimensional scale with satisfactory psychometric properties. Moreover, it is a good instrument to be used in assessing and allaying perceived COVID-19-related stress among university students.

Implications for Clinical Practice

The study sought to address the growing concerns arising from the challenges that students around the world are facing due to the COVID-19 pandemic and from its potential negative effects on their psychophysical health conditions, by providing a brief, valid and meaningful tool, namely the COVID-19 Student Stress Questionnaire (CSSQ).

The CSSQ presented here is a brief multidimensional tool, conceived to be helpfully used by members from different areas within universities (e.g., human resources, health units, student affairs) to promote a deeper understanding of the nature of COVID-19-related stressors perceived by students, in order to define tailored policies and support interventions.

In line with this, the CSSQ could be useful to early identify those students in need of psychological support. Indeed, due to the perceived risk of contagion, the consequent modifications of all significant relationships in daily life may induce, among university students, loss of contact with formal and informal support networks and growing risk of isolation. Therefore, it becomes pivotal to make all the possible efforts to assure careful monitoring of their perceived levels of stress and psychological wellbeing.

Finally, the adoption of the CSSQ in the clinical practice can significantly help social and health practitioners, serving as a monitoring and evaluation tool to define more tailored evidence-based counseling interventions. Indeed, since tapping different stressors that could have been experienced due to the COVID-19 outbreak (i.e., stressors related to Relationships and Academic Life, Isolation, and Fear of Contagion), the adoption of this tool can help to underline those areas requiring more attention within counseling interventions and to assess the effectiveness of the interventions by evaluating potential changes over time.

Limitations and Future Research

Despite these strengthens, some limitations need to be underlined. Firstly, the administering of the questionnaire was online, potentially limiting the enrollment in the study of those without Internet access. However, since the target population of Italian university students (taking into account both the age and the provision of distance learning during the COVID-19 pandemic), we consider this limitation could have influenced our results to a little extent. Secondly, the participant pool comprised a self-selected sample of students enrolled only in one university (i.e., students enrolled in Philosophy, Modern Languages and Literature, and Psychology degree courses) with a majority being female (and therefore, tests for gender differences were not possible). Further investigation on bigger and more representative samples is needed to confirm the results provided by the present study (e.g., a nationally representative sample with more male participants). Thirdly, the study relies on participants' self-reports, and, therefore, findings could be affected by the risk of social desirability bias. Future research could, hence, include a broader range of sources of data. Furthermore, future studies could also consider the meaningfulness to adopt newly developed COVID-19-related instruments (e.g., FCV-19S) to test concurrent validity. Indeed, at the time of study design and data collection, the Italian versions of these specific measurement tools were not available yet. Another limitation is the lack of available data for a more robust examination of reliability beyond internal consistency, such as test-retest. Consequently, future studies could be designed with the aim to also conduct test-retest analysis. Finally, cultural and social variables may have potentially influenced the construct of the questionnaire as well as it's convergent and discriminant validity. Consequently, further applications of this instrument in other countries are needed to allow gaining further information about sources of stress influencing students' wellbeing according to different countries worldwide.

Notwithstanding these limitations, this study provided researchers and practitioners with a brief, easily administered, valid and reliable measure to assess perceived stress among university students, so supporting efforts to understand the

impact of this unique global crisis and develop tailored interventions fostering students' wellbeing.

The Covid-19 outbreak and the subsequent lockdown have profoundly impacted families' daily life, challenging their psychological resilience. Our study aimed to investigate the immediate psychological consequences of the pandemic on Italian parents and children focusing on internalizing and post-traumatic symptoms. We also wanted to explore the impact of possible risk and resilience factors, e.g., lifestyle and behaviors, emotional and cognitive beliefs, on parents and children's reaction to the emergency distress. An online survey was administered during the country's nationwide lockdown to 721 Italian parents of at least one child aged between 6 and 18 years. The respondent completed the survey for himself/herself and his/her child. The survey included socio-demographic items and validated questionnaires on parents' post-traumatic stress symptoms, depression and anxiety levels, and on children's internalizing problems. Parents were asked to fill the questionnaires twice: once referring to the current emergency condition and once recalling how they and their child felt a few months before Covid-19 outbreak. Multiple regression analyses showed that specific demographic characteristics (i.e., sex and age) and psychological factors of children and parents, such as fear of contagion and the opportunity to think about possible secondary positive effects of the pandemic, had a predictive value on the presence of internalizing symptoms of both parents and children. Moreover, parents' behaviors during the lockdown period (i.e., employment status and sport practiced) were significantly related to their own internalizing symptoms; these symptoms, in turn, had a strong and positive predictive value on children's internalizing problems. Besides, analyses of variance showed that internalizing symptoms of parents and children were significantly higher during the Covid-19 pandemic than before it started. In addition to showing a direct effect of the pandemic on the psychological health of parents and

children, the present results also give a series of important information on how parents perceive, and therefore influence, their children in this period of emergency. Our findings thus highlight the urgent need to provide parents with adequate support to take care of their own psychological wellbeing and to help their children coping with the direct and indirect effects of the pandemic.

Keywords: Covid-19, internalizing symptoms, parents, children, resilience

INTRODUCTION

The outbreak of the novel coronavirus SARS-Cov2 has led to a global health emergency with alarming implications, not only for individual and collective health, but also for emotional and social functioning (Dubey et al., 2020; Pfefferbaum and North, 2020). Children may be among the most exposed to the psychosocial consequences of the pandemic due to a major disruption in their daily life, and their immature ability to process the short- and long-term effects of the emergency. A better understanding of how children's psychological wellbeing has been affected and, more generally, how the family system has been impacted is required to find out protective and risk factors associated with mental health during the Covid-19 outbreak, and to deliver adequate support to parents and children in need.

As confirmed cases approached 110,000 patients across over 100 countries, the Covid-19 outbreak has been declared a pandemic by the World Health Organization (World Health Organization [WHO], 2020, Situation Report-51, 11th March 2020). One country after another adopted strict measures to limit the spread of the viral pneumonia, such as physical-distancing, and temporary closure of schools, universities and non-essential workplaces. Many governments indeed ordered a nationwide lockdown limiting movements of the entire population: people could not leave their home, except for a proven state of emergency or necessity. Italy was the first country in Europe to report a significant number of infections and to adopt restrictive measures. Schools and universities were closed in the worst affected regions of northern Italy in late February and, at the beginning of March, Italian prime minister announced a government decree imposing a nationwide lockdown (DPCM, 9th March 2020 in Gazzettaufficiale, 2020). The outbreak and the consequent lockdown had a profound economic and social impact and, as current literature is revealing, they significantly affected the mental health of general population: subsyndromal mental health concerns, such as depressive and anxiety symptoms, seem to be a common response to the pandemic (Rajkumar, 2020; Wang et al., 2020).

Monitoring the effects of Covid-19 outbreak across high-risk groups has become a priority and young people are likely to be among the most affected by the psychosocial consequences of the emergency (Fegert et al., 2020; Holmes et al., 2020). During Covid-19 outbreak, children's routine was drastically disrupted due to the closure of schools and lack of outdoor activities, resulting in limited connection with classmates and friends, absence of a day-to-day schedule, and increased sedentary behaviors and screen time (Xiang et al., 2020). Furthermore, children's immature ability to understand and process what was happening during and in the aftermath of the emergency made them even more vulnerable (Balaban, 2006). These arguments were supported by a preliminary study conducted in China (the first country where the epidemic developed), that reported the presence of psychological difficulties in children aged 3–18 years during the pandemic, with clinging, inattention, irritability and worries as the most severe symptoms (Jiao et al., 2020). Besides, during past epidemic diseases (i.e., N1H1, SARS, and Asian influenza), a high percentage of children who were isolated or quarantined developed acute stress and adjustment disorders: parents reported that nearly one-third of children who were quarantined met the clinical criteria for post-traumatic stress disorder (Sprang and Silman, 2013).

Overall, children exposed to emergencies and disasters can exhibit several negative psychological outcomes: they may develop internalizing problems as anxiety-related symptoms, e.g., excessive worries and fears, and depressive symptoms, e.g., becoming detached and numb, or somatic complaints, e.g., headache and stomachache (Balaban, 2006; Danese et al., 2020). It is important to bear in mind that most of these symptoms are transient, can be considered an expected reaction to intense distress, and may not require immediate clinical intervention (Danese et al., 2020). Nonetheless, we can assume that many children, during and after Covid-19 pandemic, may need special support and reassurance from their parents, as well as appropriate and simple information to understand what is happening, and they should be monitored to identify and prevent the possible development of more severe long-lasting disorders.

The direct engagement of children in systematic screening and assessment in the context of traumatic and distressing experiences should be preferred; though, if children cannot be observed directly, a widely used mean to assess the presence of children's behavioral and emotional symptoms is to ask caregivers to evaluate them, for example using the Child Behavioral Checklist Parent Report Form (Achenbach, 1991; Achenbach and Rescorla, 2001; Balaban, 2006). Although well validated, this method has been debated as parents' reports of their children's problems might be biased by their own psychopathology and by the sex of the child (Najman et al., 2001; Kroes et al., 2003). When possible, the mental health status of caregivers should be evaluated at the same time as children: many studies have shown that parental adjustments during emergencies are important predictors of children's mental health outcomes (McFarlane et al., 1987; Laor et al., 2001); moreover, one of the greatest risk factors for children to develop a psychopathology is having a parent with a psychiatric disorder (see e.g., Beidel and Turner, 1997;

Maciejewski et al., 2018). Both genetic and environmental factors seem to be involved in the familiar transmission of psychological disorders, but the exact nature of the underlying mechanisms remains still unclear.

During Covid-19 pandemic and the prolonged home confinement imposed, it is possible that children's problems may have been exacerbated by their parents' stress. Suddenly, most parents had to rearrange their schedule and find a new balance between their personal life, smart working organization, and children's management. This situation put them under great pressure, and the most vulnerable parents may have become too overwhelmed to find appropriate ways to be supportive caregivers and to address children's fears and insecurities, increasing the risk of children experiencing behavioral and emotional problems (Spinelli et al., 2020). Interestingly, during a past epidemic, Remmerswaal and Muris (2011) found that parents and children's fear of being infected were significantly correlated, and parents' fear was associated with the transmission of threat information to their offspring, which in turn was linked to children's fear of the disease (the link remained significant even when controlling for other sources of information, i.e., media, friends, school, or direct experience with the disease). Thus, parents could have a great influence on children's wellbeing in this period of emergency, and taking into account the whole family system becomes essential.

The main aim of the present study was to investigate the immediate psychological effects of Covid-19 pandemic and the consequent lockdown on children, as reported by their parents, and on parents themselves. We focused on internalizing and post-traumatic stress symptoms, controlling for those demographic factors that are most associated with their incidence (i.e., age and gender; Altemus et al., 2014). We expected that internalizing problems (i.e., behavioral and emotional problems, often occurring concurrently, with prominent anxiety, withdrawal, depressive and somatic symptoms unexplained by medical conditions; Achenbach et al., 2016) might have increased (with respect to normative data) during the health emergency in both parents and children (see e.g., Jiao et al., 2020; Wang et al., 2020) and that parents' difficulties might have had a negative impact on children's wellbeing (see e.g., Spinelli et al., 2020). Furthermore, little is known about which factors may be associated with parents and children's mental health during a health emergency. Therefore, we aimed at exploring the impact of possible risk and protective, resilience factors on parents and children's reaction to the emergency distress: such as lifestyle and behaviors (i.e., the amount of sport practiced by the parents, parents' employment status, and the number of children's close friends), and emotional and cognitive beliefs (i.e., parents' fear of being infected by SARS-Cov2 and parents' ability to broaden their biased attention on the pandemic crisis by thinking about its possible secondary positive effects or implications). Finally, parents and children's current wellbeing could have been partly influenced by their prior condition, thus we were also interested in incorporating a retrospective research design (i.e., asking parent participants to report on the basis of their memories). We thus asked parents to rate their own anxiety and depression problems, and those of their children, twice: once referring to the current emergency period, and once recalling how they and their children felt before Covid-19 outbreak.

MATERIALS AND METHODS

Participants and Procedure

An online survey among parents of, at least, one child aged between 6 and 18 years living in northern or central Italy was administered from April 16 to May 07, 2020, during the country's nationwide lockdown. A member of the parenting couple completed the survey for himself/herself and his/her child. The first part of the survey included a socio-demographic questionnaire (40 items) focused on how parents and their children were experiencing the health emergency. Next, participants completed 3 validated questionnaires on impact of events, depression and anxiety levels, and the internalizing problems of their children (i.e., symptoms of anxiety, depression and somatic complaints). Parents were asked to fill the questionnaires twice: once referring to the current health emergency (a condition called Cov) and once recalling how they and their children felt the months before Covid-19 outbreak, namely the last months of 2019 (a condition called PreCov). To help participants in the PreCov condition, the survey instructions explained to them that a useful way to remember how they (and their children) felt a few months earlier, could be to observe the photos of that period that the participants could have kept on their mobile phones. The order of presentation of the questionnaires was counterbalanced across participants (i.e., there were two possible sequences: Cov, PreCov or PreCov, Cov). The impact of event scale was only filled once with reference to the current health emergency.

Participants were initially recruited using word-of-mouth and through contacting school leaders and school teachers; the questionnaires were initially equally distributed in the two sequence orders. Then, participants were also recruited by snowball sampling overall resulting in 849 respondents though not perfectly counterbalanced in terms of the two questionnaires' sequence orders (see **Table 1**). Thus, we decided to take the sequence order factor into consideration in the data analysis. All data were collected using Google Forms. The procedures were approved by the local Ethics of the University of Udine and were in accordance with the Helsinki Declaration guidelines. All participants provided informed consent.

As mentioned above, 849 respondents completed the survey. After excluding parents with serious physical or psychiatric conditions (55 participants), parents of atypically developing children (53 participants), those who had been infected with Covid-19 (1 participant) or whose child was not between 6 and 18 years old (17 participants), and 2 respondents who had not completed the survey correctly, we obtained a sample of 721 healthy parents of typically developing children (mean age 42.80 $\pm$ 5.47 years; 103 males, 14.2%; mean age of children 10.08 $\pm$ 2.52 years; 372 males, 51.6%) on which we based the following analyses.

The sample was mainly composed of Italian parents (709, 98.3%), who were married (524, 72.6%); most of them had

Raw scores (mean and standard deviation, SD) of questionnaires (completed with reference to the Covid-19 health emergency: Cov) for the whole sample of respondents (parents of children and adolescents aged 6–18 years who rated their own symptoms of post-traumatic stress, anxiety and depression and then rated those of their children) and by function of Sex (of parents and children), Sport, Work, Fear, Friends_Child and a "broadening of biased attention" on the pandemic crisis expressed in terms of participants' thinking about its possible secondary positive effects for one's life (BBA_1) and for the environment (BBA_2). Data of questionnaires filled in with reference to the period preceding the start of the Covid-19 outbreak (last months of 2019: PreCov) are reported in the bottom part of the table. N/a, not available. IES-R, Impact of Event Scale-Revised; HADS, Hospital Anxiety and Depression Scale; CBCL, Child Behavior Checklist. Sequence indicates the order with which HADS and CBCL questionnaire were compiled by parents [PreCov_Cov = Sequence ('0') and Cov_PreCov = Sequence ('1')].

1 or 2 children (194, 26.9 and 415, 57.6%, respectively) and had a high-school diploma or a higher education level (371, 51.4%). The majority of the sample was living in a village with <2,000 inhabitants (330, 45.8%) or a small city of 2,000–10,000 inhabitants (268, 37.2%), in a house with more than 125 sqm (364, 50.5%), and had access to a garden (633, 87.7%).

Measures

Socio-Demographic Questionnaire

A socio-demographic questionnaire was developed for the purpose of this study. The first part included 13 demographic questions about participants' age, sex, nationality, education, physical and/or psychiatric conditions, marital status, number of children, the characteristics of the place of residence, the characteristics of their house, i.e., its size and if it has an outdoor space, and the number of people with whom they were living. The second group of questions (5 items) focused on parents' lifestyle during the last 2 weeks: their employment status, the amount of time they spent every day practicing sport (range of possible answers: 0–>2.5 h per day) and with their child (<1–>5 h per day), the number of times they left home (0–>5 times) and the amount of time spent outside (<1–>4 h). Third, parents were asked to report their direct experience with the COVID-19 infection (6 items): if they had been tested with the swab, if they were positive, if they experienced COVID-19 symptoms, how much they feared being infected (no fear – very much fear of contracting the virus) and the amount of time they spent inquiring about the pandemic in the media since COVID-19 breakdown in China on January 2020 (<1–>2 h per day). Then, there were 14 questions regarding their child and his/her lifestyle before and during the pandemic: which child they were referring to (their only child, the firstborn, etc.) and why they had chosen him/her, the child's age, sex, nationality, grade attended, if he/she had a learning support teacher and why, if he/she had a physical or psychiatric condition, how many times per week he/she used (before the Covid-19 outbreak) to meet friends outside from school (<1–≥3 times a week), which sports he/she preferred, how many close friends he/she had (0–≥4 close friends) and the amount of time he/she spent every day with the respondent parent (<1–>5 h per day). Finally, there were 2 items that aimed at exploring if parents could broaden, in the past 2 weeks, their biased attention on the pandemic crisis by thinking about its possible secondary positive effects. This aspect was operationalized as having thought (never – very often) during the past 2 weeks of the health emergency about its possible related implications or opportunities for one's life, i.e., giving oneself more space or slowing down the frenetic pace of life, and for the environment, i.e., reducing pollution and undertaking in the future a more environmental friendly lifestyle.

Impact of Event Scale-Revised

After completion of the socio-demographic questionnaire, participants filled in three questionnaires. The Italian adaptation of the IES-R (Weiss and Marmar, 1996; Craparo et al., 2013) is a 22-item self-report measure of current subjective distress in response to a specific traumatic event. It comprises three subscales representative of the major symptoms clusters of post-traumatic stress: intrusion (item example: "I thought about it even when I did not mean to"), avoidance (item example: "I tried not to think about it"), and hyper-arousal (item example: "I found myself acting or feeling like I was back at that time"). The responses are rated on a 4-point Likert scale ranging from 0 (never) to 3 (very often). In the present study the participants were asked to refer to the symptoms of distress they may had experienced during the last week regarding the emergency of COVID-19 pandemic and the consequent restrictive measures adopted by the government. Overall sample Cronbach's alpha: IES-R = 0.93.

Hospital Anxiety and Depression Scale

The Italian adaptation of the HADS (Zigmond and Snaith, 1983; Costantini et al., 1999) is composed of two 7-item scales that assess emotional disturbance: one for anxiety (item example: "Worrying thoughts go through my mind") and one for depression (item example: "I look forward with enjoyment to things"). Each item is scored from 0 to 3, so the respondent can score between 0 and 21 for either anxiety or depression, with higher scores denoting higher levels of anxiety or depression. The participants of this study were asked to fill the HADS twice: once referring to the current health emergency (taking the last 2 weeks as a time reference) (the Cov condition) and once recalling how they felt the months before Covid-19 outbreak (the PreCov condition). Overall sample Cronbach's alpha: total HADS-Cov score = 0.87; total HADS-PreCov score = 0.84.

Child Behavior Checklist (6–18)

The Italian adaptation of the CBCL/6-18 (Achenbach, 1991; Achenbach and Rescorla, 2001; Frigerio, 2001) is a caregiver report form used to assess behavioral and emotional problems in children and adolescents aged 6–18 years. In the present study we used 3 syndrome scales: anxious/depressed (13 items; item example: "Cries a lot"), withdrawn/depressed (8 items; item example: "There is very little he/she enjoys"), and somatic complaints (11 items; item example: "Feels dizzy or lightheaded"). Each item is scored from 0 (not true) to 2 (very true or often true), and the sum of the scores of the 3 scales corresponds to the broader dimension of internalizing problems (higher scores denote higher internalizing problems). The participants of this study were asked to fill the CBCL/6-18 twice: once referring to their child's problems of the past 2 weeks (the Cov condition) and once recalling their child's problems the months before Covid-19 outbreak (the PreCov condition). Overall sample Cronbach's alpha: total CBCL-Cov internalizing score = 0.88; total CBCL-PreCov internalizing score = 0.87.

Data Analysis

Continuous measures were summarized reporting mean and standard deviation (SD) of raw scores for both the whole sample of respondents and separately for the two levels ('1' and '0') of each dichotomous variable considered in the following analysis (i.e., sex of the participant, sex of his/her child, amount of sport practiced by the parent, parent's employment status, parent's fear of contagion, parent's broadening of biased attention on the crisis regarding oneself and the environment, number of child's close friends, sequence of questionnaires: Cov, PreCov or PreCov, Cov) (**Table 1**).

The main analyses focused on the Cov condition and concerned a series of multiple linear regression models on continuous responses reported by the participants about: (1) their own levels of current post-traumatic stress (IES-R_Cov), anxiety (HADS_Cov Anxiety) and depression (HADS_Cov Depression)

and (2) their children's levels of current internalizing symptoms, in the three components of anxiety (CBCL_Cov anxiety), depression (CBCL_Cov withdrawn/depression), and somatic complaints (CBCL_Cov somatic complaints).

Dichotomous and continuous variables were introduced in the models at one single step of computation. In particular, for each of the three models concerning parents' stress and internalizing symptoms, we introduced: (1) four demographic variables, such as sex and age of both parents and their children (Age_Parent; Age_Child; Sex_Parent; Sex_Child); (2) two dichotomous variables concerning the amount of sport practiced each day during the past 2 weeks (Sport: 0–1 vs. >1 h per day) and the participants' current employment status (Work: unemployed or temporarily suspended vs. remote or on-site worker); (3) three dichotomous variables concerning the psychological factors of fear of infection (Fear: none or little fear vs. much or very much fear of contracting SARS-CoV2 virus) and a "broadening of biased attention" (BBA) on the pandemic crisis, which was reflected by participants' thinking about (never or sometimes vs. often or very often during the last 2 weeks of the health emergency) its possible secondary positive effects or implications: for one's life (for example giving oneself more space or slowing down the frenetic pace of life: BBA_1) and for the environment (for example reducing pollution and undertaking in the future a more environmental friendly lifestyle: BBA_2). Finally, a last dichotomous variable was included in the models reflecting the Sequence with which participants had to rate their own symptoms (and those of their children) of anxiety and depression. As already mentioned, there were two possible sequences: Cov, PreCov and PreCov, Cov. The impact of event scale (IES-R) was only filled once with reference to the current health emergency but the Sequence variable was maintained in the corresponding regression model.

With regards to parents' rate of children's internalizing symptoms, similar regressions models were ran. In particular, for each of the three models (CBCL_Cov anxiety, CBCL_Cov withdrawn/depression, CBCL_Cov somatic complaints) the same Age_Parent, Age_Child, Sex_Parent, Sex_Child, Fear, BBA_1, BBA_2, and Sequence variables were entered. Moreover, we included parents' total HADS_Cov scores (anxiety plus depression) and the number of close friends (Friends: 0–2 vs. at least 3), who parents reported their children had before the health emergency started. Sport and Work were excluded from the three models concerning children's internalizing symptoms.

For each regression model, significance, coefficient of determination (R^2), and model coefficients (Bs with their standard error –SE- and corresponding standardized values βs) were reported. Variance inflation factors (VIFs) were calculated to avoid multicollinearity in each regression model (i.e., VIF was considered too high if ≥5; in the analyses reported below no value exceeded 1.5). To avoid alpha-inflation the alpha-level was set to 0.01 in each regression model. Effect sizes for R^2 were considered small (0.02), medium (0.13) and large (0.26) (Cohen, 1988).

As secondary analysis, we compared parents' reported Cov and Pre_Cov anxiety and depression scores, both when they gave description of themselves and of their children (see bottom part of **Table 1** for the raw data concerning the Pre_Cov condition). We ran five mixed model ANOVAs with repeated measures including anxiety, depression and somatic complaints scores as within-subject variables at two levels (Time: HADS_Cov Anxiety vs. HADS_PreCov Anxiety; HADS_Cov Depression vs. HADS_PreCov Depression; CBCL_Cov Anxiety vs. CBCL_PreCov Anxiety; CBCL_Cov Withdrawn/Depressed vs. CBCL_PreCov Withdrawn/Depressed; CBCL_Cov Somatic Complaints vs. CBCL_PreCov Somatic Complaints) and Sequence (Cov_PreCov vs. PreCov_Cov) as between-subject variable. Overall, we used a statistical significance threshold of $p < 0.05$ in all ANOVAs and we reported effect sizes as partial eta squared (η_p^2). Effect sizes were considered small (0.01), medium (0.06) and large (0.14) (Cohen, 1988; Miles and Shevlin, 2001). The overall data were analyzed with Statistica 8 (StatSoft, Inc., Tulsa, OK, United States). The data that support the findings of this study are available from the corresponding author, upon request.

RESULTS

Descriptive Statistics of the Sample

Table 1 reports the raw scores of participants in all questionnaires used in the present study. Referring to the cut-off and norming groups for these questionnaires (IES-R: Creamer et al., 2003; Wang et al., 2020; HADS: Zigmond and Snaith, 1983; Costantini et al., 1999; CBCL 6-18: Achenbach, 1991; Achenbach and Rescorla, 2001; Frigerio, 2001) and considering the questionnaires filled in by parents with reference to the current Covid-19 health emergency (the Cov condition), the data showed that the mean scores for post-traumatic stress, anxiety and depression symptoms of parents and internalizing problems of children were within normal ranges when compared against normative data. Nonetheless, we found that many parents reported moderate to severe post-traumatic stress symptoms (195, 27.0%; IES-R score ≥ 33); elevated symptoms of anxiety (90, 12.4%; HADS Anxiety score ≥ 8); elevated symptoms of depression (64, 8.8%; HADS Depression score ≥ 8). As regard parents evaluation of children's internalizing problems, it emerged that a high percentage of children showed elevated anxiety (191, 26.4%; CBCL Anxious/Depressed T score ≥ 65) and depression (175, 24.2%; CBCL Withdrawn/Depressed T score ≥ 65) and, with less incidence, somatic complaints (65, 9.0%; CBCL Somatic complaints T score ≥ 65).

The socio-demographic questionnaire revealed that 309 parents (42.8%) were unoccupied or temporarily suspended from their job during the health emergency, and 130 parents (18.0%) had never left home or went outside once in the last 2 weeks. As regards participants' daily activities during the last 2 weeks, 213 (29.5%) reported to practice sport every day (1 or more hours per day). Finally, the vast majority (628, 87.1%) spent more than 5 h per day with their children, while, before the lockdown, only 254 parents (35.2%) reported spending that same time with their children. Of all respondents, 35 (4.8%) were tested with the Covid-19 swab and the response was negative (the only respondent who resulted positive to Covid-19 infection was excluded from the sample). Nevertheless, 12 respondents believed

they had been infected by the novel coronavirus (1.6%), and 60 participants (8.3%) affirmed that, in the last weeks or at the time they were filling the survey, they have had one or more Covid-19 related symptoms, such as fever, dry cough, pain muscle, nasal congestion, sore throat, diarrhea or pneumonia. Since the Covid-19 breakdown in China on January 2020, 210 parents (29.1%) have spent more than 2 h per day reading or watching the news about the health emergency on TV, newspapers or Internet (which may suggest the importance of understanding the possible effects of repeated media consumption during the crisis; Holmes et al., 2020). 111 parents (15.3%) reported being very afraid of being infected by the novel coronavirus. Finally, more than half of the parents reported that in the last 2 weeks they could broaden their attention on the pandemic crisis to consider some possible secondary positive effects such as the chance of giving oneself more space or slowing down the frenetic pace of life (369 respondents thought about it often or very often, 51.1%), and the chance to reduce pollution and undertake a more environmental friendly lifestyle (458 respondents thought about it often or very often, 63.5%).

Multiple Regression Analyses

In **Table 2**, regression analyses globally predicting post-traumatic, anxiety, depression and somatic symptoms of parents and their children (as rated by their parents) are presented. Each regression model was significant and the total variance explained generally reflected a medium effect size (Cohen, 1988; Miles and Shevlin, 2001). **Figure 1** reports a schematic representation of t-values (absolute values are reported) for each multiple regression coefficient. In relation to the dependent variable IES-R_Cov, measuring parents' symptoms of post-traumatic stress, the results showed that having high fear of being infected positively predicted IES-R_Cov scores. Reduced post-traumatic scores were instead predicted by a higher tendency to broaden biased attention on the crisis to think about its possible positive secondary effects for one's life (BBA_1) and for the environment (BBA_2).

With regards to HADS_Cov anxiety, the results indicated that, similarly to IES-R_Cov scores, to be female and have high fear of contagion positively predicted parents' anxiety scores, while BBA_1 and BBA_2 were negatively related with anxiety levels. Moreover, a negative marginal relation between the amount of sport practiced by parents in the last 2 weeks and HADS_Cov anxiety was also found.

As far as HADS_Cov depression is concerned, the results again showed the positive relations between being a female and having high fear of contagion and parents' depression scores, as well as the negative relation between depression symptoms and BBA_1 and BBA_2. Moreover, we found that the amount of sport practiced and the parents' employment status (on-site or remote work vs. suspension of work or unemployment) were negatively related to parents' level of depression.

Turning to how parents rated their children's levels of anxiety, depression and somatic complaints, the first regression model concerning CBCL_Cov Anxiety showed that parents rated their children as more anxious as they were considered to have less close friends. A strong positive relation between children's anxiety level and parents' total HADS_Cov scores (anxiety plus depression) was also found. Finally, an effect of Sequence was found: to have filled in the CBCL anxiety questionnaire referring first to the actual health emergency condition (CBCL_Cov Anxiety) and then considering the period before the Covid-19 outbreak (CBCL_PreCov Anxiety) positively predicted current anxiety symptoms of children as rated by their parents.

As far as CBCL_Cov Withdrawn/Depressed is concerned, the results highlighted again a strong positive relation with parents' total HADS_Cov scores and a negative relation with children's number of close friends. Remarkably, we found that parents' fear of contagion negatively predicted children's depression: to have none or little fear of being infected positively predicted children's level of depressive symptoms as reported by their parents.

Finally, with regards to CBCL_Cov Somatic complaints, the results further showed the strong and positive predictive value of parents' total HADS_Cov scores, as well as the negative relation with parents' fear of being infected.

In sum, the findings of the multiple regression analyses showed that specific psychological and behavioral factors of parents and children, such as fear of contagion, the opportunity to think about possible secondary positive effects of the pandemic and the number of children's close friends, had a predictive value on the presence of internalizing symptoms of both parents and children. Moreover, parents' behaviors during the lockdown period were significantly related to their own internalizing symptoms; these symptoms, in turn, had a strong and positive predictive value on children's internalizing problems.

Analyses of Variance

In the following analysis, we directly compared parents' reported Cov and Pre_Cov data for each HADS and CBCL subscale. For each measure, we ran a mixed model repeated-measure ANOVA considering the between-subject factor of Sequence (Cov_PreCov and PreCov_Cov) and the within-subject factor of Time (i.e., the two repetitions of a questionnaire). For parents' anxiety and depression symptoms (measured with the two subscales of the HADS questionnaire), both ANOVAs showed a significant main effect of Time [Cov > PreCov; $F(1,719) = 109.11$, $p < 0.01$, $\eta_p^2 = 0.131$ and $F(1,719) = 38.53$, $p < 0.01$, $\eta_p^2 = 0.051$, respectively for HADS Depression and Anxiety] and a significant Time × Sequence interaction with small effect sizes [$F(1,719) = 9.69$, $p < 0.01$, $\eta_p^2 = 0.013$ and $F(1,719) = 5.13$, $p < 0.03$, $\eta_p^2 = 0.007$, respectively for HADS Depression and Anxiety]. The interaction was due to the two sequences mainly differing in the PreCov condition in which scores were higher when this condition comes first (Sequence: PreCov_Cov) than second (Sequence: Cov_PreCov) (**Table 1** and **Figure 2**).

Similarly to parents' HADS data, for the CBCL, the three ANOVAs also returned a significant main effect of Time [Cov > PreCov; $F(1,719) = 48.01$, $p < 0.01$, $\eta_p^2 = 0.062$, $F(1,719) = 3.88$, $p < 0.05$, $\eta_p^2 = 0.005$ and $F(1,719) = 15.06$, $p < 0.01$, $\eta_p^2 = 0.021$, respectively for CBCL Withdrawn/Depressed, Anxiety and Somatic Complaints] and a significant Time × Sequence interaction with small (CBCL

Vertical bar in each graph indicates significance level at $p < 0.01$. IES-R, Impact of Event Scale-Revised; HADS, Hospital Anxiety and Depression Scale; CBCL, Child Behavior Checklist. Cov, completion of questionnaires with reference to the Covid-19 health emergency.

Withdrawn/Depressed and CBCL Somatic Complaints) and large (CBCL anxiety) effect sizes [$F(1,719) = 14.56$, $p < 0.01$, $\eta_p^2 = 0.019$, $F(1,719) = 158.70$, $p < 0.01$, $\eta_p^2 = 0.180$, and $F(1,719) = 18.70$, $p < 0.01$, $\eta_p^2 = 0.025$, respectively for CBCL Withdrawn/Depressed, Anxiety and Somatic Complaints]. Similarly to parents' data, the interactions concerning CBCL Withdrawn/Depressed and Somatic Complaints were due to the two sequences differing in particular in the PreCov condition. By contrast, the effect for the CBCL Anxiety was due to a cross-over interaction as the two sequences also differed in the Cov condition: participants assigned to the Cov_PreCov Sequence rated their children having higher anxiety in the Cov vs. PreCov condition, while participants assigned to the PreCov_Cov Sequence rated their children having higher anxiety in the PreCov vs. Cov condition (see **Table 1** and **Figure 2**).

Overall, the findings obtained from the analyses of variance showed that, in general, internalizing symptoms of parents and children were reported to be significantly higher during the Covid-19 pandemic than before it started. Nonetheless, they also showed that the sequence with which parents had to rate their own anxiety and depression symptoms (and those of their children) significantly influenced their assessments.

DISCUSSION

The aim of this study was to investigate the immediate impact of the Covid-19 outbreak on families' mental health. We focused on internalizing symptoms, such as anxiety and depression, of the responding members of the parenting couples who evaluated their own symptoms (through the HADS and the IES-R questionnaires) and those of their children aged between 6 and 18 years (through the CBCL questionnaire). In order to have a self-reported baseline measure of these symptoms, participants had to fill in the questionnaires (HADS and CBCL but not IES-R) twice: once referring to the current health emergency

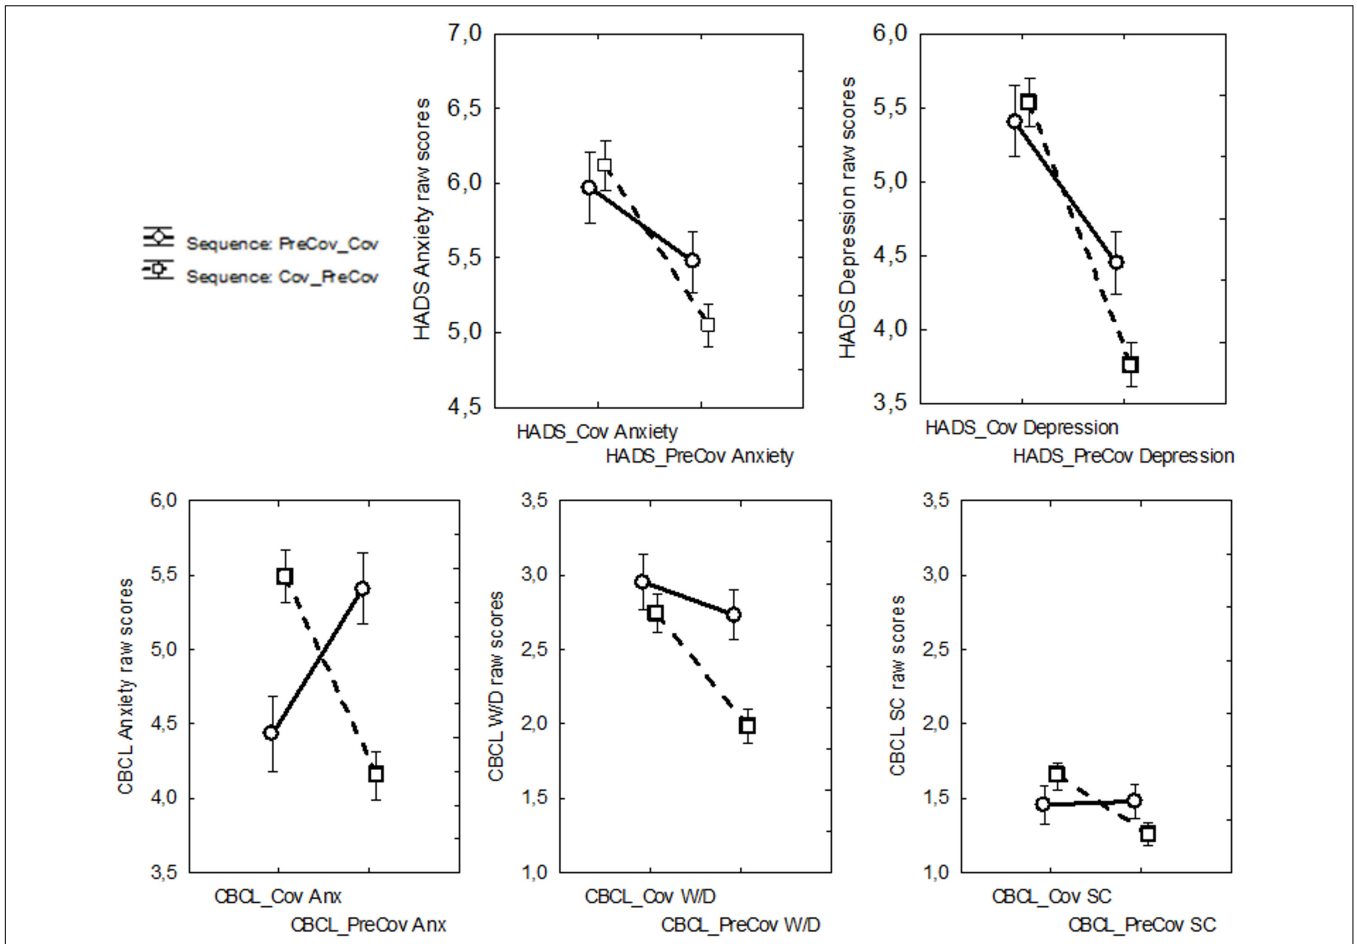

FIGURE 2 | Time (the two repetitions of a questionnaire in the Cov – with reference to the Covid-19 health emergency- and Pre_Cov - with reference to the period preceding the start of the Covid-19 outbreak- conditions) × Sequence (PreCov_Cov and Cov_PreCov) interaction obtained from mixed model repeated-measure ANOVAs for the measures (1) HADS (Hospital Anxiety and Depression) Anxiety, (2) HADS Depression, (3) CBCL (Child Behavior Checklist) Anxiety, (4) CBCL Withdrawn/Depressed, and (5) CBCL Somatic Complaints. W/D, withdrawn/depressed; SC, somatic complaints. Error bars indicate standard errors of the means.

(the Cov condition) and once referring to before it started (the PreCov condition).

The present findings suggest that most parents likely had enough psychosocial resources to respond to the pandemic emergency distress: in fact, present sample's mean levels of current anxiety, depression and post-traumatic stress did not differ from those of the normal population. Nonetheless, the results also suggest that the pandemic may still have affected the mental health of a considerable number of parents and children, contributing to raise their levels of internalizing problems. First, focusing on the Cov condition, we found that approximately a quarter of the parents reported moderate to severe post-traumatic stress symptoms while about one in 10 showed elevated symptoms of anxiety and depression. As regard parents' evaluation of children's internalizing problems, about a quarter of children was rated as having elevated anxiety and depression while about one in ten was rated as having clinically relevant somatic complaints problems. Moreover, internalizing symptoms of parents and children were globally reported to be higher during the Covid-19 pandemic than before it started.

Globally, these data corroborate previous findings highlighting the negative psychological impact of quarantine and lockdown periods, linked to both Covid-19 outbreak and other past health emergencies such as SARS, Ebola, H1N1 influenza pandemic, on mental health symptoms of both adults and children, including post-traumatic stress, depression, anxiety and emotional symptoms (Brooks et al., 2020; Di Giorgio et al., 2020, PREPRINT; Spinelli et al., 2020).

More specifically, the main analyses of the present study focused on the Cov condition and employed a series of multiple linear regression models carried out on parents and children's anxiety and depression symptoms and on parents' post-traumatic stress and children's somatic complaints symptoms. Most importantly, the results showed that to have much fear of being infected by the new coronavirus positively predicted post-traumatic, anxiety, and depression scores of parents. By contrast, having thought often or very often during the emergency (as happened to approximately half of the sample) about possible secondary positive effects or implications of the pandemic, negatively predicted parents' internalizing and post-traumatic

stress symptoms. To continue working and practicing sport during the health emergency also protected parents from internalizing problems (and in particular from depression).

The data on parents' internalizing symptoms suggest that fear of contagion is an important psychological factor that negatively impacts psychological well-being of healthy adult individuals, subject to isolation and confinement to prevent spread of the new coronavirus. This is in line with results of previous studies showing that fear of infection was a significant stressor during quarantine (see the reviews by Brooks et al., 2020) or, more generally but specifically related to Covid-19, that higher perceived risk of infection increased individuals' stress and anxiety (Simione and Gnagnarella, 2020). Of interest, in one study investigating the school's communities response to school closure during the H1N1 2009 influenza pandemic (Braunack-Mayer et al., 2013), it was found that the individuals who were more concerned about becoming infected or spreading the virus to others tended to be those with young children (or to be pregnant women). Unfortunately, in our study we did not ask details about why the participants were afraid of being infected (i.e., if they were afraid of infecting their children or older family members or being infected by them). Nonetheless, it is worth noting that, in our sample, increased levels of parents' internalizing problems were found in women and in the participants with younger children.

Taken together, our results suggest the need for psychoeducational and psychological support interventions that can reduce excessive fear of contagion in parents, even in those reasonably protected from fatal complications related to the SARS-CoV2 virus (such as the participants in our sample who were without serious clinical conditions and with an average age of about 40 years). Such interventions, which could be delivered online or through smartphone technology, could be designed to make fear manageable and not overwhelming. This could be obtained by means, for example, of cognitive-behavior and mindfulness-based therapies that may, on the one hand, challenge cognitive biases of individuals with exaggerate fear and perception of the risk of being infected and, on the other hand, help individuals to enhance stress management and reduce maladaptive coping strategies such as avoidance and excessive self-criticism (Fischer et al., 2020; Ho et al., 2020; Matiz et al., 2020). The effect of such interventions could therefore help diluting the direct negative effects of fear on the levels of anxiety and stress and depression of individuals, also indirectly affecting the quality of relationships of these people (see Simione and Gnagnarella, 2020 for similar arguments).

Physical activity and the possibility of continuing to work, from home or in the workplace, act as protective factors against the internalizing problems of the parents, especially in favor of depressive symptoms. On the one hand, these data corroborate and extend the results of other research, carried out both within the current health emergency and before it began (e.g., Schuch et al., 2016; Maugeri et al., 2020), demonstrating the positive impact of a physically and intellectually active lifestyle to relieve the symptoms of depression. On the other hand, the present findings suggest the importance of not giving up physical activity even during periods of isolation and social confinement, possibly underlining its importance through targeted psychoeducational and support interventions that, however, should be able to calibrate the right amount of exercise for each individual person, in terms of frequency, duration and intensity of physical activity (Carriedo et al., 2020), also taking into account the possible frustrations that could arise due to the restrictions imposed by the epidemic on physically more active people (Zhang et al., 2020).

What we called "broadening of biased attention" was another important factor that negatively predicted parents' internalizing problems and post-traumatic stress during the Covid-19 outbreak. This factor reflected the propensity of the parents to think, during the lockdown period, about possible secondary implications of the pandemic, both for their own life and for the environment, and could reveal an emerging element of resilience in the face of adversity (Smith et al., 2020). From this point of view, broadening of biased attention to the crisis by perceiving possible secondary implications can mean not being pervaded and overwhelmed by the uncertainty and stress connected to it; it can rather mean preserving and nurturing a system of meaning, individual but also shared with one's family, which can bring security and hope during the pandemic. Recent evidence suggests that a crucial aspect of family resilience in response to the Covid-19 pandemic would indeed be the optimization of a system of family beliefs that help the individuals in providing a framework of understating events related to the pandemic (Prime et al., 2020). Accompanying policies to help parents and families during these times of uncertainty will be crucial to identify vulnerability of some households, in order to work to promote paths toward greater capacity for resilience (Prime et al., 2020).

Turning to the regression analyses on children's internalizing symptoms (as rated by their parents), they primarily highlighted the high and positive predictive value of parents' current internalizing problems. Children were then evaluated as more depressed and with more symptoms of somatic complaints as their parents had no or little fear of contagion. In other words, the more afraid they were of the infection, the lower the depression and somatic complaints symptoms attributed to their children. These data confirm previously described associations between children and parents' psychopathological symptoms including depression (e.g., Sellers et al., 2013; Yap et al., 2014). Thus, parents' experience of symptoms of anxiety and depression during the health emergency was associated with the tendency to attribute similar symptoms to children. Nevertheless, specific symptoms that have to do with the withdrawal, depression and somatization of children seem less recognized by parents having much fear of being infected by the new coronavirus. One hypothesis could be that these parents find themselves excessively involved, and eventually overwhelmed, in their concerns and fear that they could not recognize specific experiences of their children. It is known that being emotionally overwhelmed by situations can compromise the ability to judge oneself, others and events (e.g., Izard, 2002). It is interesting to note that the fear of contagion did not play a predictive role with regard to the anxiety of children that perhaps was more manifest and externalized and thus observable by parents.

In line with these arguments, the direct comparison between parents' reported Cov and Pre_Cov data as a function of the order with which each questionnaire was completed showed that participants tended to report a smaller difference between Cov and PreCov symptoms of anxiety and depression when they first assessed the latter and then the former symptoms. This may suggest that parents' report of PreCov anxiety and depression tended to be influenced by the current emergency condition in which participants found themselves while they had to, for the first time (at least in the context of our survey), reflect on their psychological well-being and that of their children.

Beyond these interpretations, it is worth noting that fear of contagion had a different predictive role when parents evaluated themselves with respect to their children, just as the "broadening of biased attention" factor that mediated parents' internalizing symptoms but not those attributed to children. These data confirm that the perception of a child's internal experience reported by the parent is founded in a relationship composed of many characteristics both of the child and of the parent, as well as being influenced by factors such as, for example, the purpose of the evaluation and the contingent conditions under which the parent has the opportunity to observe the child (Smith, 2007). It is therefore not surprising that the variables that help explaining parents' self-perception may diverge, at least in part, from those playing a role in the assessment of children.

The observed findings extend to middle childhood and to internalizing problems previous findings of researches on the psychological sequelae of the Covid-19 pandemic that showed, in children of 4 years of age, an interplay between mothers' reported difficulties in regulating their own emotions and those of their children in inhibitory self-control (Di Giorgio et al., 2020 PREPRINT). Yet related to Covid-19 outbreak, another study carried out on Italian parents of 2–14 years old children (mean age = 7 years) has recently shown that the impact of lockdown on children's emotional and behavioral problems was mediated by their parents' individual and dyadic stress: the higher the parents' individual and dyadic stress, the more psychological problems children had (Spinelli et al., 2020). A hypothesis was put forward by these authors that lockdown made more difficult for parents to be supportive for their children and this could contribute to the manifestation of their problems. In line with this, previous findings showed that higher levels of anxiety and depression among youth is associated with weaker support from parents (Yap et al., 2014) and that children's perception of being rejected or accepted by their caregivers is linked to their psychological well-being (Khaleque, 2015).

Taken together, our and previous data indicate the importance of organizing psychological support interventions aimed at families that take into consideration the mental health of parents, but which also take into account the reduced personal resources of the children to face the many changes imposed by the pandemic (Sprang and Silman, 2013). For example, in order to reduce the negative impact of the pandemic on children, it appears necessary to help parents communicate effectively with their children regarding the restrictions imposed by the health emergency (Dalton et al., 2020; Spinelli et al., 2020). Moreover, parents should also be helped so that they can in turn generate hope and instill security in their children as well as, more practically, know how to negotiate family rules, rituals, and routines in the new balance imposed by the pandemic (Prime et al., 2020).

The observed findings need to be interpreted bearing in mind some study limitations that may be addressed by future research. The first limitation concerns the absence of a direct assessment and observation of children and the sole use of self-report measures, which rely on participants' capabilities to evaluate themselves, as well as being susceptible to desirable responding, acquiescence, and possibly biased by semantic understanding of the scales (Schwarz, 1999). Moreover, particular caution should be given in the interpretation of retrospective questionnaires, collected during emergency periods, before people have been able to restore a sufficient sense of security that may allow them to "decenter" from the current situation, possibly regaining greater clarity and objectivity in the assessments. In our study it is worth noting that we found significant and positive correlations between parents' current level of post-traumatic stress symptoms (IES-R_Cov) and their current (HADS_Cov total score and CBCL_Cov total Internalizing score), but also past assessments (HADS_PreCov total score and CBCL_PreCov total Internalizing score; all Rho > 0.29, $p < 0.001$).

Second, we compared the mean scores obtained by our sample at the IES-R with non-national normative data. Third, our sample lived in northern and central Italy and these areas were among the most affected by the new coronavirus infections; therefore, we cannot assume that our findings can be generalized to the whole Italian national population. Also, our choice to limit the aims of the present investigation to internalizing problems can be extended in future studies to children's externalizing behaviors. Of importance, we need to consider that internalizing symptoms, and possibly to a lesser extent externalizing behaviors, attributed to children by parents may be underestimated by them, as suggested by previous research in samples of non-clinical children (Smith, 2007). It would also be important that future longitudinal studies extend the current findings in order to monitor parents and children's changes in mental health on the basis of the progress of the various phases of the current and any future global health emergencies.

A final issue concerns the limited scope of our analyses, which did not deepen the exploration of possible intervening mechanisms also due to the possibility that the retrospective data collected could have been influenced by the current emergency situation. Future studies using mediation analysis may shed light on the mechanisms underlying the observed relationships between variables, e.g., whether parents' behaviors during the lockdown had mediated the relationship between parents' mental health before and during the pandemic as well as their views of their children's psychological health. Determining the mechanisms that explain the increased rates of internalizing problems will inform the policies used to manage the pandemic to achieve a better balance between infection control and mitigation of negative psychosocial effects (Holmes et al., 2020).

In conclusion, in addition to showing a direct effect of the pandemic on the psychological health of parents and children, the

present results also give a series of important information on how parents perceive, and therefore influence, their children in this period of emergency. Our findings thus highlight the urgent need to provide parents with adequate support to take care of their own psychological wellbeing and to help their children coping with the direct and indirect effects of the pandemic.

Novel Coronavirus Outbreak and Career Development: A Narrative Approach Into the Meaning for Italian University Graduates

*Anna Parola**

Department of Humanities, University of Naples Federico II, Naples, Italy

Introduction: In times of economic crisis, the literature shows that young people have always been in the high-risk category. The COVID-19 outbreak and the consequence on the economic level have increased the sense of uncertainty and precariousness experienced by young people. The current scenario has forced young people at the school-to-work transition point to re-think their career plans. Although the difficulties of the school-to-work transition already lead to distress and mental health problems in young people, the slowdown imposed by the coronavirus could add up to these difficulties. The present study aimed to explore the process of career development and career planning in the coronavirus era. Twenty Italian university graduates were involved.

Methods: A quantitative measure was used to evaluate the affective (positive/negative) experience. A narrative prompt was used to understand the individual dimensions of career planning. Cluster analysis was carried out by an unsupervised ascendant hierarchical method to explore the themes of the narration.

Results: Italian young adults have tended to experience negative affects in the recent weeks of quarantine. The themes highlighted in the narratives showed that Italian young adults experience feelings of fear, uncertainty, and anxiety about the post-pandemic future.

Conclusion: The results appear as a starting point to re-think possible interventions for this group post-lockdown and post-pandemic.

Keywords: COVID-19, young adult, mental health, unemployment, school-to-work transition, narrative approach, cluster analysis

INTRODUCTION

The current coronavirus disease (COVID-19) has had a massive impact on the people in the world and on many dimensions of life. One of these concerns the economic fallout of the crisis on the people, young adults in particular. In times of economic and financial crisis, young people have always been in the category at risk. For example, after the 2008 economic crisis the NEET phenomenon (young not engaged in Education, Employment or Training) into EU-28 (EU NEET-rate, 28.8%, Eurostat, 2019) came to light. The latest report of the International Labor Organization (2020) highlights that young people represent the most vulnerable group when it comes to the social and economic impact of the virus pandemic. According to the International Labor Organization (2020), the COVID-19 economic crisis with its vast increases in

unemployment may result from significant exclusion of young people from the labor market.

Currently, the conditions imposed for the COVID-19 outbreak may increase the sense of uncertainty and precariousness experienced by young people.

The novel coronavirus has forced young people in school-to-transition points to re-think their career plans. From a theoretical point of view, individuals have an active role in the construction of their career paths. Consistent with life-span developmental psychology (Baltes et al., 1980; Lerner, 1982; Lerner and Tubman, 1991; Bates et al., 1998; Bynner and Parsons, 2002), career development constitutes a life-long process from childhood (e.g., Magnuson and Starr, 2000; Hartung et al., 2005, 2008; Watson and McMahon, 2008; Ferrari et al., 2015; Bakshi, 2017) through adolescence (e.g., Blustein, 1997; Skorikov and Vondrecek, 2007; Skorikov and Vondracek, 2011), adulthood (e.g., Lea and Leibowitz, 1992; Vondracek and Kawasaki, 1995), and old age (e.g., Bohlmann et al., 2018) affected by both personal and contextual factors.

Several studies have shown possible intrinsic dimensions (e.g., personality, Rossier, 2015; cognitive style, Rogers et al., 2008; goal-orientation, Grant and Dweck, 2003; career adaptability, Rottinghaus et al., 2005; Savickas and Porfeli, 2012; identity, Kunnen, 2013; personal interest, Lent et al., 2010; Nyamwange, 2016; self-efficacy, Howard et al., 2009; Fan et al., 2014; Guan et al., 2015; Hui and Lent, 2018), and extrinsic influences (social support, Seibert et al., 2001; Kracke, 2002; Wiesenberg and Aghakhani, 2007; peers, Steinberg et al., 1992; parents, Paa and McWhirter, 2000; Halpern, 2005; Greenhaus and Powell, 2006; Schultheiss, 2006; Marcionetti and Rossier, 2016; teachers and educators, Howard et al., 2009; Gokuladas, 2010; Cheung et al., 2013; Cheung and Arnold, 2014) that affect the career development process in life span. Moreover, other studies have highlighted that cultural aspects have an impact on career choices (Mau, 2000; Caldera et al., 2003; Wambu et al., 2017; Akosah-Twumasi et al., 2018; Hui and Lent, 2018; Tao et al., 2018).

Transversally, the context in which individuals construct their careers are changing over time. Therefore, different cohorts of adolescents will experience their career outcomes differently. Indeed, the construction of career plans follows changes in the environment. Several studies show that the context of youth transitions is critically important in determining their shape and their outcomes (Baltes et al., 1980; Bynner and Parsons, 2002; Bynner, 2012; Lerner and Tubman, 1991).

In this century characterized by uncertainty and instability of the labor market, employment insecurity, and fragmented career paths (Baruch and Bozionelos, 2011), the difficulties in school-to-work transition could lead to distress (Bjarnason and Sigurdardottir, 2003; Parola and Donsì, 2018, 2019; Fusco et al., 2019; Parola et al., 2019; Stea et al., 2019), anxiety, discouragement, and maladaptive behavior (Schwartz et al., 2005; Arnett, 2007; Reifman et al., 2007). Moreover, this condition could impact on mental health (McKee-Ryan et al., 2005; Paul and Moser, 2009; Parola and Donsì, 2018; Bartelink et al., 2019), quality of life (Forma et al., 2017; Kivijärvi et al., 2019), and life satisfaction (Santilli et al., 2017).

The COVID-19 pandemic could exacerbate the school-to-work transition and add further difficulties that concern the labor market, such as the economic crisis of companies, temporary closure of offices, and the blocking of new job hires. Along with this, the unpredictability of the future, post-COVID-19, must also be considered.

Furthermore, the recent psychological literature on COVID-19 showed that young people are the highest-risk category for mental illness (Cao et al., 2020; Huang and Zhao, 2020). Studies on the psychological impact of the coronavirus in China have shown a psychological effect as moderate-to-severe, and about one-third of the population reported moderate-to-severe anxiety (Wang et al., 2020). Few recent studies on the Italian context showed that young adults have experienced internalizing and externalizing health problems during quarantine (Parola et al., 2020). Alongside this, research on previous epidemics (i.e., SARS and MERS) showed a wide range of psychosocial impacts on people during outbreaks of infection, i.e., fear of falling sick, feelings of helplessness (Hall et al., 2008; Van Bortel et al., 2016) anxiety, post-traumatic stress symptoms, and anger (for a review, Brooks et al., 2020). Moreover, several studies have highlighted significant psychiatric morbidities in non-infected younger age during the SARS epidemic (Sim et al., 2010).

The community of vocational psychology has recently broken down the problem and launched a debate on the relationship between unemployment and/or unemployment risk and health in this coronavirus era (Blustein et al., 2020). As recommended by the authors, the need arises to give a voice to young people by focusing on their experiences through qualitative and quantitative research methods. It is urgent to explore the shifts in youths' sense of identity and their career aspirations, which may be dramatically affected by the crisis.

This study aims to understand the youth perception of how the pandemic could affect their work-transition. Therefore, the current study focuses on the construction of their career plans, the school-to-work transition, the future time perspective, and the health consequences in the coronavirus era. This is also an attempt to provide a contribution to developing psychological interventions that take into account the impacts of this situation on young people and their career plans. Indeed, counseling programs must always take into account changes in the context (Masdonati, 2019).

MATERIALS AND METHODS

Participants and Procedure

Twenty Italian university graduates took part in this study (M_{age} = 24.4, SD_{age} = 2.04; range 22–29). The sample included six males and fourteen females. Participants were Italians from a Southern region characterized by serious youth unemployment problems (28.8%, Istat, 2019). All students lived at parental homes in the data collection procedure.

Non-probability sampling was used. In line with the explorative nature of the study, and also with the complex current historical moment, the choice of non-probability sampling makes the design for collecting data more flexible. Non-probability

sampling techniques allow for drawing samples from a larger population without requiring a random selection. The specific characteristic of this sampling is the subjective judgments of the researchers that chose which units of the population to include (Henry, 1990; Tansey, 2007). Specifically, consistent with purposive sampling, young adults who would be reasonably likely to be moving into jobs were involved (Lincoln and Guba, 1985). The participants were recruited by asking guidance counselors and mentors of theses of the University of Naples Federico II.

Approval of the University Research Ethics Committee was obtained for collecting data. Due to COVID-19, students were enrolled online. Participants were informed about a complete guarantee of confidentiality and the voluntary nature of participation. Participants voluntarily accessed the online platform used for data collection. No time limit was handed out, giving freedom of expression to the participants. The respondents did not receive payment for their participation.

Measures

For this study, mixed methods were used. A quantitative measure in the form of self-report to evaluate affective experience (positive/negative) of young people in the COVID-19 pandemic, with qualitative ones, in the form of a narrative prompt to understand the subjective dimensions of career planning experience were used.

Positive and Negative Affect (PANAS; Watson et al., 1988; Terraciano et al., 2003): The instrument consists of 20 self-rating items corresponding to adjectives that describe different states, feelings, and emotional experiences linked to positive (PA; 10-items; e.g., "Excited," "Active") and negative affects (NA; 10 items; e.g., "Nervous," "Distressed"). Participants responded to each item on a 5-point Likert scale. Each rating seeks to measure the intensity of that specific feeling or emotion during a given timeframe for the participant from 1 (= *very slightly or not at all*) to 5 (= *extremely*). Simple amendments to the original instructions of the PANAS can be implemented to better address state fluctuations in PA and NA. In this study, participants were asked to rate their feelings "during the past few weeks."

Narrative Prompt (Pizzorno et al., 2014): The narrative method (McAdams et al., 2001) was chosen to collect the career stories of participants. The narrative written prompt was designed following Pizzorno and colleagues (2014). Individuals were asked to create their career stories, recall the past, analyze the present, and anticipate the future. The questions addressed were: "Where are you in your life, and how have you arrived there? Start from whatever point you like. Were there any turning points in this story? On these occasions, what choices did you make, what difficulties did you encounter, how did you take things forward? What are your projects for the future? Now that you have told me your story, do you think the current moment could influence the realization of your plans?"

Data Analysis

In the first step, preliminary analysis (means and standard deviations) on the quantitative data were carried out. Following Margherita and Tessitore (2019), the results of quantitative measures were used as an illustrative variable in the analysis of the interviews. Specifically, the results obtained by PANAS were dichotomized (PA and NA) according to the tendency of positive or negative affectivity of the participant and used as descriptive variables during the analysis of the interviews.

In the second step, the corpus of autobiographical narration was analyzed from data analyses of textual data (Lebart and Salem, 1994; Lebart et al., 1998) using the T-Lab software. The tools are the ones most used in health psychology (for a review, Mazzoni et al., 2018). The corpus was previously handled by customizing the dictionary through (a) lemmatization and (b) disambiguation of words. Lemmatization is the reduction of corpus words to their respective lemma. According to the linguistic issue, the entry corresponds to a lemma that defines a set of words with the same lexeme and the same grammatical category. The disambiguation allows for distinguishing the significant meanings among the different forms, i.e., the same graphic form but different meanings. Firstly, preliminary analysis of lexical richness were performed. Then, a cluster analysis (CA) through thematic analysis of elementary context was carried out by an unsupervised ascendant hierarchical method (bisecting K-means algorithm) characterized by the co-occurrence of semantic features (Karypis et al., 2000; Savaresi and Boley, 2001). The unsupervised clustering consists of the (a) construction of a data table context units x lexical units, (b) TF-IDF normalization and scaling of row vectors to unit length according to the Euclidean norm; (c) clustering through the method bisecting K-means and the measure of cosine coefficient; and (d) choice of the obtained partition and construction of a contingency table lexical units x clusters, χ^2 test, and correspondence analysis. In this phase, the dendogram allows us to check the tree structure of the various bisections and the characteristic words of each cluster.

The tool segments narratives into elementary context units (e.c.u.) classified according to the distributions of their lemmas in terms of co-occurrences. For this study, in line with the literature (Bolasco, 1999), to guarantee the reliability of statistical computations, a minimum frequency threshold to select lemmas was set at 3. Each thematic cluster, determined by an algorithm that uses the relationship between intercluster variance and total variance, and it takes as optimal partition the one in which this relationship exceeds the threshold of 50%, consisted of a set of keywords, which were ranked according to the decreasing value of chi-square.

Through cluster analysis, it was possible to construct and explore the contents of the narrations and allows them to map the specific topics of participants (Lancia, 2004, 2008). The clustering procedures allow for a better understanding of youth discussion topics (Santelli et al., 2018; De Stefano and Santelli, 2019; Felaco and Parola, 2020). Finally, the clusters and the illustrative variables in a factorial plane graphically showed the relationship between clusters and variables. Gender and PA/NA variables were used as illustrative variables.

RESULTS

The preliminary analysis of PANAS showed that the NA dimension was higher than the PA dimension (M_{NA} = 3.30,

SD_{NA} = 0.81; M_{PA} = 2.95, SD_{PA} = 0.64). The propensity of PA or NA dimensions showed that 65% of young people (n = 13) had experienced more negative affectivity in recent weeks, while 35% of young people (n = 7) more positive affectivity. These results were used as an illustrative variable in the analysis of the interviews.

The preliminary analysis of textual data showed that the corpus was constituted of 20 elementary contexts (e.c.), 754 lemmas, 6,249 tokens, and 744 types. In line with the propensity of PA or NA dimensions, the indexes of lexical richness showed 38.40% of the textual corpus contained the POS narrations and 61.60% of the NEG narrations.

The thematic analysis of elementary contexts produced 4 clusters (**Figure 1** and **Table 1**), named "Lack of Future" (10%, 2 e.c.), "Future Planning" (10%; 2 e.c.), "Career Paths" (10%; 2 e.c.), and "Dark Future" (70%; 16 e.c.).

The first cluster, "Lack of Future," included lemmas that refer to an uncertain future vision (lemmas "uncertainty," "insecurity"). The lemmas "instrument," "impotence," and "stop" described the impasse in which young people have found themselves, without those "instruments" to deal with the current situation. In addition to it, this condition impacts the mood and sense of loneliness felt (lemmas "mood," "loneliness").

Examples of e.c.u.:

"The heaviest thing in this condition is to have no security and feeling like every moment you have to question yourself, without having any instrument."

"The uncertainty of the future right now is the frequent feeling that I happen to be ridden with."

"Stuck at home, all I do is feel restless. Unfortunately, all we can do is surrender to the evidence of a future that we cannot build because it has been taken from us."

The second cluster, "Future Planning" described the future projects and aspirations of young people (lemmas "realization," "dreams," "plans") that are entwined to a desire for "normality," "opportunity," and "positivity."

Examples of e.c.u.:

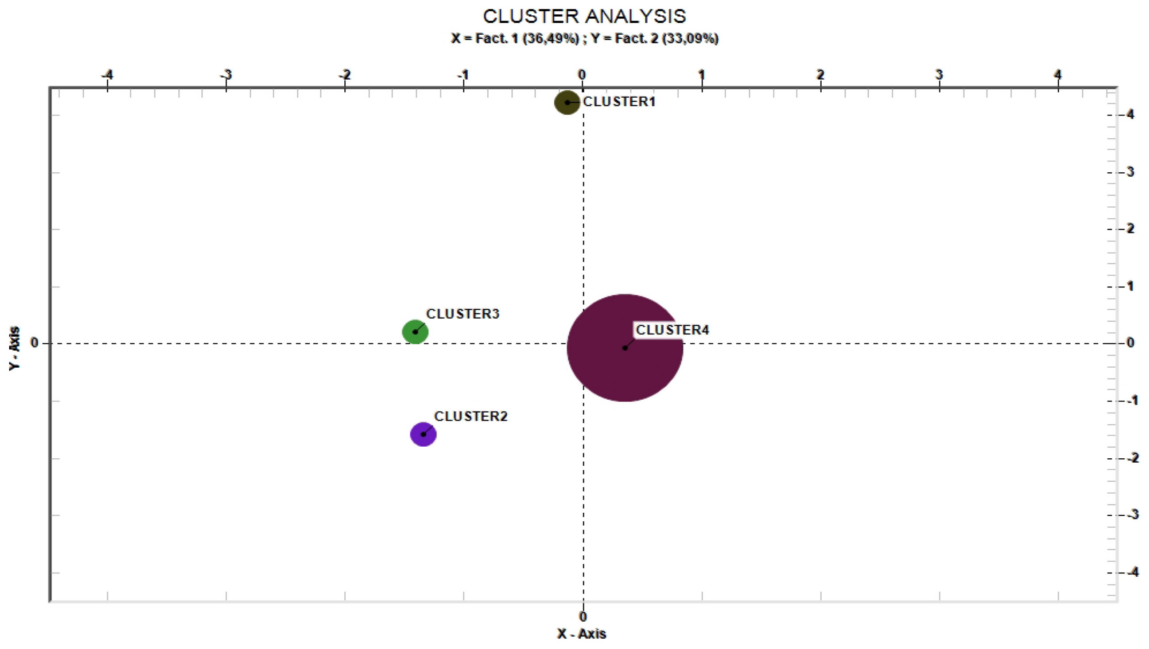
"I am worried about my plans given the situation we are experiencing nowadays, but I try to be positive thinking that everything will soon return to normal, and I will be able to carry out my plans."

"We will get back to normality and achieve what we have fought for in these years."

The third cluster "Career Paths" offered a reflection on the transition to the labor market. This cluster described the choices that these individuals had to make in building their careers (lemmas "degree," "studying"), also analyzing the "skills" acquired during their paths. It took into account how these skills could enhance a transition to the labor market. Moreover, the family dimension was considered (lemma "parents") as support in the career construction process.

Examples of e.c.u.:

"I just graduated. Studying is a revelation for me, although many times, I asked myself if I was attending the right faculty. The degree, however, allowed me to acquire the proper knowledge and skills to be able to work in the area that I have chosen for myself."



Note. Cluster 1 = Lack of Future (10%); Cluster 2 = Future Planning (10%); Cluster 3 = Career Paths (10%); Cluster 4 = Dark Future (70%).

FIGURE 1 | Cluster analysis. Cluster 1, Lack of Future (10%); Cluster 2, Future Planning (10%); Cluster 3, Career Paths (10%); Cluster 4, Dark Future (70%).

TABLE 1 | Clusters, associated lemmas, χ^2 values, and significance.

Clusters	Lemmas
Cluster 1 Lack of Future (10%)	Right now ($\chi^2 = 99.491$; $p < 0.001$); Heavy ($\chi^2 = 99.491$; $p < 0.001$); Instrument ($\chi^2 = 90.676$; $p < 0.001$); Uncertainty ($\chi^2 = 58.595$; $p < 0.001$); Insecurity ($\chi^2 = 48.847$; $p < 0.001$); Feeling ($\chi^2 = 42.574$; $p < 0.001$); Restlessness ($\chi^2 = 42.549$; $p < 0.001$); Resignation ($\chi^2 = 41.481$; $p < 0.001$); Stop ($\chi^2 = 32.787$; $p < 0.001$); Loneliness ($\chi^2 = 30.307$; $p < 0.001$); Impotence ($\chi^2 = 22.012$; $p < 0.001$); Mood ($\chi^2 = 20.012$; $p < 0.001$)
Cluster 2 Future Planning (10%)	Normality ($\chi^2 = 142.937$; $p < 0.001$); Opportunity ($\chi^2 = 37.787$; $p < 0.001$); Positive ($\chi^2 = 29.013$; $p < 0.001$); Realization ($\chi^2 = 16.685$; $p < 0.001$); Plans ($\chi^2 = 13.685$; $p < 0.001$); Degree ($\chi^2 = 10.286$; $p < 0.001$); Thinking ($\chi^2 = 9.935$; $p = 0.002$); Projects ($\chi^2 = 7.474$; $p = 0.006$); Dreams ($\chi^2 = 4.489$; $p = 0.034$); Living ($\chi^2 = 4.489$; $p = 0.034$)
Cluster 3 Career Paths (10%)	Faculty ($\chi^2 = 46.910$ $p < 0.001$); Collocation ($\chi^2 = 31.218$; $p < 0.001$); Choice ($\chi^2 = 16.182$; $p < 0.001$); Studying ($\chi^2 = 16.182$; $p < 0.001$); Obtaining ($\chi^2 = 7.474$; $p = 0.006$); Skills ($\chi^2 = 5.084$; $p = 0.024$); Interests ($\chi^2 = 5.084$; $p = 0.024$); Labor market ($\chi^2 = 5.084$; $p = 0.024$); Family ($\chi^2 = 5.064$; $p = 0.024$)
Cluster 4 Dark Future (70%)	COVID Spread ($\chi^2 = 99.491$; $p < 0.001$); Dark Future ($\chi^2 = 99.491$; $p < 0.001$); Anxious ($\chi^2 = 42.549$; $p < 0.001$); Opportunity ($\chi^2 = 29.013$; $p < 0.001$); Epidemic ($\chi^2 = 22.012$; $p < 0.001$); Reaching ($\chi^2 = 10.248$; $p < 0.001$); Slowing down ($\chi^2 = 5.084$; $p = 0.024$); Difficult ($\chi^2 = 5.069$; $p = 0.024$); See myself ($\chi^2 = 4.217$; $p = 0.024$); Life ($\chi^2 = 4.217$; $p = 0.024$)

"The instrumental support of my family, but also the emotional one, allowed me to carry on my choices, graduate, and get to where I am now."

The fourth cluster "Dark Future" presented the impact of COVID on the future, which, according to young people, has slowed down the transition to the labor market (lemma "slowdown"). The transition becomes even more "difficult" and the future "darker." Then, in this cluster lemmas that refer to the health condition of young people emerged. Young people described distress in situations and anxiety. The presence in this cluster of the lemmas "COVID Spread" could inform on the fact that young people consider the economic consequences of the coronavirus on their future as workers.

Examples of e.c.u.:

"I am anxious about the future and seeing how the situation will be after the crisis."

"Once we overcome COVID-19, what future will be there for us young people in the labor market?"

"The long-term effects of COVID-19 will be worse than those of the economic crisis that we are experiencing in recent years. We, young people, are always the ones who will pay the consequences."

"Before the pandemic, I started looking for work, I even had it, a real job, of those with a proper contract. Then everything stopped, they told me they don't know if they can hire me. They will let me know. Yes, but when? We really didn't need this pandemic."

"It is a very difficult period to manage emotionally. The pandemic is slowing down my plans. I can't see after the quarantine; I can't understand what will happen. I don't think the epidemic will make me change my personal and professional life plans, but it has certainly made their realization more difficult."

"This period of the pandemic has fueled even more of my fear of not being able to fulfill myself because with the economic crisis we are living with, and we will live with in the future. I believe that the working world can offer me, as well as everyone, even fewer opportunities."

"I am anxious about the future and seeing what the situation will be after the crisis."

The relationship between the clusters and gender variables showed that the elementary contexts associated with the female modality were present in the third cluster (15.38%) and the fourth cluster (69.23%); while the elementary contexts related to the male modality were present in cluster one (28.57%) and cluster four (71.43%).

The relationship between the cluster and the affected variables showed that the elementary contexts associated with the POS modality were present in cluster two (71.43%) and cluster three (28.58%); while the elementary contexts associated with NEG were present in cluster one (15.38%), cluster three (15.38%), and cluster four (69.23%).

DISCUSSION

The present study aimed to understand the experiences of the career planning of young people in the coronavirus era.

The quantitative data illustrated the current affect dimensions of young adults. Results showed that Italian young adults tended to experience negative affects in the recent weeks of quarantine. This evidence is in line with several studies that show the impact of epidemics on mental health (Brooks et al., 2020), and also with some studies that indicated higher levels of anxiety, distress, and depression in a young adults' sample (Cao et al., 2020; Huang and Zhao, 2020). Young people can represent a high-risk category for mental illness, and this was also confirmed by recent Italian studies (Parola et al., 2020; Rossi A. et al., 2020).

The quarantine condition has imposed significant limitations, forcing young people to stay at home with their parents, limiting sports activities, and the avoidance of any contact with friends with whom they regularly experience moments of conviviality at a young age (Benedetto et al., 2018); it has allowed online relationships as the only opportunity (Faccio et al., 2019; Boursier et al., 2020). The condition of inactivity and the mandated social distance have probably triggered a state of discomfort, distress, and loneliness among young people (Rossi et al., submitted).

The participants of this study were representatives of a section of young Italians. They had completed their university studies with the achievement of their degree shortly before the lockdown period. For the young people in the school-to-work transition phase, quarantine has also imposed a limitation on the time horizon, forcing aspirations and plans for the future to be blocked. This scenario has occurred at a time of difficulty for young people in the transition from school to the labor market, which already represents a risk factor for mental health

(McKee-Ryan et al., 2005; Paul and Moser, 2009), specifically in the Italian context (Parola and Donsì, 2018).

The analysis of the narrative data showed how young people are stuck in the present time, almost suspended, aware of their skills given by the years of training and university courses, but without knowing how and where to direct their strengths. Young people described distress, feelings of discomfort, and helplessness in uncertain situations in which they have no control. Results showed that young Italian adults experience psychological problems, feelings of impotence, restlessness, but also anxiety. Furthermore, these young people felt damaged by the pandemic's potential economic fallout. These findings were strongly shown in cluster 4, which contained 70% of the youth narratives. Moreover, this cluster grouped elementary content units of young people that have experienced more negative affectivity in the weeks before the administration.

The results appear as a starting point to re-think possible interventions for this risk-group. The need for preventive interventions to support career paths during this moment of emergency seems urgent. In this sense, the narrative fosters a mediation between young people and experience (Tessitore and Margherita, 2019, 2020; Felaco and Parola, 2020; Parola and Felaco, 2020). Following Blustein et al. (2020), counseling programs must take into account the difficulties that young people will encounter in the school-to-work transition after the pandemic. Interventions must be aimed at supporting the daunting challenge of this transition and recovering from the psychological and vocational fallout of this pandemic. Even more, interventions should guarantee a positive orientation toward future vision promoting hope and optimism (Ginevra et al., 2018; Santelli et al., 2018) and enhancing the development of effective coping strategies (i.e., career adaptabilities, Savickas, 1997).

Alongside this, interventions that facilitate help-seeking for young people and improve their well-being would be desirable. The risk is that young people, even after the lockdown implementation, will find themselves even more lost in career construction. Recent studies showed that a large number of young people avoid seeking psychological help (Sareen et al., 2007; Mannarini et al., 2017a, 2018, 2020; Mannarini and Rossi, 2019; Rossi and Mannarini, 2019; Rossi Ferrario et al., 2019; Rossi Ferrario and Panzeri, 2020). In this sense, guidance and counseling activities located in universities could play a central role in supporting young people in the recovery after the pandemic. Furthermore, the request for a clinical setting becomes urgent in situations of profound fear and anxiety (Sommantico et al., 2017; Merlo, 2019a,b; Settineri et al., 2019).

The present study is not free from limitations. First of all, the bias of the non-probability sampling techniques (e.g., the selection bias) that although allows the researcher to control the selection process severely limits the generalization of the results (Flick, 2011). Secondly, the small group of participants should be increased to make more generalizable results. Although the literature on qualitative research does not indicate the determination of sample size, several studies recommend a range of 20–30 interviews for grounded research and 15–30 interviews for case studies (Marshall et al., 2013). According to the general guideline of qualitative research (Boddy, 2016) in this study the sample-size depended to the scope of the study and nature of the topic (Morse, 2000), the contact time to be spent on each research participant for career interviews (Marshall et al., 2013), and the homogeneity of the population under consideration (Trotter, 2012). Furthermore, the sample was only composed of graduates who came from the Campania region in Southern Italy. Therefore, the sample is not representative of the Italian population. Results need to be replicated in other geographical areas (northern and southern region) to provide more robust data and determine their generalizability. Thirdly, the sample is not gender-balanced, and the discussion section did not concern the gender variables. Further studies with balanced samples are needed to determine gender influence over the thematic clusters that emerged. Moreover, the study does not take into account some dimensions that could be useful for a better understanding of young experiences. Future investigations can be oriented to investigate the role of social support (Ratti et al., 2017), specifically the parental support (Balottin et al., 2017; Manna and Boursier, 2018) and love relationships (Mannarini et al., 2013, 2017b; Margherita et al., 2018).

Despite the limitations, this study contributes new knowledge about young adults' perception of school-to-work transition in this historical moment. The current findings have several conceptual and practical implications that highlight the importance of providing tangible support to the transition from university to the world of work during this crisis. Moreover, from a methodological point of view, the study confirms the importance of the joint use of qualitative and quantitative methods in psychology. Using both a quantitative method and a narrative prompt yielded more in-depth information than either method alone would have yielded. The mixed methods have allowed, on the one hand, to quantitatively figure out the positive/negative affects related to the coronavirus through using the validated instrument; and, on the other hand, to understand the meaning given to the career paths and how coronavirus could impact on their school-to-work transition in depth, through the use of a narrative prompt.

DATA AVAILABILITY STATEMENT

The datasets presented in this article are not readily available because to ensure the privacy of the participants. Requests to access the datasets should be directed to Anna Parola.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Local Ethical Committee for research in Psychology of University of Naples Federico II. The patients/participants provided their written informed consent to participate in this study.

Inoculating Against Fake News About COVID-19

Sander van der Linden[1], Jon Roozenbeek[1] and Josh Compton[2]*

[1] Cambridge Social Decision-Making Laboratory, Department of Psychology, School of Biology, University of Cambridge, Cambridge, United Kingdom, [2] Institute for Writing and Rhetoric, Dartmouth College, Hanover, NH, United States

The outbreak of the SARS-CoV-2 novel coronavirus (COVID-19) has been accompanied by a large amount of misleading and false information about the virus, especially on social media. In this article, we explore the coronavirus "infodemic" and how behavioral scientists may seek to address this problem. We detail the scope of the problem and discuss the negative influence that COVID-19 misinformation can have on the widespread adoption of health protective behaviors in the population. In response, we explore how insights from the behavioral sciences can be leveraged to manage an effective societal response to curb the spread of misinformation about the virus. In particular, we discuss the theory of psychological inoculation (or *prebunking*) as an efficient vehicle for conferring large-scale psychological resistance against fake news.

Keywords: COVID-19, fake news, misinformation, inoculation, infodemic

INTRODUCTION

The emergence of the novel coronavirus (SARS-CoV-2) in December of 2019 has quickly led to a global pandemic claiming hundreds of thousands of deaths worldwide already (Roser et al., 2020). In the absence of an effective treatment or vaccine, researchers have pointed out that managing the pandemic response will require leveraging insights from the social and behavioral sciences, particularly with regard to non-pharmaceutical interventions and containing the spread of misinformation about COVID-19 (Depoux et al., 2020; Habersaat et al., 2020; Van Bavel et al., 2020). In fact, the spread of misleading information about the virus has led the World Health Organization (WHO) to warn of an on-going "infodemic" or an overabundance of information—especially misinformation—during an epidemic (World Health Organization, 2020b; Zarocostas, 2020). This makes it harder for people to find trustworthy and reliable information when they need it. In this article, we ask three critical questions to help better inform societal response to the infodemic, namely; (1) what is the scope and reach of misinformation about COVID-19 in the general population, (2) what evidence is there to suggest that misinformation about the virus is undermining public support for—and the adoption of— preventative health behaviors; and (3) how can insights from psychology be leveraged to effectively manage societal response to help limit the spread of influential misinformation? In particular, in order to "immunize" people against the misinformation virus we draw on the theory of psychological inoculation and its real-world application.

MISINFORMATION ABOUT COVID-19

Misinformation about COVID-19 has proliferated widely on social media, ranging from the peddling of fake "cures," such as gargling with lemon or salt water and injecting yourself with bleach

(World Health Organization, 2020a), to false conspiracy theories that the virus was bioengineered in a lab in Wuhan (Andersen et al., 2020; Cohen, 2020), or that the 5G cellular network is causing or exacerbating symptoms of COVID-19 (BBC News, 2020). The conspiracy film "*Plandemic*" appeared online on May 4th of 2020, garnering millions of views and quickly becoming one of the most widespread examples of coronavirus-related misinformation (Cook et al., 2020). The video promotes dangerous health advice, for example, falsely suggesting that wearing a mask actually "activates" the coronavirus. Fake news about the virus has also been actively promoted by political elites, such as President Trump and Brazilian President Jair Bolsonaro, who falsely claimed that hydroxychloroquine is "working in all places" as a treatment against the virus (Constine, 2020). But misinformation about COVID-19 is not limited to information that is blatantly true or false, which widens the scope of the problem. For example, although the harms and benefits of hydroxychloroquine as a potential treatment are indeed being studied, there is currently no scientific consensus on its effectiveness (Geleris et al., 2020; Meyerowitz et al., 2020). Thus, even deciding what counts as misinformation about COVID-19 is a complicated matter, as insights into the causes of and treatments for the virus develop over time. Nonetheless, it is becoming increasingly clear that misinformation about COVID-19 is a common problem. For example, a poll by Ofcom in the United Kingdom found that almost half (46%) of the United Kingdom population reported exposure to fake news about the coronavirus (Ofcom, 2020). Similar results (48%) have been reported by Pew in the United States (Mitchell and Oliphant, 2020). In particular, amongst those exposed, nearly two-thirds (66%) reported seeing it on a daily basis, which is problematic as repeated exposure is known to increase belief in fake news (Pennycook et al., 2018). Although mass endorsement of conspiracy theories about the virus is not yet widespread, substantial minorities (typically about a third of the sample) in the United Kingdom and the United States report to believe that the virus is either manmade or produced on purpose by powerful organizations (Freeman et al., 2020; Roozenbeek et al., 2020b; Uscinski et al., 2020). Indeed, a YouGov survey found that about 28% of Americans and 50% of Fox News viewers think that Bill Gates is planning to use the COVID-19 vaccine to implement microchips in people (Sanders, 2020). Moreover, a recent analysis of the most viewed coronavirus YouTube videos found that over 25% of the top videos about the virus contained misleading information, reaching over 62 million views worldwide (Li et al., 2020).

HOW IS THE SPREAD OF MISINFORMATION HARMING SOCIETAL RESPONSE TO THE PANDEMIC?

Another emerging insight is that COVID-19 conspiracies and rampant misinformation can adversely impact the effectiveness of containment strategies. Indeed, misinformation about COVID-19 can fundamentally distort people's risk perception of the virus (Krause et al., 2020). This is important as risk perception has been linked to the adoption of COVID-19 preventative health behaviors (Dryhurst et al., 2020). A recent study by Uscinski et al. (2020) found that belief in conspiracies about the virus is associated with a propensity to reject information from expert authorities. Similar findings were reported by Freeman et al. (2020), who also noted a link between belief in COVID-19 conspiracies and an increase in vaccine hesitancy. For example, people who endorsed the conspiracy that the virus is bioengineered were less likely to report compliance with public health guidelines (e.g., staying at home) and were less likely to report to accept a COVID-19 vaccine (see also Imhoff and Lamberty, 2020). These effects are problematic because at present polls show that only 50% of Americans are willing to get a potential vaccine if one becomes available, which undermines the potential for herd immunity against the coronavirus (Cornwall, 2020). Importantly, misinformation about the virus has been shown to have other serious societal consequences as well. Recent reports have indicated that coronavirus misinformation has been linked to mob attacks, mass poisonings (Depoux et al., 2020), and acts of vandalism (Spring, 2020). In the United Kingdom alone, people have set fire to least 50 phone masts in response to the 5G conspiracy (BBC News, 2020) and research finds that belief in the 5G conspiracy is linked to violent intentions (Jolley and Paterson, 2020). In addition, an analysis of over 60 million geo-coded cell phones found reduced social distancing in pro-government areas after Brazil's president inaccurately portrayed the risks of COVID-19 (Ajzenman et al., 2020). Similar analyses have been conducted in the United States in response to political polarization over COVID-19 preventative health behaviors (Allcott et al., 2020), highlighting the disruptive potential of high-profile misinformation for both individual and societal well-being.

LEVERAGING INSIGHTS FROM PSYCHOLOGY: INOCULATING AGAINST COVID-19 MISINFORMATION

So far, little attention has been paid to insights from the social and behavioral sciences to combat misinformation about COVID-19, despite the ample availability of research to draw from Van Bavel et al. (2020). One insight that has emerged is that fact-checks tend to spread slower on social media than misinformation (Vosoughi et al., 2018), making it difficult for fact-checking to be effective on its own. A review by *Politico*, for example, found that Facebook's fact-checking efforts did little to prevent coronavirus conspiracies from being shared widely in private groups on the platform (Scott, 2020). Further complications arise from the "continued influence effect" of misinformation, which states that people may continue to believe misinformation even after it has been debunked (Ecker et al., 2010; Lewandowsky et al., 2012). In addition, while media literacy initiatives are important and can be effective under the right conditions (Bode and Vraga, 2015; Guess et al., 2020; Van Bavel et al., 2020), they are often expensive to develop, slow to roll out, and *reactive* rather than *proactive*.

In particular, given the practical challenges of fact-checking and the difficulty of correcting misinformation after the damage

is already done, researchers have started to explore *prebunking* (i.e., preemptive debunking). Because misinformation spreads through networks much like a real virus "infecting its host" and rapidly transmitting falsehoods from one mind to another, the natural antidote is a psychological vaccine against fake news (van der Linden and Roozenbeek, 2020).

Inoculation Theory

The theory of psychological inoculation takes the historic practice of vaccination in medicine into the realm of resistance to persuasion (McGuire, 1964). In a medical inoculation, a virus is weakened to the point where it will not make the person sick, but it will trigger protective responses, like antibodies. In a persuasion inoculation, a strong challenge (e.g., a conspiracy theory) is weakened to the point where it will not change the person's position—the person's healthy state—but it will trigger protective responses, like enhanced critical thinking (McGuire, 1964; Compton, 2013). In both contexts, a similar process is at work: exposure to weakened challenges leads to resistance to stronger challenges. In psychological inoculation, the weakened challenge often consists of two elements (Compton, 2013), namely; (a) a forewarning of a threat or attack on one's attitudes and (b) a preemptive refutation of counter-arguments (or prebunking). Preemptive refutation of misinformation weakens the misinformation, just as a medical vaccine is often comprised of weakened virus. For example, in a study on misinformation about climate change, participants were (a) forewarned that some political actors try to mislead people on the issue and (b) provided with facts and arguments to refute the misinformation—preemptively—that is, before they were exposed to a full dose of misinformation later on (van der Linden et al., 2017). The study found that the inoculation partially immunized people against climate misinformation (see also Maertens et al., 2020a).

A number of things happen during the inoculation process of resistance to influence. One of the most important is threat—the motivation to engage in resistance. In inoculation research, threat is a response to vulnerability (McGuire, 1964; Compton, 2013)—for example, when a preemptive inoculation message raises and refutes a persuasive attack (e.g., Banas and Richards, 2017), or when an inoculation message exposes reasoning fallacies (Cook et al., 2017). The cognitive and affective processes unleashed by threat are varied and powerful, including increased counterarguing (Pfau et al., 2006), increased attitude accessibility (Pfau et al., 2003), less psychological reactance against the inoculation-informed campaign (Richards and Banas, 2015), and more psychological reactance against attack messages (Miller et al., 2013). For conventional, *prophylactic* inoculation to take hold, the desired position needs to already be in place—a healthy state (Compton, 2013). This is the classic approach of inoculation theory. In the context of the coronavirus, this would imply protecting the attitudes of those people who are already following public health guidelines. Strengthening their attitudinal defenses will decrease the potency of misinformation attacks. However, a more recent approach within inoculation theory expands its efficacy to also include a *therapeutic* application—inoculation treatments that target an unhealthy state (Compton, 2020). New work in this latter area expands inoculation theory's reach by inoculating audiences who have already been "afflicted" with the informational virus. Therapeutic inoculation works by boosting immune defenses and decreasing the probability that people will spread the virus. For example, people with skeptical attitudes toward climate science can still benefit from inoculation against misinformation in the sense that they generate stronger attitudes toward the scientific consensus (Cook et al., 2017; van der Linden et al., 2017).

The health domain boasts a particularly strong record for inoculation theory—appropriately enough in the context of COVID-19. Much of this work has looked at how inoculation theory-informed public health messages could help shore up resistance to unhealthy pressures, like smoking cigarettes (Pfau et al., 1992) or binge drinking (Parker et al., 2010). More recently, inoculation work has explored ways of enhancing beneficial health behaviors, like committing to exercise programs (Dimmock et al., 2016) or strengthening vaccination intentions (Wong and Harrison, 2014), especially in response to conspiracy theories (Jolley and Douglas, 2017). For example, vaccination intentions only improved when participants were presented with anti-conspiracy arguments *prior* to exposure to the vaccination conspiracy theories but not when presented with counter arguments afterward.

Actively Inoculating Against Misinformation

Two further advances have been proposed in inoculation research that hold promise for the scalability and broad applicability of inoculation interventions, particularly in the context of misinformation: a renewed focus on active inoculations (McGuire and Papageorgis, 1961; Roozenbeek and van der Linden, 2018), and a shift in attention from inoculating against individual examples of unwanted persuasion (e.g., climate change or vaccination) to the manipulation *techniques* that underpin most fake news such as using emotional language (Brady et al., 2017), conspiratorial reasoning (Lewandowsky et al., 2013; van der Linden, 2015) or impersonating experts online (Goga et al., 2015). The idea behind active inoculation is to let people generate their own "antibodies." A practical application of active inoculation theory is the award-winning online browser game *Bad News*.[1] The game offers a simulated social media environment in which people take on the role of a fake news creator and learn about six common misinformation techniques over the course of six levels, or "badges" (for a detailed theoretical overview see Roozenbeek and van der Linden, 2019; van der Linden and Roozenbeek, 2020). The inoculation component in the game consists of a combination of (a) warnings about fake news and (b) pre-exposure to weakened doses of the techniques used in the production of fake news. Both processes can potentially increase the inoculation effect by facilitating retention in memory for longer periods of time (Pfau et al., 1997, 2005). Research has shown that *Bad News* significantly improves players' ability to resist misinformation techniques after gameplay, and increase players' confidence in

[1] www.getbadnews.com

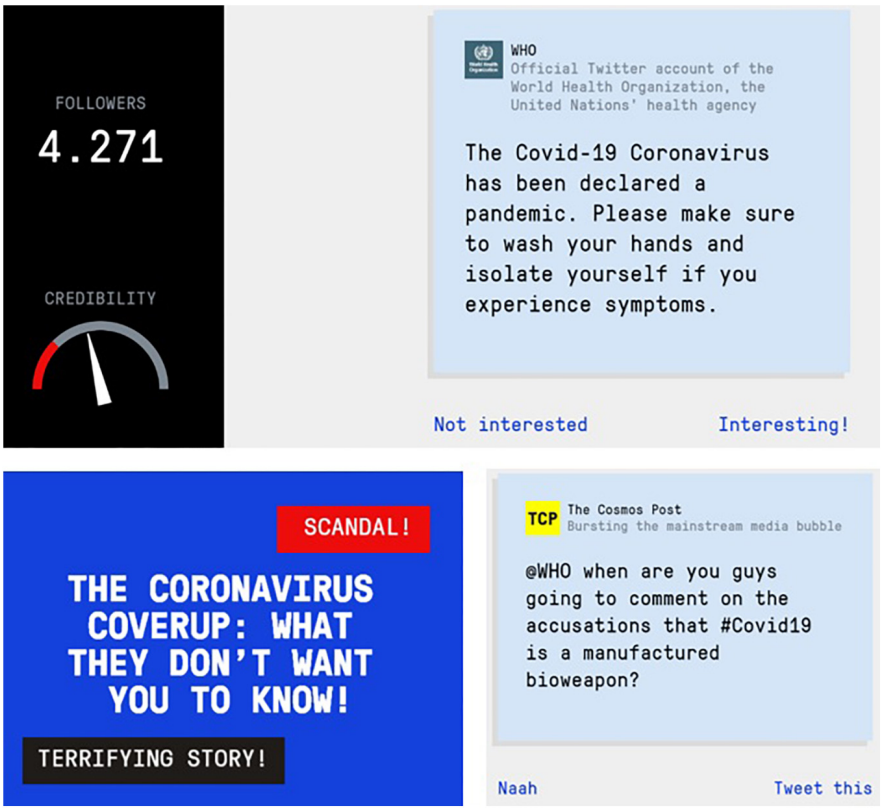

FIGURE 1 | Screenshots from the *Bad News* game about coronavirus (www.getbadnews.com). Images and links reproduced with permission from *Bad News*.

spotting misleading information (Basol et al., 2020). In addition, in collaboration with the United Kingdom Foreign Office, the game has been translated internationally and its effectiveness as an inoculation intervention has been replicated across five different language versions (Roozenbeek et al., 2020c). The inoculation effect itself can last for months (Pfau and Bockern, 1994), including with regular "top-ups" or "booster shots" following gameplay (Maertens et al., 2020b). In response to the outbreak of the coronavirus pandemic, we altered the *Bad News* game's "conspiracy" scenario to feature weakened doses of conspiracies about the virus. **Figure 1** shows a number of screenshots from the game. Players are tasked with inventing and spreading a fake conspiracy theory about COVID-19, and learn about the negative consequences of their actions in the form of replies by social media users in their network, thus exposing how misinformation is created, spread and shared.

The relatively easy adaptation of the *Bad News* game to immunize people against misinformation specifically about the COVID-19 pandemic highlights the potential to translate theoretical laboratory findings into scalable real-world inoculation interventions: the game is played by about a million people worldwide (Roozenbeek et al., 2020c), thus "inoculating" a large number of people who voluntarily navigate to the *Bad News* website. Importantly, it is not necessary for every single individual to receive the "vaccine": if enough people have developed antibodies against the techniques used to spread misinformation about COVID-19, in theory, societal herd immunity could be achieved.

CONCLUSION

Prevention is better than cure. This is true as much for diseases as it is for the spread of misinformation. Although the *Bad News* game is a useful tool, more work is needed to curb the spread of misinformation about COVID-19, including a multi-layered defense system against "post-truth" science denial (van der Linden, 2019) which will include effective debunking and real-time rebuttal in addition to inoculation (Schmid and Betsch, 2019). A practical application of inoculation theory in the context of COVID-19 misinformation is the new online game, *Go Viral!*,[2] developed in collaboration with the United Kingdom government and the WHO in which players learn to resist three manipulation techniques commonly used to spread misinformation about the coronavirus: fearmongering, the use of fake experts, and conspiracy theories. An open question in active inoculation research is the extent to which inoculation can boost *truth-discernment* skills, that is, not just the ability to spot and resist misinformation attacks but also the ability to better identify real or credible news (Guess et al., 2020; Roozenbeek et al., 2020a). Compton et al. (2016)

called for more "work that pushes forward our understanding of persuasion and has applied value as a health messaging strategy to help combat serious threats to healthy living" (p. 1). Promoting accurate beliefs about COVID-19, and encouraging healthier, safer behaviors related to COVID-19 prevention, would certainly answer this call. Indeed, COVID-19 health messaging can harness both ways in which inoculation theory is used to protect healthier beliefs and actions: building resistance to unhealthy influence, like conspiracy theories, and encouraging healthier behaviors, like social distancing and wearing a mask in public. We look forward to future research on both prophylactic and therapeutic applications of psychological inoculation in the context of COVID-19.

Traumatic Stress in Healthcare Workers During COVID-19 Pandemic: A Review of the Immediate Impact

Agata Benfante, Marialaura Di Tella, Annunziata Romeo and Lorys Castelli*

Department of Psychology, University of Turin, Turin, Italy

The disease caused by respiratory syndrome coronavirus 2 (SARS-CoV-2) called COVID-19 resulted in a pandemic that has demanded extraordinary physical and mental effort from healthcare workers. This review provides an overview of studies that have explored traumatic stress in healthcare workers and associated factors between January and May 2020. The focus is on the most relevant literature investigating the prevalence of trauma- and stressor-related symptoms. Articles were selected from PubMed and PsycINFO databases using the search terms, "healthcare workers," "COVID-19," and "posttraumatic stress" in different combinations and with various synonyms. Among the seven studies that fulfilled our criteria, five assessed traumatic stress response, one assessed acute stress symptoms, and one focused on vicarious traumatization. Overall, the available findings highlight the presence of trauma-related stress, with a prevalence ranging from 7.4 to 35%, particularly among women, nurses, frontline workers, and in workers who experienced physical symptoms. Future studies should clarify the long-term effects of the COVID-19 pandemic on the mental health of healthcare workers, with particular focus on posttraumatic stress disorder.

Keywords: trauma, acute stress, vicarious traumatization, COVID-19, healthcare workers

INTRODUCTION

The World Health Organization (WHO) declared COVID-19 as a pandemic on March 11, 2020, when infections and deaths began to increase exponentially worldwide. The first cases were reported during December 2019 in Wuhan, China (WHO, 2020).

This virus belongs to the coronavirus family, which can cause respiratory infections in humans that resemble the common cold, as well as lethal illness similar to that associated with Middle East Respiratory Syndrome (MERS) and Severe Acute Respiratory Syndrome (SARS; Carver and Phillips, 2020). The symptoms of the new respiratory syndrome coronavirus 2 (SARS-CoV-2) can be fever, cough, tiredness, pains, nasal congestion, headache, and conjunctivitis, but they can also include pneumonia, acute respiratory syndrome, kidney failure, and death. Transmission is believed to occur *via* droplets (Carver and Phillips, 2020; Lechien et al., 2020; WHO, 2020). By May 22, 2020 the number of global confirmed infections and deaths had reached ~4,893,000 and ~323,000, respectively (WHO, 2020). Such an extraordinary event will have long-term effects on mental health according to previous studies of epidemics and quarantine (Maunder et al., 2006; Brooks S. K. et al., 2020; Kisely et al., 2020). The COVID-19

pandemic is classifiable as a traumatic event of exceptional magnitude that transcends the range of normal human experience with exposure to risk of death (Dutheil et al., 2020). These aspects can trigger psychopathologies such as acute stress disorder (ASD) and posttraumatic stress disorders (PTSD). Healthcare workers (HCWs) have been faced with unprecedented demands, both professionally and personally, in efforts to manage a disease with unclear etiology and pathology, no cure, no vaccine, and a high mortality rate. They are obliged to make difficult ethical decisions and function professionally under conditions of fear for themselves and their loved ones (Dutheil et al., 2020; Gavin et al., 2020; Kisely et al., 2020; Wong et al., 2020).

The aim of this review is to provide an overview of studies focusing on traumatic stress in HCWs during the COVID-19 pandemic.

MATERIALS AND METHODS

Research Approach

In order to determine the immediate impact of COVID-19 among HCWs in terms of stress- and trauma-related symptoms (TRSs), a scoping review was conducted in line with existing PRISMA guidelines. A scoping review may summarize the findings related to constructs examined with heterogeneous methods and identify the aspects that future research should focus on (Tricco et al., 2018).

Search Strategy

A literature search was conducted in the first 2 weeks of May 2020 in the following bibliographic databases: PubMed and PsycINFO. The databases were queried using the following strings (using Boolean operators): ("healthcare workers" OR "health care workers") AND ("COVID-19" OR "SARS-CoV-2") AND ("mental"); ("healthcare workers" OR "health care workers") AND ("COVID-19" OR "SARS-CoV-2") AND ("stress"); and ("healthcare workers" OR "health care workers") AND ("COVID-19" OR "SARS-CoV-2") AND ("post-traumatic stress"). The last run was conducted on May 17, 2020. With the use of this search string, 99 titles were identified between January and May 2020 (see **Figure 1** for the flow diagram of article selection).

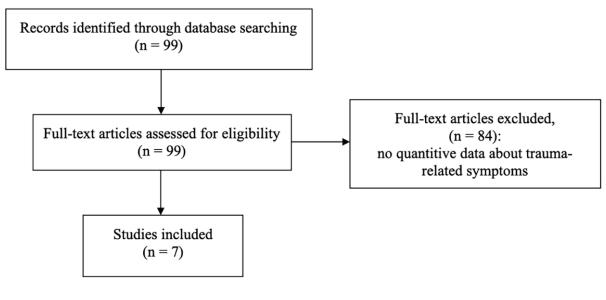

FIGURE 1 | Flowchart of articles selection.

Reports were also extracted using cross references, but in this way no additional article has been found.

Eligibility Criteria

This review aimed to identify peer-reviewed academic articles that aimed to provide a measure of stress- or trauma-related symptoms. All types of peer-reviewed papers (original research articles, commentaries, letters to editors, and reviews) that were published in English were eligible for inclusion in this review. Exclusion criteria were as follows:

1. Papers referring to data on the impact of previous epidemics.
2. Papers that did not include validated measures to investigate stress- or trauma-related symptoms.
3. Studies that used *ad hoc* constructed surveys or qualitative methods.
4. Studies that included only the general population. However, the studies that used the general population as a comparison group for the HCWs have been included in the present review.
5. Papers published but not peer reviewed or under review at the time the search was carried out.

Study Selection

Study selection was done by two authors (AB and MDT) who read the full text of all publications to screen for eligibility, because most of these articles did not include the abstracts (i.e., letter to editor and commentaries).

After the initial search, another co-author (AR) performed the literature search again, following the steps described in the study selection section above, to ensure that no records were missed and/or excluded during the selection process.

Disagreements on the inclusion or exclusion of publications were discussed by all authors until agreement was reached.

Data Extraction

The characteristics of all included studies were extracted by one author (AB). Data items that were extracted from each included study were author and year of publication, sample and country of origin, instruments used to measure stress- and trauma-related symptoms and other psychological variable, trauma-related results, and other main results.

RESULTS OF SELECTION

Table 1 and **Appendix A** summarize the main findings of the included articles. Five studies proceeded in China, one was in Singapore and one was a study of Singapore and India. All studies used self-report questionnaires disseminated through online surveys and had a cross-sectional study design. Three studies sampled only doctors and nurses, three included ancillary HCWs in hospitals such as pharmacists, physiotherapists, technicians, administrators, clerical staff, and maintenance workers, and one analyzed the general public and frontline and non-frontline nurses (nFLNs). All studies found higher percentages of females (64.3–82.7%) and nurses (up to 82.7%),

TABLE 1 | Summary of trauma-related results of the included studies.

Authors	Samples (n) – location	Instrument	Trauma-related results
Chew et al. (2020)	HCWs (906) – Singapore (480) and India (426)	IES-R†	7.4% (67) exceeded cut-off for TRSs; 7.5 and 7.3% of HCWs from Singapore and India, respectively. Thirty-four total respondents had moderate to severe symptoms.
Kang et al. (2020)	Medical staff (994): doctors (183) and nurses (811) – China	IES-R*	People with physical symptoms were more likely to screen positive. Mean (SD) IES-R scores are 6.1 (4.4.), 22.9 (4.8), 39.9 (5.4), and 60 (9.8) in groups with subthreshold, mild, moderate, and severe mental disturbance, respectively.
Lai et al. (2020)	Medical staff (1257): doctors (493) and nurses (764) – China	IES-R*	Exposure to infected persons increased for each group. 71.5% (899) had TRSs; levels were moderate to severe in 35% (440): 163 (33%) physicians and 277 (36.2%) nurses. Being female, intermediate professional titles and frontline work were associated with severe TRSs; working outside Hubei province was associated with lower risk of TRSs.
Li et al. (2020)	FLNs (234), nFLNs (292), and general public (214) – China	Vicarious traumatization questionnaire	Scores were significantly lower for FLNs than general public and nFLNs. No significant difference was found between general public and nFLNs. nFLNs had significantly increase scores than FLNs.
Tan et al. (2020)	HCWs (470) Singapore	IES-R†	7.7% (36) screened positive for TRSs. IES-R scores were significantly higher for non-medical, than medical staff with means (SD) of 9.4 (10.1) and 5.8 (9.2), respectively.
Xiao et al. (2020)	Medical staff (180): doctors (82) and nurses (98) – China	SASR	Mean (SD) SASR score was 77.6 (29.5). Social support and self-efficacy scores were negatively correlated with stress scores; anxiety scores were positively correlated with stress scores; SARS scores were positive correlated with sleep quality scores.
Zhang et al. (2020)	HCWs (1563) – China	IES-R*	73.4% had TRSs. Comparisons on impact of event between individuals with and without insomnia: sub-clinical (3.4 vs. 39.7%), mild (23.9 vs. 42.7%), moderate (42.7 vs. 15.8%), and severe (30 vs. 1.7%) TRSs.

FLNs, frontline nurses; HCWs, healthcare workers; IES-R, Impact of Event Scale – Revised; nFLNs, non-frontline nurses; SASR, Stanford Acute Stress Reaction questionnaire; SD, standard deviation; and TRSs, trauma-related symptoms.[*]*Cut-off > 26. Scores: normal/sub-clinical (0–8), mild (9–25), moderate (26–43), and severe distress (44–88).*
[†]Cut-off > 24 for clinical relevance of trauma-related symptoms. Scores: normal (0–23), mild (24–32), moderate (33–36), and severe (>37).

with average ages ranging from 26 to 40 years (Chew et al., 2020; Kang et al., 2020; Lai et al., 2020; Li et al., 2020; Tan et al., 2020; Xiao et al., 2020; Zhang et al., 2020).

The studies examined acute stress reaction (n = 1), vicarious traumatization (n = 1), and traumatic stress (n = 5). Their findings are discussed below.

Acute Stress Reaction

Xiao et al. (2020) investigated acute stress response among medical staff. Acute stress reaction is an anxious response, which in its most serious cases can be accompanied by manifestations associated with reliving the traumatic event or signs of reactivity (Walton et al., 2020). In accordance with the criteria of fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), a diagnosis of ASD requires at least nine of 14 symptoms, including negative mood, intrusion, dissociation, avoidance, and arousal (such as sleep difficulties, irritability, and inattention), that were initiated or worsened shortly after the event (Bryant, 2018). The study of Xiao et al. (2020) was conducted during the 1st month of the COVID-19 outbreak in China and the Stanford Acute Stress Reaction (SASR) questionnaire was used. This questionnaire evaluates consequential symptoms of traumatic events with higher scores corresponding to higher levels of stress-related symptomatology (range 0–150; Cardeña et al., 2000). The average score of for SASR was 77.6. Social support and self-efficacy scores correlated negatively with stress scores, and positive correlations were identified between anxiety and stress scores and between stress and sleep quality scores in that study. The main objective of that study was to determine the effects of social support on sleep quality among doctors and nurses, considering several other psychological aspects. Associated with this, social support indirectly affected the sleep quality of HCWs, reduced stress and anxiety levels and improved self-efficacy, while confirming that high levels of stress (with high anxiety levels and low self-efficacy) reduce sleep quality (Xiao et al., 2020).

Vicarious Traumatization

Li et al. (2020) investigated levels of vicarious traumatization in frontline and non-frontline nurses and in a general population. The concept of vicarious traumatization, also defined as secondary traumatic stress, includes various traumatic conditions, in which psychological abnormalities are related to the sympathy of HCWs toward people who are primarily traumatized. The symptoms associated with vicarious traumatization are loss of appetite, fatigue, sleep disorders, irritability, inattention, fear, and interpersonal conflict, which often remain at sub-clinical levels (Sabin-Farrell and Turpin, 2003; Li et al., 2020). The questionnaire adopted in their study comprised physiological and psychological dimensions. The psychological dimension included items associated with emotional, behavioral, and cognitive responses, and life beliefs. The results suggested that

the general public, frontline and non-frontline nurses suffered from vicarious traumatization, but between-group differences emerged. Frontline nurses (FLNs) had significantly lower scores than the other two groups, which did not significantly differ. In addition, married, divorced, or widowed nurses had more severe symptoms than unmarried nurses.

These results might be explained by the fact that the frontline nurses were composed of voluntarily selected professionals, who were trained with sufficient psychological preparation, with a middle-level professional title, and with work experience. Furthermore, the increased vicarious traumatization of nFLNs, as well as of general public, would derive from the sympathy and worry felt for COVID-19 patients and frontline workers, who instead sympathize only with patients and are more experienced about pandemic (Li et al., 2020).

Considering the recognition of the propensity of frontline nurses to suffer from vicarious traumatization (Taylor et al., 2016), it is essential to pay attention to the psychological health of these professionals, but also to take care of nFLNs, according to the findings of the study of Li et al. (2020).

Traumatic Stress

Five selected studies investigated the psychological impact of COVID-19-related trauma in HCWs using the Impact of Event Scale – Revised (IES-R; Chew et al., 2020; Kang et al., 2020; Lai et al., 2020; Tan et al., 2020; Zhang et al., 2020). The IES-R is a 22-item scale (range 0–88) that measures intrusive, avoidance, and hyperarousal symptoms typical of trauma. It is relatively independent from trauma- and stress-related disorders included in DSM-5, but considering that it examines symptoms in PTSD, it has often been used to identify this disorder (Wu and Chan, 2003). Chinese studies interpreted the IES-R scores as follows: normal/sub-clinical (0–8), mild (9–25), moderate (26–43), and severe distress (44–88), with a cut-off of 26 (Wu and Chan, 2003; Kang et al., 2020; Lai et al., 2020; Zhang et al., 2020). In contrast, studies conducted in Singapore and India evaluated IES-R scores as follows: normal (0–23), mild (23–32), moderate (33–36), and severe (>37), with a cut-off of 24 indicating possible PTSD (Creamer et al., 2003; Chew et al., 2020; Tan et al., 2020). These studies included 470–1,563 respondents (Tan et al., 2020; Zhang et al., 2020).

Lai et al. (2020) conducted a hospital-based survey that was stratified for the region where the participants worked. The IES-R scores showed that 899 (71.5%) of 1,257 physicians and nurses had traumatic stress symptoms and the level was moderate/severe in 440 (35%) of them. Specifically, 163 (33%) physicians and 277 (36.2%) nurses had clinically relevant symptoms (Lai et al., 2020).

Furthermore, women, nurses, and those working in Wuhan reported more severe symptoms of trauma stress and worse outcomes for anxiety, depression, and insomnia, with respect to men, physicians, and those working in Hubei outside Wuhan and outside Hubei. In particular, being women and having an intermediate technical title were associated with increased anxiety, depression, and TRSs. Being a frontline worker, directly engaged in the diagnosis and treatment of patients infected with COVID-19, was an independent risk factor for higher scores not only at the IES-R, but also at other measures used in the study (Lai et al., 2020). These prevalences were similar to those of Zhang et al. (2020), who found that 73.4% of HCWs respondents had IES-R scores ≥9, indicating the presence of traumatic stress symptoms. The main objective of that study was to determine the prevalence of insomnia and associated factors, the authors compared the levels of psychological impact of the event between HCWs with and without insomnia. Individuals with insomnia reported a significantly higher psychological impact compared to those without insomnia (symptoms of traumatic stress based on IES-R: moderate 42.7 vs. 15.8% and severe 30 vs. 1.7%; Zhang et al., 2020).

Kang et al. (2020) conducted a study on the mental health of HCWs, exploring also their psychological needs and access to mental health services. The HCWs were assigned to four groups (1–4) based on scores for depression, anxiety, insomnia, and traumatic stress. Groups 1, 2, 3, and 4 had subthreshold, mild, moderate, and severe disturbances (36, 34, 22.4, and 6.2% of the sample, respectively) and mean IES-R scores of 6.1, 22.9, 39.9, and 60, respectively. These findings indicated that group 4 was exposed to possible COVID-19 positive persons more often, had less access to psychological material and worse self-perceived health status, than the other three groups. Ultimately, that study showed that exposure to infected patients negatively impacted mental health, which in turn influenced subjective perception of physical health. Access to mental health services had a partial mediating effect between the risk of contact with COVID-19 positive patients and the mental health of the respondents (Kang et al., 2020).

The prevalence data differed in other countries. Tan et al. (2020) found that only 7.7% of their respondents screened positive for TRSs. In addition, the percentage was higher among non-medical, than medical personnel (10.9 vs. 5.7%). The authors assumed that the scores were lower than those found in studies of previous epidemics because the medical personnel might have been more mentally prepared due to previous experience (Tan et al., 2020). The results of the study by Chew et al. (2020) were similar; 7.4% of the total sample of HCWs exceeded the IES-R cut-off (Singapore, 7.5%; India, 7.3). Like to the finding of Chew et al. (2020) and Kang et al. (2020) associated having physical symptoms with an increased probability of high scores for trauma-related stress. A possible explanation for this result is that nonspecific symptoms, such as headache, sore throat, cough, breathlessness, lethargy, myalgia, and loss of appetite, are also part of the symptomatology of milder forms of COVID-19 infection (Chew et al., 2020; Lechien et al., 2020).

Thus, the presence of TRSs differed according to IES-R in these studies, with prevalence ranging from 7.4 to 35% (Chew et al., 2020; Lai et al., 2020).

DISCUSSION

To the best of our knowledge, this is the first review on the issue of COVID-19 trauma- and stress-related symptoms in

HCWs. Other literature reviews of previous epidemics and/or the COVID-19 pandemic have focused on generic psychological distress and/or anxiety and depressive symptoms. Meta-analyses have found a high prevalence of anxious and depressive symptoms among HCWs, especially among women and nurses (Pan et al., 2020; Pappa et al., 2020). In addition, a series of recent reviews highlighted that risk factors, such as being female, younger, being a nurse, lack of adequate protective equipment, and exposure to infected people, have been found to be associated to TRSs in previous epidemics (Brooks S. K. et al., 2020; Kisely et al., 2020; Rajkumar, 2020; Spoorthy, 2020; Walton et al., 2020).

Regarding the recent COVID-19 outbreak, the available studies show an important presence of COVID-19 trauma and stress-related symptoms in the general population and in patients (Bo et al., 2020; Rajkumar, 2020; Ren et al., 2020; Wang et al., 2020). However, to date, only few studies have analyzed this specific aspect in HCWs.

The psychological traumatic impact of COVID-19 in frontline and non-frontline HCWs is a great issue, as emerged by almost all the included studies (Kang et al., 2020; Lai et al., 2020; Xiao et al., 2020; Zhang et al., 2020). Contrasting results seem to emerge only in the studies of Lai et al. (2020) and Li et al. (2020), which found a different prevalence of TRSs between frontline vs. non-frontline HCWs. However, this discrepancy could be explained considering the different constructs the two studies examined and the heterogeneity of the samples they enrolled.

The present review highlighted an important impact of the COVID-19 pandemic on the mental health of HCWs. The prevalence of clinically relevant TRSs ranged from 7.4 to 35% (Chew et al., 2020; Lai et al., 2020), while in Chinese general population the prevalence of TRSs is ~7% (Ren et al., 2020; Wang et al., 2020). The differences among these results could be explained by different contagion rates and pressure on health care systems, the different incidence of the risk factors and different of access to psychological support. Particularly, being female, younger, a frontline worker, a nurse, having less work experience, exposure to infected people, poor social support, difficult access to psychological material, insomnia and physical symptoms are all risk factors for traumatic symptoms in HCWs (Chew et al., 2020; Kang et al., 2020; Lai et al., 2020; Xiao et al., 2020).

Furthermore, the multiple sources of distress that face HCWs are important to consider, such as concern about the spread of the virus, their own health, the health of their loved ones, and changes in the work environment (Cacchione, 2020; Gavin et al., 2020; Lai et al., 2020; Menon and Padhy, 2020; Neto et al., 2020). The HCWs are also at risk for moral injury, that is psychological distress derived from actions (or the impossibility of implementing actions) that violate their personal ethical and moral codes (Greenberg et al., 2020; Williamson et al., 2020). All these aspects contribute to the possibility that HCWs develop psychopathological disorders such as PTSD, severe depression, and substance abuse (Brooks S. K. et al., 2020). Future studies should clarify the long-term effects of the COVID-19 pandemic on the mental health of HCWs, with particular focus on PTSD.

However, HCWs that appear to be less at risk or who have mild traumatic stress symptoms should also be considered (Chew et al., 2020; Kang et al., 2020; Li et al., 2020; Tan et al., 2020). For example, Kang et al. (2020) showed that HCWs with low levels of mental health disturbances expressed the need to improve their skills to mitigate mental distress, both for themselves and for others.

Early symptoms of psychological trauma, together with symptoms of anxiety, depression, and insomnia, must be recognized, so that appropriate interventions can consider the organizational needs of HCWs, risk and protective factors, and possibly include actions to promote post-traumatic growth (Brooks S. et al., 2020; Conversano et al., 2020; Romeo et al., 2020; Shah et al., 2020; Shanafelt et al., 2020). The literature suggests that people exposed to trauma can experiment with positive responses, reconsidering their values and appreciating their lives more as well as their work in emergency situations. These aspects can be fostered by psychological interventions (Xu et al., 2016; Brooks S. et al., 2020).

This review has some limitations, due both to the limited number of studies specifically investigating post-traumatic symptoms of COVID-19 on HCWs, and to the methodological differences (e.g., cross-sectional design) of the selected studies themselves.

AUTHOR CONTRIBUTIONS

AB, MDT, AR, and LC conceived and designed the review. AB, MDT, and AR carried out the literature searches and screening. AB and LC wrote the manuscript. All authors concluded the results, discussed and approved the final version of the manuscript.

FUNDING

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

The birth of a child is a critical and potentially stressful experience for women, entailing several changes both at the individual and interpersonal level. This event can lead to different forms of distress, ranging in intensity and duration. Many studies highlighted medical, psychological, and social variables as risk factors potentially influencing the onset or aggravation of perinatal maternal conditions. The current pandemic emergency and the restrictive measures adopted by local governments to prevent the spread of the coronavirus infection may negatively affect mothers-to-be and new mothers potentially increasing the likelihood of anxiety, depressive or post-traumatic symptoms to develop. Moreover, the forced quarantine combined with the limited access to professional or family support may increase feelings of fatigue and isolation. The present study aims to investigate women's psychological well-being during pregnancy and in the first months after childbirth, integrating the evaluation of some traditionally studied variables with the specificities of the current situation. 575 Italian women have been administered an online self-report questionnaire assessing the presence of anxiety disorders, depressive and post-traumatic symptoms as well as the expectations toward childbirth (for mothers-to-be) or the subjective experience of childbirth (for postpartum women). Findings revealed a higher percentage of women than that reported in the literature scored above the clinical cut-off both during pregnancy and postpartum on a series of measures of psychological well-being, thus demonstrating that this period was perceived as particularly challenging and stressful and had significant impact on the women's well-being. Moreover, some socio-demographic, medical, and pandemic-related variables, especially the lack of presence and support from one's partner during labor and delivery as well as in the first days postpartum was found to predict women's mental health. These findings suggest the need for developing specific interventions targeted at women who cannot benefit from the support of their partners or family.

Keywords: expectant mothers, new mothers, COVID-19, restrictive measures, psychological well-being

INTRODUCTION

The birth of a child represents a critical experience in a woman's life, entailing several changes both at the individual (physical and psychological) and interpersonal level (Lawrence et al., 2008; Guzzo and Hayford, 2020). This experience may negatively impact on individual well-being, leading to several forms of distress and/or diseases including anxiety, mood and post-traumatic stress disorders (Paulson and Bazemore, 2010; Meltzer-Brody et al., 2017; Mohamied, 2019; Pellowski et al., 2019).

Most of the literature has focused on postpartum adjustment, however a growing body of research has progressively investigated women's well-being also during pregnancy (Molgora et al., 2020a). Both pregnancy and childbirth can be considered as potentially stressful, even traumatic, events requiring women to cope with changes in their lifestyles, habits, and even in their self-image and identity (Molgora et al., 2018). Moreover, it is important to underline that the psychological well-being of expecting mothers can influence their subjective experience of childbirth (Molgora et al., 2020b), as well as the medical-obstetric aspects of labor and delivery, for example in terms of prolonged labor and greater likelihood of undergoing operative deliveries or cesarean-sections (Fenaroli et al., 2016).

Psychological Well-Being of Expectant Mothers

Previous research on pregnant women has extensively studied the impact and prevalence of antenatal anxiety and depression reporting high rates of such conditions across various countries (Biaggi et al., 2016; Falah-Hassani et al., 2017; Nasreen et al., 2018; van de Loo et al., 2018). In this respect, although differences have been reported across studies due to the methodological approaches used, the prevalence of anxiety disorders among pregnant women has been found to be approximately 15% (Dennis et al., 2017). Antenatal depression, on its side, has been reported to affect 10–20% of expectant mothers—depending on the different cut-off scores used in the studies (Zaers et al., 2008; Pampaka et al., 2018; Sunnqvist et al., 2018).

Furthermore, during pregnancy many women develop a severe fear of childbirth; this latter is a clinical condition characterized by several symptoms (sleep disorders, panic attacks, etc.) which greatly impair women's ability to conduct their everyday life while also negatively affecting their ability to cope with labor and childbirth (Fenwick et al., 2009; O'Connell et al., 2017; Molgora et al., 2018). Although past research on this topic reported a great variability in prevalence rates, according to different cut-off scores and other methodological choices, the meta-analysis by O'Connell et al. (2017) estimated a prevalence of severe (i.e., clinical) fear of childbirth among 14% of pregnant women.

Several variables have been considered to be associated with fear of childbirth and overall maternal well-being, in this respect, different risk factors have been detected, both at an individual and interpersonal level. Some demographical dimensions (e.g., age, level of education, parity, etc.) have been investigated with contrasting results. For example, some studies reported multiparous mothers to be at higher risk of distress (Lainer and Jonson-Reid, 2014; Bassi et al., 2017), whereas other studies found nulliparous women to be at greater risk for severe fear of childbirth (Rouhe et al., 2008). Furthermore, distressing experiences occurring before or during pregnancy (e.g., serious physical illness, loss of a loved one, etc.) as well as a variety of medical-obstetric variables prior to and during pregnancy (e.g., previous miscarriages, high risk pregnancy, etc.) have been found to impact on pregnant women's mental health (e.g., Devlin et al., 2016; Furtado et al., 2018). Again, a personal history of mental illness prior to pregnancy has been reported to increase the risk of developing a psychological disorder during pregnancy, thus underling the continuity of psychological disorders (Cox et al., 2014; Biaggi et al., 2016).

At an interpersonal level, many studies have highlighted the association between expectant mothers' psychological well-being and relational variables, specifically quality of the couple relationship and social support, both during pregnancy and delivery (Lukasse et al., 2014; Figueiredo et al., 2018; Poggi et al., 2018): the lack of social support both from one's partner or extended network has been found to be one of the most important predictor of antenatal anxiety and depression (Biaggi et al., 2016). Specifically, partner's support resulted to mediate the relation between pregnant women's concerns and their psychological well-being (Ilska and Przybyła-Basista, 2017). Moreover, the social support perceived by mothers during pregnancy represented a protective factor against postpartum depression while also reducing the negative aspects of the experience of childbirth (Tani and Castagna, 2017).

Psychological Well-Being of Postpartum Women

Research on postpartum women has identified a wide range of clinical conditions that may impact on their well-being following childbirth: from the more common baby blues, that is a physiological and transitory condition (Rezaie-Keikhaie et al., 2020), to more severe conditions, such as anxiety and mood disorders, puerperal psychosis, and post-traumatic stress disorder (Paulson and Bazemore, 2010; Meltzer-Brody et al., 2017; Mohamied, 2019; Pellowski et al., 2019). Specifically, the prevalence of anxiety spectrum disorders has been found to be around 10% (15% for anxiety symptoms) (Dennis et al., 2017), whilst depressive symptoms have been reported in 10–22% of mothers, depending on the different cut-off scores used in the studies (Zaers et al., 2008; Pampaka et al., 2018; Sunnqvist et al., 2018). Moreover, a considerable number of women have been reported to have had a negative childbirth experience, specifically, the study by King et al. (2017) reported that about one-third of the women in the sample described their childbirth as very negative or traumatic. Finally, postpartum PTSD was found to be around 6% at 6 weeks postpartum and around 15% at 6 months postpartum (Zaers et al., 2008), while another study (Yildiz et al., 2017) reported a 4% mean prevalence of postpartum PTSD in community samples, and a 18.5% prevalence among high-risk groups.

Several variables have been analyzed in association with maternal psychological health postpartum. First, mothers' subjective experience of childbirth has been found to predict their postpartum well-being (MacKinnon et al., 2017; Molgora et al., 2020b). The quality of this experience can be shaped by numerous variables (e.g., medical, demographical, psychological, social) that have been analyzed as risk/protective factors (Fenaroli et al., 2016, 2019). For example, fear of birth, the use of epidural analgesia, and the duration of the expulsive phase have been found to significantly predict the mothers' experience of birth (Fenaroli et al., 2019). Considering the interpersonal dimension, women who received more intra-partum support and care, especially from their partner, had shorter labors, a more positive birthing experience characterized by higher levels of satisfaction, and a better postnatal psychological functioning (Collins et al., 1993; Hodnett, 2002; Hodnett et al., 2011; Michels et al., 2013). Mothers' psychological health is a key variable that needs to be carefully considered given the impact of maternal well-being on the quality of their first interaction with the newborn, on the baby development as well as on the overall family functioning (Choi et al., 2017; van de Loo et al., 2018).

Psychological Well-Being During the Covid-19 Pandemic

Starting from December 2019, the Covid-19 pandemic has affected several nations around the world. A growing number of studies have investigated the psychological impact of this pandemic on the general population reporting an increase of emotional distress and social disorders following the outbreak, especially among women (e.g., Rajkumar, 2020; Thapa et al., 2020). In particular, a previous Italian nationwide study, carried out during the first period after the Covid-19 outbreak and aimed at investigating the social and psychological impact of the pandemic, reported a widespread decrease in psychological well-being, especially among women younger than 50 and with previous health risk factors (Favieri et al., 2020).

Specifically, the outbreak and the restrictive measures enforced by local governments to prevent the spread of the coronavirus infection can be considered as additional major stressors for mothers-to-be and postpartum women, whose vulnerability is potentially increased by this specific situation, thus leading to detrimental effects on their psychological well-being (Thapa et al., 2020). Most of the studies published in the last months on the effect of the Covid-19 pandemic on pregnancy and childbirth have mainly focused on medical conditions and risk factors and have attempted to pinpoint the measures and clinical recommendations required to contain the Covid-19 spread (e.g., Chen et al., 2020; Liang and Acharya, 2020). The scant literature that has addressed the psychological impact of the Covid-19 pandemic on expectant and postpartum women has found higher levels of anxiety and depressive symptoms among participants when compared to similar cohorts assessed before the outbreak (Ceulemans et al., 2020; Lebel et al., 2020; Liu et al., 2020; Patabendige et al., 2020). An Italian study investigating the psychological effects of the pandemic on pregnant women found a significant change in their expectations toward pregnancy and childbirth as well as an increase in their concerns and distress, especially if they had a previous history of psychological distress in press (Ravaldi et al., 2020). Furthermore, women showed significant concerns mainly related to the risk of coronavirus infection and to the fear of consequent complications for themselves and the fetus and were more likely to complain about insufficient antenatal support (Haruna and Nishi, 2020). In this respect, it is important to underline that the pandemic has had an effect on both antenatal care as well as on birth management and postpartum care (Coxon et al., 2020). During the pandemic, and especially during the lockdown period, pregnant and postpartum women have experienced a limited access to their formal and informal support network, thus facing new and unforeseen struggles potentially putting their mental health in jeopardy. The presence of a support network has, in fact, been widely recognized as a crucial protective factor for prospective mothers and postpartum women alike (Friedman et al., 2020; Huschke et al., 2020). The importance of such support is particularly relevant in family centered cultures, such as the Italian one, where – also thanks to the geographic proximity – children tend to turn to their parents for support also during adulthood (Scabini, 2000). For example, an Italian study by Agostini et al. (2014) found that women with low levels of social support were more likely to experience depressive symptoms.

The Italian Situation

Italy has been the first European–and more generally Western country–to report some coronavirus cases. The outbreak occurred in late February in Northern Italy and, since then, the local government has adopted a series of restrictive measures to contain the pandemic that have been considered among the strictest in Europe.

In particular, on February 23 the Italian government issued the first decree (D.L. n.6, 23/2/2020) establishing quarantine red-zones around the most severely hit Northern cities. People living in the area were forbidden to exit while those living outside were denied access, moreover, people were invited to remain at home unless absolutely necessary. On March 9, a new government order (D.P.C.M. 9/3/2020) was issued, extending the quarantine zone to the whole national territory: gatherings of more than two people were prohibited and companies invited to encourage working from home. On March 11 all shops and factories selling or manufacturing non-necessary goods were closed. On March 20 a new government order (D.P.C.M. 20/3/2020) enforced further limitations: parks and gardens were closed to the public and physical activity was allowed only within the premises of one's house. On April 10 the Italian prime minister announced that the above-mentioned restrictions would be enforced until May 3, the official end of the first phase of the emergency.

Besides these restrictions that affected the whole population forcing millions of people to change their habits, routines and lifestyle, pregnant and postpartum women had to face further limitations. While such restrictions varied greatly across regions and even within the same region, all the hospitals adopted some sort of limitations that impacted on pregnant and postpartum women. More specifically, women could not attend antenatal classes; both non-urgent pre- and post-natal screenings and

checkups were canceled or postponed; women had to attend visits unaccompanied; hospital access to fathers at postpartum was either completely forbidden or greatly limited and in many cases prospective fathers were denied access during childbirth and delivery; finally, some women were denied access to epidural analgesia due to medical staff being occupied with facing the pandemic emergency.

The Current Study

The present study aims at investigating Italian women's psychological well-being during pregnancy and in the first months after childbirth. To reach this aim, our research integrates the evaluation of some traditionally studied variables that are known to influence childbirth and delivery with the investigation of some variables strictly related to the coronavirus emergency. In particular, we will consider some psychological outcomes (i.e., anxiety symptoms, depressive symptoms and fear of childbirth for pregnant women, and anxiety symptoms, depressive symptoms, post-traumatic stress disorders and subjective experience of labor and delivery for postpartum women) and assess the role of several factors (anamnestic and personal information, relational variables, contextual variables), both related and unrelated to the current emergency, in predicting these outcomes.

In particular, it is possible to assume that the usual distress several women undergo due to the important and critical experience of motherhood would be amplified by the pandemic. Indeed, this situation has already been demonstrated to have had a negative impact on prospective mothers' and postpartum women's psychological well-being. Specifically, previous studies on Italian women found higher level of anxiety symptoms (Saccone et al., 2020) along with increased concerns and fears about childbirth (Ravaldi et al., 2020) among pregnant women. Moreover, international studies found greater rates of depression, anxiety and stress among mothers of infants and young babies (Cameron et al., 2020). Considering these preliminary results, we can hypothesize that pregnant and postpartum women are at greater risk of developing anxiety, depression, or post-traumatic symptoms. Such adverse outcomes may occur due to being infected or having a family member infected with the virus, experiencing the hospitalization or the death of a loved one, the increase of household and caregiving tasks, isolation, financial instability, domestic violence or abuse following the quarantine, and uncertainty about the future (Shah et al., 2020).

MATERIALS AND METHODS

Participants and Procedure

The present cross-sectional study involved 575 Italian expectant mothers and postpartum women. Participants were recruited through social media (i.e., Facebook and Instagram) and invited to fill-in an online anonymous questionnaire. Data were collected between March 1, 2020 and May 3, 2020 (the so-called phase 1 of lockdown, characterized by the exceptionally strict measures adopted to prevent coronavirus spread). Inclusion criteria were: being above 18 years of age, being fluent in Italian, and being either pregnant or having had a baby for less than 6 months.

After receiving a short presentation of the research goals and proving their informed consent, all participants were asked to fill in a questionnaire on the platform Qualtrics. Informed consent forms and all the study materials have been approved by the Institutional Review Board of the authors' institution.

Seven hundred eighteen questionnaires were collected: 130 were excluded because of missing or incomplete data, another 13 women were excluded because they did not fit inclusion criteria (i.e., their child was older than 6 months). The final sample comprised 575 women, 389 pregnant women and 186 postpartum women.

Measures

In order to study the impact of the Covid-19 pandemic outbreak and of the above-mentioned restrictive measures on pregnancy and childbirth, researchers developed a questionnaire that was disseminated online. Besides gathering socio-demographic data (i.e., age, education, job title, parity, etc.), data on psychological well-being (i.e., number and type of stressful life events experienced at the time of data collection, such as economic problems, work problems, bereavements; number and type of previous psychological disorders (such as eating disorders, drug addition, alcoholism), and basic information regarding the pregnancy (i.e., mode of conception, number and type of complications occurred, type of pregnancy, etc.) and delivery (i.e., type of delivery, occurrence of health risk for the mother or the baby, access to epidural analgesia, etc.) were collected.

Furthermore, the questionnaire also included some questions specifically pertaining the Covid-19 emergency. Specifically, participants were asked if they or one of their family members had resulted positive to Covid-19, if their partners continued to commute to work during lockdown, if their partners were present (or if they believed they would be present in the case of pregnant women) at childbirth and if they could (or they believed they would be allowed to) visit them at the hospital. Moreover, mothers were asked about their access to epidural analgesia as well as to some form of family or professional support (specifically, the question asked: "When your baby will be born, will you receive help from someone?" and the possible answers were: my mother, my father, my mother-in-law, my father-in-law, another relative, a professional nurse, a doula, a babysitter, other). All the questions included in the questionnaire (except one, which has not been analyzed in the current study) were multiple choice. Lastly, the questionnaire included several measures (see below) of maternal well-being.

More specifically, all the women who took part in the research completed the following instruments:

State-Trait Anxiety Inventory–STAI, Y form (Spielberger et al., 1983; Italian validated version by Pedrabissi and Santinello, 1989).

This instrument is largely used to measure state and trait anxiety. It is composed of 40 items on a four-point Likert scale (20 items for trait anxiety and 20 items for state anxiety), with a total possible range of scores of 20–80 with higher scores indicating higher anxiety levels. Internal consistency was good

for both the state (Cronbach's alpha = 0.95 for both expectant and postpartum women) and trait (Cronbach's alpha = 0.91 and 0.92, respectively for expectant and postpartum women) subscales. Based on previous studies on the Italian pregnant population (Giardinelli et al., 2012; Vismara et al., 2016), a cut-off score of 40 or higher was used to identify both state and trait clinical anxiety.

Edinburgh Postnatal Depression Scale–EPDS (Cox et al., 1987; Italian validated version by Benvenuti et al., 1999).

This instrument, originally developed to screen for postpartum depression has been validated and is currently used also during pregnancy (Kozinszky and Dudas, 2015). The scale is composed of 10 items on a four-point Likert scale, with a 0–30 total possible range of scores: the higher the score, the higher the depressive symptoms. Internal consistency was good (Cronbach's alpha = 0.87 for both expectant and postpartum women). According to Gibson et al. (2009), a cut-off value of 13 or higher was used to distinguish clinical depression.

Pregnant women were administered the following instrument:

Wijma Delivery Expectancy Questionnaire–WDEQ(A) (Wijma et al., 1998; Italian validated version by Fenaroli and Saita, 2013).

This instrument measures expectations regarding childbirth, and in particular fear of childbirth, through 33 items on a six-point Likert scale. In the present study, we used the validated 14-item Italian version of the scale that has been proven to work better with the Italian population (Fenaroli and Saita, 2013; Molgora et al., 2018, 2020a). For this version, the total score ranges from 0 to 70: the higher the score, the more negative the expectations and the greater the fear toward childbirth. Internal consistency was good (Cronbach's alpha = 0.90). Although to date there is no unique cut-off value identified as the gold standard to screen for clinical (i.e., severe) fear of childbirth, based on some studies that reported intense fear as falling in the top quartile of the continuous measure (Fenwick et al., 2009), values equal or above 35 were considered indicators of a severe fear (Molgora et al., 2020a).

Postpartum women were administered the following instruments:

Wijma Delivery Experience Questionnaire–WDEQ(B) (Wijma et al., 1998; Italian validated version by Fenaroli and Saita, 2013).

This instrument measures the childbirth experience through 33 items on a six-point Likert scale. As for the WDEQ(A), in the present study, we used the validated 14-item Italian version of the scale, whose total score ranges from 0 to 70: the higher the score, the more negative the subjective experience. Internal consistency was good (Cronbach's alpha = 0.91). Similarly to the antenatal version of the instrument, a total score of 35 or higher was considered as the cut-off to distinguish severe fear.

Perinatal PTSD Questionnaire–PPQ (DeMier et al., 1996; Callahan et al., 2006; Italian not validated version by Di Blasio et al., 2009, 2015; Ionio and Di Blasio, 2014).

This instrument was developed to assess post-traumatic symptoms related to the experience of childbirth; specifically, the scale measures intrusiveness or re-experiencing, avoidance behaviors, hyperarousal or numbing, as well as feelings of guilt. The original version is composed of 14 items measured on a dichotomous scale while the revised version uses a five-point Likert scale, with a total score ranging from 0 to 56, with higher scores indicating more severe PTSD symptoms. This study uses the modified version of the scale which, although not validated in Italian, has already been used in a previous study (Di Blasio et al., 2015) showing good consistency (Cronbach's alpha ranged from 0.85 to 0.88). Internal consistency was good (Cronbach's alpha = 0.78). According to Callahan et al. (2006), a score of 19 or higher identifies high-risk mothers.

Data Analyses

First, descriptive statistics were performed for each of the two samples separately: mean scores were calculated for age and frequencies were computed for variables such as education, job title, psychological disorders, stressful life events, etc. Measures of anxiety, depression, postpartum PTSD, and childbirth experience were dichotomized using cut-off values suggested by previous relevant studies. Those cut-off values were used to determine the percentage of women falling above the clinical range for each of the constructs under analysis.

Secondly, the expectant and postpartum mothers group were compared with respect to the socio-demographic and medical-obstetric variables as well as with respect to scores on depression and anxiety. Independent samples *t*-tests, Mann–Whitney and chi square tests were used according to the type of variable and its measurement scale.

After these preliminary steps, the two samples were analyzed separately given both the distinctive features characterizing the two conditions as well as the difference in sample size. Specifically, chi-square tests were run on both samples to investigate the relation between measures of anxiety, depression, postpartum PTSD, expectations toward or experience of childbirth and some demographic or medical-obstetric variables that are known to influence such relation. Further chi-square tests were performed on both the expectant and the postpartum mothers samples to assess the differences between women falling above the clinically significant range for the above-mentioned scales (i.e., STAI, WDEQ(A) and (B), PPQ, and EPDS) and those falling below the cut-off with respect to variables measuring the impact of the restrictions adopted to prevent the spread of coronavirus. Dummy coded versions of the dependent variables (with zero indicating the absence of a clinically relevant condition and one indicating a clinically relevant score) were used in the above-mentioned analyses. *p* values resulting from these analyses have been corrected for multiple testing using the Holm–Bonferroni method.

Finally, a set of hierarchical logistic regressions were performed on the expectant and postpartum women sample separately. Specifically, total scores for STAI, EPDS, PPQ, WDEQ(A) and (B) were entered as dependent variables in the various equation models performed. Unlike we did for chi-square tests, in this case total scores for anxiety, depression, fear and experience of childbirth, as well as postpartum PTSD were used. The choice of using continuous instead of dummy variables was determined by the willingness to retain the maximum data variability. Each of the above-mentioned variables was regressed against a set of independent variables including demographic, medical and obstetric data, as well as data regarding the impact of the pandemic emergency on the women's life. Specifically,

a three-step multiple regression procedure was used in which each criterion variable was regressed on the predictor variables in blocks. Demographic factors as well as data concerning the women's medical and psychological general condition (i.e., number of stressors, number of previous psychological conditions) were entered in the first step, followed by dimensions related to pregnancy (e.g., number of complications, etc.) and childbirth (e.g., presence of risks for the mother or the child's health, etc.). Finally, factors measuring the impact of the Covid-19 pandemic on the women's experience or expectations (e.g., perceived likelihood of father being present at delivery and during hospital stay or actual presence of father at delivery and hospitalization) were entered in the third block. Our choice was motivated by the fact that the first block contained basic variables regarding the women's demographics and well-being irrespectively of their condition, the second block included all the variables related to pregnancy and childbirth while the third block incorporated all the measures of the effect of Covid-19 pandemic on expectant and postpartum women.

RESULTS

Descriptives and Comparison Between Expectant Mothers and Postpartum Women

Pregnant women's mean age was 32.9 (SD = 4.3), 63.2% (246) of women were married to the father of their child, 35.7% (139) were cohabiting and the remaining 0.8% (3) were either single or separated/divorced. 53.2% (207) of the pregnant women in our sample did not have other children whereas 45.2% (176) were multiparous. Only a very small proportion of women (4.6%, 18) claimed that they or one of their immediate family members had resulted positive to coronavirus. Most of the women's partners (62.1%) were working from home while the remaining 38.8% were continuing to commute to work during lockdown. With respect to medical appointments and checkups, 80.5% of the women in our sample declared that they were undergoing regular doctor visits while 15.2% stated that their appointments were canceled or rescheduled due to the Covid-19 emergency. Similarly, 8.7% (34) of the women in our sample were told that they could not use epidural analgesia due to the lack of medical staff caused by the coronavirus outbreak. Finally, 7.5% of the women were told their partners could not be present during childbirth and 47.0% were unsure about their partners' presence at delivery due to the restrictive measures adopted to contain the Covid-19 spread. Similarly, 13.9% of women believed their partners would not be allowed to visit them during hospitalization.

With regards to postpartum women, mean age was 33.01 (SD = 4.19), 109 (58.6%) women were married to the father of their child while the remaining 77 (41.4%) were cohabiting, 53.8% (100) of the women did not have other children whereas 45.2% (84) had at least one more child. Similarly to what happened for pregnant women, only six (3.2%) postpartum women stated that they or one of their family members had resulted positive to Covid-19. With regards to fathers, 34.9% of women declared that their partners continued working during lockdown, 21% declared that their partners were not admitted during childbirth and 10.8% stated that they were not admitted during hospital stay.

Other data regarding women's education, job title, number and type of current stressors (independent from the coronavirus emergency), number and type of previous mental disorders, and number and type of complications during pregnancy are reported in **Table 1**.

The two samples (i.e., pregnant women and postpartum women) did not differ with regards to the socio-demographic variables investigated. Specifically, no difference between the two groups was found for age ($M_{pregnantwomen}$ = 32.90, SD = 4.32; $M_{postpartum}$ = 33.01, SD = 4.19) [$t(569) = -0.291$, $p = 0.37$], education [$U = 34126.00$, $p = 0.26$], job title [$\chi^2(5, 573) = 2.82$, $p = 0.73$], and whether they had other children [$\chi^2(1, 567) = 0.01$, $p = 0.95$].

Moreover, the two groups did not differ with regards to number of psychological disorders [$U = 34857.00$, $p = 0.45$] or stressful life events [$U = 32082.00$, $p = 0.14$] experienced in their lives and to whether they, or one of their immediate family members, had tested positive to Covid-19 [$\chi^2(1, 561) = 0.524$, $p = 0.47$].

With reference to anxiety, 64.0% (249) of expectant mothers and 57.7% (98) of postpartum women scored above the clinically significant range for state anxiety, data regarding trait anxiety revealed that 44.0% (171) of pregnant women and 46.2% (86) of postpartum fell above the cut-off score. Moreover 34.2% (133) of expectant women and 26.3% (49) of postpartum women had clinically significant levels of depression as measured by the EPDS scale. 31.7% of postpartum women reported a negative childbirth experience while 51.2% of expectant women had negative expectations regarding birth. Finally, postpartum PTSD scores were above the cut-off value in 16.7% of cases. Independent samples *t*-tests comparing state and trait anxiety and depression scores in pregnant women vs. postpartum women did not reveal any significant difference between the groups.

Although no differences between expectant mothers and postpartum women were found for anxiety and depressive symptoms, subsequent analyses have been run separately for each of the two samples given the specificity of each condition and the difference in sample size.

Psychological State of Expectant Mothers: Non-Covid Related Risk Factors

With regards to pregnant women, a set of chi square analyses were performed to explore the relationship between state anxiety, trait anxiety, fear of childbirth, and depression and a number of variables that are known to influence such relation (i.e., the presence of previous child(ren); the presence and number of past psychological disorders, the number of stressors experienced at the time of data collection, the number of complications occurred during pregnancy, etc.).

Pregnant women having more than one child [$\chi^2(1, 342) = 10.35$, $p = 0.008$] and those having suffered from

previous psychological disorders [$\chi^2(5, 348) = 20.17$, $p = 0.008$] were more likely to experience state anxiety. Similar results were found for EPDS scores, with multiparous women [$\chi^2(1, 356) = 7.46$, $p = 0.05$] and those having suffered from previous disorders [$\chi^2(5, 362) = 21.3$, $p = 0.009$] being more likely to be psychologically depressed. With regards to trait anxiety, only the presence of previous psychological disorders scored significantly, with pregnant women suffering from two or three previous disorders being more likely to fall above the clinical cut-off [$\chi^2(5, 345) = 45.48$, $p < 0.000$]. With regards to fear of childbirth, none of the above-mentioned variables was significant.

Psychological State of Expectant Mothers: Covid-Related Risk Factors

Following, further chi square tests were run to investigate the relation between the above said measures of psychological disorders (i.e., STAI state, STAI trait, WDEQ(A), and EPDS) and some variables connected to the Covid-19 pandemic and the subsequent restrictions imposed on the population. Specifically, relations between depression, childbirth expectations, state and trait anxiety and perceptions regarding access to epidural analgesia, postpartum support, possibility for fathers to be present at delivery and to visit the mother during hospitalization were investigated, together with father going vs. not going to work regularly during lockdown. Results showed that pregnant women who believed their partner could not be present at childbirth along with those who were unsure about the father being allowed to enter the delivery room were more likely to suffer from state anxiety [$\chi^2(2, 348) = 15.44$, $p < 0.000$] and to have intense fear of childbirth [$\chi^2(2, 364) = 9.08$, $p = 0.007$]. Similarly, women who believed their partner would be denied visitation and those who were not sure whether their partners would be allowed access to the hospital rooms were more likely to fall in the clinically significant range for state anxiety [$\chi^2(2, 337) = 12.99$, $p = 0.012$]. Lastly, pregnant women who believed they would not have access to any form of family or professional support after childbirth were more likely to suffer from state anxiety [$\chi^2(1, 347) = 8.01$, $p = 0.025$].

Psychological State of Postpartum Women: Non-Covid Related Risk Factors

Similar analyses were conducted also on the postpartum women sample. More specifically, dummy scores for depression, quality of childbirth experience, postpartum PTSD, state and trait anxiety were measured against number of stressful events experienced in ones' life, number of previous psychological disorders, presence of children, number of complications during pregnancy, access to epidural analgesia, presence of complications at childbirth for the mother or the child. Results showed that new-mothers who had experienced psychological disorders earlier in their lives were more likely to suffer from trait anxiety [$\chi^2(5,166) = 38.25$ $p = 0.000$], postpartum depression [$\chi^2(5, 174) = 23.00$, $p = 0.000$] and postpartum PTSD [$\chi^2(5, 154) = 12.11$, $p = 0.007$]. Moreover, mothers who experienced two or three complications during pregnancy were more likely to fall in the clinically significant range for postpartum PTSD [$\chi^2(4, 154) = 9.36$, $p = 0.05$] and to

have perceived childbirth as a negative event [$\chi^2(4, 179) = 13.58$, $p = 0.009$]. The same was true for mothers who experienced some sort of health risk during delivery: these women were more likely to develop a postpartum PTSD [$\chi^2(1, 154) = 4.95$, $p = 0.026$] and to have negative memories of childbirth [$\chi^2(1, 179) = 8.57$, $p = 0.033$].

Psychological State of Postpartum Women: Covid-Related Risk Factors

As it was the case for pregnant women, relations between depression, childbirth experience, postpartum PTSD, state and trait anxiety and Covid-19-related variables were also explored. In this case, women whose partners had not been present during delivery were more likely to experience both clinically significant state [$\chi^2(1, 167) = 4.45$, $p = 0.035$] and trait anxiety [$\chi^2(1, 166) = 6.84$, $p = 0.009$] as well as to develop a postpartum PTSD [$\chi^2(1, 154) = 4.58$, $p = 0.032$]. Postpartum women whose partners continued working regularly during lockdown also showed a greater likelihood of suffering from state anxiety [$\chi^2(1, 167) = 5.28$, $p = 0.022$].

Effects of Specific (Covid-Related) and Non-specific Factors on Pregnant Women

After having explored the relations between anxiety, depression, expectations/experience of childbirth, postpartum PTSD and a series of psycho-social and health related variables both independent from and connected to the current pandemic situation and the restrictions adopted by the Italian government to contain the coronavirus outbreak, we decided to run a set of separate hierarchical logistic regressions for each of the two samples to assess whether and to what extent such variables contributed to pregnant and postpartum women falling in the clinical vs. non-clinical range.

With regards to pregnant women, four separate hierarchical logistic regression were run to evaluate the prediction of state and trait anxiety, depression, and fear of childbirth from presence of other children, number of stressors in one's life, number of previous disorders, complications during pregnancy, prospective access to epidural analgesia, fathers' employment status (i.e., whether the prospective father was going to work regularly during lockdown), perceived likelihood of fathers being present at delivery and during hospitalization. In all the four regressions number of stressors, number of previous disorders and presence of other children were entered in the first block, number of complications and prospective access to epidural analgesia were entered in the second block, while Covid-19 related variables (i.e., father going to work regularly during lockdown, perceived likelihood of father being present at delivery and during hospitalization) were entered in the third block. Results are presented in **Table 2**.

With regards to state anxiety, all the three models tested proved to be statistically significant ($p < 0.000$), however, only presence of other children, presence of two stressful events in one's life and presence of up to three previous disorders are capable of predicting anxiety scores across all the three models. Specifically, having more than one child, experiencing two stressful live events at the time of data collection and having suffered from up to three previous psychological conditions have all proven to be significantly and positively related to an increase in state anxiety (see **Table 2**). The final model including the above-mentioned predictors accounts for 17% of the variance, $F(16, 341) = 4.13$, $p < 0.000$.

Similar results were obtained when trait anxiety was considered, with all the three regression models being statistically significant and the third accounting for 20.2% of the total variance. Again, having more than one child and having suffered from up to three disorders in the past resulted in an increase in trait anxiety scores for pregnant women.

With regards to depression, those women having more than one child and having suffered from up to three psychological conditions had also higher depression scores in step one. Similar results were found for step two and three. Moreover, in step three women who did not believe their partner would be present during childbirth obtained significantly higher depression scores ($\beta = -0.137$, $p = 0.013$). The final model accounted for 15.3% of the variance, $F(17, 355) = 3.59$, $p < 0.000$.

Finally, when fear of childbirth was considered only the first ($p = 0.038$) and third ($p = 0.014$) models proved to be statistically significant. Presence of other children and of two previous psychological conditions were positively correlated with fear of childbirth both in step one and three of the equation; moreover, when "beliefs about the presence of the prospective father at childbirth" was added to the equation in the third block, it also proved to have a significant effect on WDEQ(A) scores. Specifically, women who believed their partner would be able to assist them during childbirth reported significantly lower level of fear ($\beta = -0.154$, $p = 0.007$). The final model ($p = 0.014$) accounted for 8.8% of the total variance.

Effects of Specific (Covid-Related) and Non-specific Factors on Postpartum Women

Similarly to what had happened for pregnant women, four separate hierarchical regression were performed on the postpartum women's sample. Total scores on state and trait anxiety, depression, experience of childbirth and postpartum PTSD were regressed on a linear combination of variables investigating socio-demographic data, pregnancy- and delivery-related issues. More specifically, presence of other children, number of stressors in one's life at data collection, and number of previous psychological problems were entered in the first block; complications during pregnancy, access to epidural analgesia, presence of health risks for the mother or the child during delivery were added in the second block, and fathers' employment status (i.e., whether new-fathers had gone to work regularly during lockdown), presence of father at delivery and hospitalization, presence of a support network after childbirth were analyzed in the third block. Results are shown in **Table 3**.

With regards to state anxiety, all the three models proved to be significant ($p < 0.000$). Having suffered from up to two psychological conditions in the past significantly correlated with

anxiety scores across the three models. Incremental of F scores revealed that the addition of postpartum support in step three resulted in a significant increase in R^2 ($\Delta R^2 = 0.01$, $\Delta F = 1.67$, $p = 0.001$). In other words, new-mothers who had suffered from previous psychological disorders in the past tended to be more anxious ($\beta_{disorder1} = 0.221$, $p = 0.007$; $\beta_{disorder2} = 0.340$, $p = 0.000$) whereas women who could count on the support of either a family member or a professional figure after delivery were significantly less anxious ($\beta = -4.23$, $p = 0.019$). Similar results were obtained for state anxiety: women having experienced up to three disorders in the past also had higher trait anxiety scores ($\beta_{disorder1} = 0.265$, $p = 0.001$; $\beta_{disorder2} = 0.464$, $p = 0.000$,

**Significant at $p < 0.01$; **Significant at $p < 0.05$.*

$\beta_{disorder3}$ = 250, p = 0.002). Moreover, in this case, the fact of having experienced one stressful life event at the time of data collection significantly impacted on anxiety levels only in model one (β = 0.140, p = 0.044). and two (β = 0.141, p = 0.044) but was not significant in model three (β = 0.136, p = 0.058) (see **Table 3**).

When depression was considered, analyses revealed that new-mothers who had experienced up to two previous conditions had higher EPDS scores and this was true in all the three models (third model $\beta_{disorder1}$ = 0.229, p = 0.004; $\beta_{disorder2}$ = 0.393, p = 0.000). At the same time, mothers who could count on the presence of their partner during delivery showed significantly lower levels of postnatal depression (β = −0.147, p = 0.049). The final model including the above-mentioned variables explained 27.5% of the variance.

With regards to childbirth experience, the presence of two concurrent stressful life events significantly impacts on WDEQ(B) scores and this variable plays a significant role across the three models (third model $\beta_{stressor2}$ = 0.192, p = 0.015). On the contrary, the presence of up to two previous disorders resulted to be related to WDEQ(B) scores only in model one ($\beta_{disorder1}$ = 0.158, p = 0.045; $\beta_{disorder2}$ = 0.186, p = 0.024) while not being significant in model two ($\beta_{disorder1}$ = 0.133, p = 0.088; $\beta_{disorder2}$ = 0.123, p = 0.137) and three ($\beta_{disorder1}$ = 0.129, p = 0.099; $\beta_{disorder2}$ = 0.101, p = 0.225). While not being significant in the first model (β = 0.132, p = 0.077), the presence of other children becomes significant in the second (β = −0.132, p = 0.039) and third (β = −0.180, p = 0.022) model, showing that multiparous women have lower scores with respect to childbirth experience and, thus, perceive it as less negative. The same happens for epidural analgesia: while not being significant in the second step (β = −0.148, p = 0.067) of the model, this variable is significant in the third (β = −0.161, p = 0.048) (see **Table 3**). Therefore, the possibility of using epidural analgesia resulted in a significantly more positive evaluation of the experience of childbirth. The presence of problems for the baby's health during delivery (β = 0.251, p = 0.001) was also positively correlated with an increased perception of childbirth as a negative event. Lastly, women who could count on the presence of their partner during delivery scored significantly lower than those who were alone (β = −3.068, p = 0.021). The final model accounted for 25% of the variance.

With regards to postpartum PTSD, the presence of one stressful life event at the time of data collection resulted significant only in step one (β = −0.175, p = 0.025) and three (β = −0.151, p = 0.050). The presence of two previous psychological conditions, on the contrary, was positively and significantly correlated to PPQ scores across the three models (first model $\beta_{disorder2}$ = 0.386, p = 0.000; second model $\beta_{disorder2}$ = 0.327, p = 0.000; third model $\beta_{disorder2}$ = 0.312, p = 0.001). Moreover, the presence of three complications as well as the presence of problems for the baby's health during delivery were also related to an increase in PPQ scores in model two ($\beta_{complications3}$ = 0.227, p = 0.009); ($\beta_{babyhealthproblems}$ = 0.207, p = 0.013) and three ($\beta_{babyhealthproblems}$ = 0.204, p = 0.015). In other words, new-mothers who had experienced past psychological disorders, those who experienced numerous complications or whose baby's health was at risk during childbirth were more likely to have higher postpartum PTSD scores. Finally, those mothers whose partners were present at childbirth scored significantly lower for postpartum PTSD (β = −0.230, p = 0.018). The final model including all the above-mentioned variables accounted for 28.4% of the variance.

DISCUSSION

Findings of this study confirmed that expectant and postpartum women's psychological well-being can be influenced by several factors. Specifically, alongside some widely investigated dimensions that have proven to have an impact on mothers' mental health (e.g., socio-demographic variables, previous psychological disorders, etc.), also specific pandemic-related factors (i.e., the restrictive measures enacted by the government to prevent and contain the spread of the coronavirus infection) have been found to shape the experience of motherhood, thus confirming our hypothesis as well as previously published studies findings (Ravaldi et al., 2020; Saccone et al., 2020; Thapa et al., 2020) that the responses enacted to prevent the spread of the virus are putting pregnant and postpartum women's mental health in jeopardy.

First of all, a high percentage of women, both during pregnancy and in the postpartum, reported scores above the clinical cut-off for several measures of well-being. Moreover, such scores are higher than those reported in previous studies on the same topic. Although a certain variability among the various studies due to methodological choices has to be acknowledged, the prevalence of anxiety spectrum disorders was found to be around 15% in pregnant women and 10% in new-mothers (15% for anxiety symptoms) (Dennis et al., 2017); when our sample is considered, 44–64% (considering respectively trait and state anxiety) of pregnant women and 46.2% (trait anxiety)–57.7%(state anxiety) of postpartum women scored above the clinical cut-off for anxiety symptoms. Similar findings were found for depressive symptoms: depression rates reported in the literature range from 10 to 20% for pregnant women (depending on the different cut-off scores used in the studies) and from 10 to 22% for new-mothers (Zaers et al., 2008; Pampaka et al., 2018; Sunnqvist et al., 2018), however our participants showed clinically significant depressive symptoms in a much greater proportion: 34.2% during pregnancy and 26.3% at postpartum. Such figures are extremely relevant, especially if we consider that the highest possible threshold reported in the literature (i.e., 13 or above) has been used as the cut-off value for depression in the current study. When anxiety and depressive symptoms are compared, this study confirms that anxiety is usually more prevalent than depression among expectant mothers as already found in previous studies (Nasreen et al., 2018; van de Loo et al., 2018). However, while depression and anxiety symptoms are quite common among pregnant and postpartum women, the women in our sample were significantly more at risk for developing anxiety and depressive symptoms; these findings suggest that the pandemic and the measures adopted to fight its spread have had a negative impact on expectant and postpartum women' well-being, thus constituting an additional

risk factor for this specific population. We can hypothesize that social isolation, lack of support and control over one's health may have negatively impacted women's outcomes. Specifically, support both during pregnancy and in the postpartum have been found to be protective factors against depression (Collins et al., 1993; Hodnett, 2002; Hodnett et al., 2011; Michels et al., 2013; Goodman and Leiferman, 2016); similarly, an external health locus of control has been found to be associated with depressive symptoms in postpartum women (Richardson et al., 2012; Mollard, 2015).

Again, in our sample, fear of childbirth was above the cut-off value for more than half of expectant mothers, while 32% of postpartum women reported a negative childbirth experience. Research on this topic reported a great variety among fear of childbirth scores depending on the cut-off scores used and on some other methodological variables; however, the meta-analysis by O'Connell et al. (2017) estimated the presence of a severe (i.e., clinically significant) fear of childbirth in 14% of pregnant women. With regards to new-mothers, King et al. (2017) reported that about one-third of women describe their childbirth as very negative or traumatic, with a percentage that is in line with our study.

Finally, while postpartum PTSD scores ranged from 6% at 6 weeks postpartum to around 15% at 6 months postpartum in Zaers et al. (2008) study and from 4% for community samples to 18.5% in high risk samples as reported by Yildiz et al. (2017), our data show a percentage as high as 16.7%, thus assimilating the women in our sample to a high risk population. These findings suggest that fear, hyperarousal and other stress-related symptoms have been a constant in many women's lives, potentially affecting their ability to take care of themselves and their child(ren).

Overall, women who gave birth or were pregnant during the acute phase of the current pandemic are at greater risk of developing depressive, anxiety or post-traumatic symptoms and of experiencing intense fear toward childbirth and this may lead to more complicated labors, greater pain at childbirth as well as to an impaired capacity of taking care of the baby while also affecting the overall family stability (Goodman and Leiferman, 2016, Molgora et al., 2020). In this scenario, both personal (especially the parity condition and the presence of previous disorders) and situational variables (especially the presence of the fathers both during labor and delivery, as well as during hospital stay) were found to predict mothers' psychological mental health both during pregnancy and in the postpartum, distinguishing between clinical and non-clinical conditions on the investigated dimensions of psychological well-being.

Specifically, as for pregnant women, our results showed how multiparous women and those having suffered from previous psychological disorders were more likely to report anxiety and depressive symptoms, confirming previous studies (Cox et al., 2014; Lainer and Jonson-Reid, 2014; Biaggi et al., 2016; Bassi et al., 2017). Furthermore, expectant mothers who believed their partner could not be present at childbirth as well as those who believed their partner would be denied visitation were more likely to report higher levels of state anxiety symptoms or a severe fear of childbirth. Similarly, pregnant women who believed they would not have access to any form of family or professional support after childbirth were more likely to suffer from state anxiety. These results further confirm the crucial role social variables-especially the partner's presence and support both during labor and delivery and in the postpartum (also in terms of mothers' expectations)-have on expectant women's psychological well-being (Lukasse et al., 2014; Biaggi et al., 2016; Figueiredo et al., 2018; Poggi et al., 2018).

As for postpartum women, our findings confirmed previous studies reporting that women who had experienced psychological disorders earlier in their lives were more likely to suffer from postpartum psychological distress and, in particular, anxiety, depression and PTSD (Cox et al., 2014; Biaggi et al., 2016). Moreover, postpartum women who experienced several complications during pregnancy were more likely to report postpartum PTSD and to report a negative experience of labor and delivery. This result is in line with other studies that have found an association between medical-obstetric dimensions of pregnancy and the subjective experience of childbirth as well as postpartum mental health (Devlin et al., 2016; Fenaroli et al., 2016, 2019; Furtado et al., 2018). Finally, women whose partners had not been present during delivery were more likely to experience both postpartum anxiety symptoms (state and trait) and PTSD thus underling the importance of (intra-partum and postpartum) partners' support in preventing postpartum psychological distress (Collins et al., 1993; Hodnett, 2002; Hodnett et al., 2011; Michels et al., 2013; Tani and Castagna, 2017). On a similar note, previous studies (Kainz et al., 2010) have underlined the importance of prospective fathers or other caregivers during labor, explaining that these figures have a key role in infusing mothers with feelings of empowerment and well-being. It is within such framework that the association between fathers' commuting to work and mothers' anxiety can be understood: those women whose partners continued working regularly during lockdown showed a greater likelihood of suffering from state anxiety as they could not count on their daily support and they were constantly exposed to the risk of being infected thus adding an element of uncertainty and stress to an, already stressful, situation. In this respect, previous studies have demonstrated that women were extremely worried about themselves, their babies or one of their loved ones being infected with the virus and this resulted in an increased stress and fear (Cameron et al., 2020; Saccone et al., 2020).

Overall, these results underlined differences between primiparous and multiparous women, both during pregnancy and in the postpartum: women who already have other children seem to be more vulnerable than those who do not. We can suppose that the presence of other children made it more difficult for women to cope and manage everyday chores around the house, especially during the lockdown with all the schools being closed and the didactic activities provided at a distance. Due to the extremely severe measures adopted by the government, Italian mothers often found themselves to simultaneously take care of the house, help their children with school and carry out their work from home, thus multiplying their efforts and strains. The limitations imposed by the government during the first phase of lockdown (that is when data were collected) greatly hindered the women's possibility to access to formal and informal support, thus potentially increasing feelings of

isolation and fatigue which lead to the development of anxiety and mood disorders.

This study presents several limitations. First, it is a cross-sectional study that assesses expectant and postpartum women well-being only during the initial phase of the outbreak (the lockdown period). Thus, it is not possible to know whether the effects of the restrictive measures enforced by the Italian government will have long-lasting effects on the women's well-being. Another methodological limitation concerns the data collection: data in this study have been collected online and this may affect the comparability with other studies using data collected in person. However, several other studies (Mott et al., 2011; Koletzko et al., 2015) have already used online surveys and did not report any difference in terms of the severity of the symptoms registered. Moreover, while the online modality might discourage some women from seeking help, it certainly helps in terms of reducing social desirability.

Another limitation has to do with the fact that the presence of a formal or informal support network has not been investigated in terms of its potentially moderating effect on the variables under investigation. Future studies might consider the possibility of investigating the effect of mediating and moderating variables. Finally, only a very limited number of women and their immediate family members resulted positive to Covid-19, thus making it impossible to conduct further analyses on the effects of contracting the virus on maternal well-being.

Despite these limitations, the present results clearly show that the pandemic emergency and the restrictions imposed on the population greatly impacted on prospective mothers' and postpartum women's well-being putting their mental health and emotional stability at stake. It is widely known that pregnancy and puerperium are extremely delicate moments in a woman's life: not only women are called to re-negotiate their own identity and integrate the maternal role into their established role set (Rubin, 1975), they also enter a condition in which an increased attunement to their babies happens at the cost of their own self and often causes a general decline in their cognitive functions (Davies et al., 2018). Whether we call it "baby brain" (Davies et al., 2018) or "primary maternal preoccupation" (Winnicott, 1956), this particular state entails greater emotional instability and fragility as well as an increased need for protection. This is particularly true during stressful events, such as the ones experienced during a pandemic. In this perspective, it is key that health care facilities and medical staff keep under great consideration the role played by the support network in predicting both pregnant women and new-mothers' well-being. Specifically, pregnant and postpartum women should be granted the presence of a companion of choice during delivery and in the first days after childbirth, as also suggested by the World Health Organization (2016). Not only granting such support results in better maternal outcomes but it has also been reported to favor bonding between all family members (Child and Family Research Partnership, 2014; Carvalho Coutinho et al., 2016). Moreover, the present study seems to suggest the need for developing specific interventions targeted at women who cannot benefit from the support of their partners or family.

Objective: We aim to determine the psychological status of medical students during the COVID-19 outbreak and civil war in Libya.

Methods: A cross-sectional study was conducted among medical students from 15 medical schools between April 20 and May 1, 2020. The demographic characteristics, generalized anxiety disorder 7-item (GAD-7) scale, and patient health questionnaire (PHQ-9) results were collected.

Results: Of the 3,500 students, 2,430 completed the survey. The mean (± SD) score of anxiety symptoms determined by the GAD-7 was 7.2 (5.1). A total of 268 (11%) students had a GAD-7 score of ≥15, which is indicative of moderate to severe anxiety. A total of 1,568 (64.5%) students showed different degrees of anxiety: mild, 910 (37.5%); moderate, 390 (16%); and severe, 268 (11%). Anxiety was significantly associated with living status and internal displacement ($P < 0.05$). The mean (+ SD) score of depressive symptoms determined by the PHQ-9 was 9.7 (6.3). A total of 525 (21.6%) students had a PHQ-9 score of ≥15, which is indicative of moderate to severe depression. A total of 1,896 (88%) students were diagnosed with mild (PHQ ≥ 5) depression. Suicidal ideation was present in 552 patients (22.7%). Depression was only statistically associated with the year of study ($P = 0.009$).

Conclusion: These data highlight that medical students in Libya are at risk for depression, especially under the current stressful environment of the civil war and the COVID-19 outbreak.

Keywords: depression, PHQ-9, anxiety, GAD-7, medical student, COVID-19, SARS-CoV-2, civil war

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was identified in the city of Wuhan, Hubei Province, China in December 2019 (Chan et al., 2020; Zhou F. et al., 2020; Zhou P. et al., 2020). It causes severe viral pneumonia that has been designated COVID-19. Since December 2019, it has spread rapidly, and the World Health Organization (WHO) declared it a worldwide pandemic in February 2020 (Mahase, 2020; World Health Organization, 2020). On August 26, 2020, the WHO announced that 23.9 million people were infected and more than 820,000 had died (Dong et al., 2020; Huang et al., 2020).

Because of COVID-19, medical schools have suspended their function and closed for this period, and some countries have applied social distancing measures and curfews. These preventive measures may have increased stress and psychological pressure on medical students as they are unable to complete their studies and are at high risk of being infected with SARS-CoV-2 (Lai et al., 2020; Li et al., 2020; Reger et al., 2020; Wang et al., 2020). Addressing potential stressors during this time is important; possible disease exposure, economic privatization, and decreased social support may carry an increased risk for suicide and decreased mental and physical performance (Chandratre, 2020; Ullah and Amin, 2020).

Medical students are at higher risk of depression and anxiety for several reasons, including mentally and emotionally demanding medical school programs (Wolf, 1994), financial pressure, high workload, and sleep deprivation. In addition, exposure to sick and dead people can have a negative impact on their mental health (Wolf et al., 1988; Guthrie et al., 1998; Williams et al., 2005; Sreeramareddy et al., 2007; Boland et al., 2016). These demanding conditions put students in high stress positions, with anxiety being reported in one-third of medical students worldwide, especially those who reside in the Middle East and Asia (Quek et al., 2019). Other studies have reported a prevalence of up to 65.5% for anxiety and 66.5% for depression outside of North America (Hope and Henderson, 2014).

Medical schools in Libya use the 7-year program, comprising a preparatory year of biomedical science, followed by a 5-year program of 3 years of basic science and 2 years of clinical science, and 1 year of mandatory internship training.

Since 2011, Libya has suffered from several civil wars and conflicts with militias, causing increased insecurity and financial crises, as well as the kidnapping, rape, and killing of innocent people (Zeiton, 2011). Furthermore, the lack of funds for mental health services puts Libyan people at higher risk of mental disorders (Charlson et al., 2012; Abuazza, 2013; Rhouma et al., 2016), especially in large cities. Conflicts in the country have caused more than 217,000 people to be internally displaced, according to the United Nations Refugee Agency (UNHCR) report (Miller and Rasmussen, 2010; Reed et al., 2012; Newnham et al., 2015; UNHCR, 2020). In addition, they have affected the medical education system in Libya, several medical schools were temporarily closed for several periods during the war, which resulted in delays in the graduation and medical education of thousands of medical students. These stressors can have substantial negative effects on the psychological statuses of students.

Since the emergence of the first case of COVID-19 in Libya on March 24, 2020 (Elhadi et al., 2020a), the number of COVID-19 cases has substantially increased in many cities, with up to 11,834 confirmed cases and more than 210 deaths by August 26, 2020. The unpreparedness of the Libyan healthcare system toward the COVID-19 pandemic, which can be explained by the large number of cases and shortage of medical supplies, as well as the ongoing conflict, have placed an increased burden on Libyan medical students and the general population; the civil war has caused a financial crisis and reduced the ability of the healthcare system to provide adequate training opportunities for newly graduated medical students (Elhadi and Msherghi, 2020; Elhadi et al., 2020b). This, coupled with the closure of medical schools during the COVID-19 pandemic, along with extended electrical blackout issues, may have resulted in substantial frustrations and increases in anxiety and depression among medical students, especially for those in high-conflict areas or who were internally displaced from their homes.

Today's medical students are tomorrow's doctors; therefore, their mental wellbeing is crucial. However, few studies have addressed the impact of the COVID-19 pandemic on the mental health of medical students (Cao et al., 2020; Soled et al., 2020; Ullah and Amin, 2020). There is an urgent need to perform high-quality research and collect data on the effects of the COVID-19 outbreak on mental health (Holmes et al., 2020). Therefore, we aimed to determine the psychological status of medical students during the COVID-19 outbreak and civil war in Libya and determine factors associated with depression and anxiety among Libyan medical students.

MATERIALS AND METHODS

Study Design

This is a cross-sectional study of medical students from 15 medical schools and colleges in Libya, located in the main cities. Data were collected from April 20, 2020 to May 1, 2020. Data were collected in paper and electronic forms using anonymous surveys that were sent to medical students by email and through the social media groups of medical students. The questionnaires were anonymous to ensure the reliability and correctness of the data, and were sent to more than 3,500 medical students. To avoid observer and selection bias, the survey was blinded: for the paper survey, the students completed the survey anonymously without identifiable data and left the completed paper survey at a designated collection point in each medical school to avoid any potential bias. For the online version, the students were asked to fill out the survey anonymously without identifiable data.

Study Participants and Settings

Active medical students who were currently enrolled in medical schools were included, while those who were not currently enrolled in medical school were excluded. Those with a previous history of mental illness or missing data were excluded from the study. Students of any age and gender were included. The survey was conducted in the following cities: Tripoli, Al-Zawia, Misrata, Sebha, Gharyan, Albayda, Benghazi, Al-Khums, Tarhuna, Alzintan, Tobruk, and Sabratha.

Study Tools

The questionnaire was divided into three parts. The first part contained demographic characteristics, including age, gender, year of study, availability of steady financial sources, living status (living alone or with family), presence of friends or family infected with COVID-19 infection that they know, and occurrence of internal displacement due to the civil war.

The second part was comprised of the generalized anxiety disorder 7-item (GAD-7) scale. This tool includes questions

regarding seven anxiety symptoms and their frequencies within the last 2 weeks. It has a specificity of 82% and a sensitivity of 89% (Spitzer et al., 2006; Toussaint et al., 2020), and has been validated in several previous studies and has excellent internal consistency (Cronbach's α = 0.83–0.93). In each of the questions students were asked to rate symptoms using a 4-item Likert scale of 0 (not at all), 1 (several days), 2 (more than half of the days), and 3 (nearly every day), with a total score of 0–21 (Ruiz et al., 2011; Johnson et al., 2019). A score of 0–4 was regarded as normal, 5–9 was regarded as mild, 10–14 was regarded as moderate, and 15–21 was regarded as severe (Kroenke et al., 2007). A GAD-7 score of ≥15 was regarded as the cutoff score to detect anxiety symptoms (Spitzer et al., 2006).

The third part consisted of the patient health questionnaire (PHQ-9), which is a validated 9-item questionnaire to assess depression severity in individuals. It has a specificity of 85% and a sensitivity of 88% (Levis et al., 2019). Each of the 9-item questions rates depression using a 4-item Likert scale of 0 (not at all), 1 (several days), 2 (more than half the days), and 3 (nearly every day), with a total score of 0–27 (Kroenke et al., 2001). A score of 0–4 was regarded as minimal, 5–9 was regarded as mild, 10–14 was regarded as moderate, 15–19 was regarded as moderately severe, and 20–27 was regarded as severe (Urtasun et al., 2019). A PHQ-9 score of ≥15 was regarded as the cutoff score to detect depressive symptoms (Kroenke et al., 2001; Levis et al., 2019).

Statistical Analysis

The independent-samples *t*-test was used to determine if there was a significant difference between the means of the two groups. The chi-square test for association was used to determine the association between categorical groups. Spearman's rank-order correlation was used to determine the association between continuous/ordinal variables. A *P*-value of less than 0.05 was considered statistically significant. Statistical analyses were performed using IBM SPSS Statistics for Windows (Version 25.0).

Ethical Standards

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committee on human experimentation with the Helsinki Declaration of 1975, as revised in 2008. Ethical approval for this study was obtained from the Bioethics Committee at the Biotechnology Research Center in Libya. All participants provided consent before participating in the study.

RESULTS

Demographic Characteristics

A total of 2,430 out of 3,500 students completed the survey. Of these, 1,327 (54.6%) were from the University of Tripoli. The mean age of the study participants was 23.30 ± 2.61 years, and 734 (30.2%) students were in the 5th year of their medical course. The vast majority (1,919 out of 2,430 [78.97%]) were female, and 511 (21.03%) were male. **Table 1** provides the demographic characteristics of the study participants.

Mental Health Assessments

Anxiety

Anxiety symptoms were assessed using the GAD-7 scale, and participants were classified into four grades, as shown in **Table 2**. The GAD-7 score ranged from 0 to 21, with a median of 6 (IQR, 4–10), while the mean (+ SD) score of anxiety symptoms determined by the GAD-7 was 7.2 (5.1). A total of 268 (11%) students had a GAD-7 score of ≥15, which is indicative of

TABLE 2 | Frequencies and percentages of grades of depression and anxiety.

Category	Grade	Frequency	Percentage (%)
Depression (PHQ-9)	Minimal (0–4)	534	22
	Mild (5–9)	855	35.2
	Moderate (10–14)	516	21.2
	Moderately severe (15–19)	289	11.9
	Severe (20–27)	236	9.7
Anxiety (GAD-7)	Normal (0–4)	862	35.5
	Mild (5–9)	910	37.5
	Moderate (10–14)	390	16
	Severe (15–21)	268	11

moderate to severe anxiety. However, according to the GAD-7 grades categories, 862 (35.5%) medical students had no signs or symptoms of anxiety. While 1,568 (64.5%) had different degrees of anxiety: mild, 910 (37.5%); moderate, 390 (16%); and severe, 268 (11%). **Table 3** demonstrates the relationship between the baseline characteristics and different degrees of anxiety. Anxiety was significantly associated with living status and internal displacement ($P < 0.05$). Students living alone had a higher prevalence of anxiety. In addition, students internally displaced due by the civil war were more statistically associated with anxiety symptoms than were non-displaced students. The gender, age range, year of study, having a steady financial income, and having family members or friends infected with COVID-19 were not statistically associated with anxiety symptoms ($P > 0.05$). Spearman's correlation was used to assess whether there was a relationship between anxiety score and study characteristics, and there was no statistically significant correlation between the anxiety score determined by the GAD-7 scale and the age ($r_s = -0.030$, $P < 0.141$). However, there was a statistically significant negative correlation between the anxiety score and the year of study ($r_s = -0.41$, $P = 0.042$).

Depression

The PHQ-9 scale assessed depression and participants were classified into five grades, as shown in **Table 2**. The PHQ-9 score ranged from 0 to 21, with a median of 9 (IQR, 5–14), while the mean (+ SD) score of depressive symptoms determined by PHQ-9 was 9.7 (6.3). A total of 525 (21.6%) students had a PHQ-9 score of ≥15, which is indicative of moderate to severe depression. Additionally, 855 (35.2%) of the medical students had mild (PHQ 5–9) depressive symptoms. Suicidal ideation was present in 552 (22.7%) students, as follows: 342 (14.1%), several days; 90 (3.7%), more than half of the days, and 120 (4.9%), nearly every day. **Table 2** provides the frequencies of each grade of depression according to the PHQ-9 categories. Depression was only statistically associated with year of study ($P = 0.009$), where medical students in higher years of study had a higher prevalence of depressive symptoms compared to those in earlier years. However, gender, age range, steady financial income, living status, internal displacement, and having a family member or friend infected with COVID-19 were not statistically associated with depressive symptoms ($P > 0.05$). Spearman's correlation was used to assess whether there was a relationship between the PHQ-9 depressive score and age and year of study. The results showed that there was a statistically significant negative correlation between the year of study and depression score ($r_s = -0.76$, $P < 0.001$). For the age of the participants, there was a statistically significant negative correlation between age and depression score ($r_s = -0.054$, $P < 0.008$). **Table 4** presents the depression grades of study participants in association with COVID-19.

DISCUSSION

The COVID-19 pandemic and civil war in Libya has likely had psychological effects on medical students, which can be demonstrated by the high level of anxiety and depression shown in this study. The study determined the psychological status of medical students during the civil war conflicts and the COVID-19 pandemic in Libya. The results demonstrated that 64.5% of students had different degrees of anxiety. Of these, about 11, 16, and 37.5% reported severe, moderate, and mild anxiety symptoms, respectively. In addition, 21.6% had moderate to severe depression symptoms, and suicidal ideation was present in 552 (22.7%) participants.

The high level of anxiety and depression might be related to the civil war (Wells et al., 2011), and overwhelming and exacerbating news that increases their fear of the virus (Ayittey et al., 2020), transmission to family or friends, virus complications, and psychological pressure due to quarantine and isolation (Burtscher et al., 2020; Cao et al., 2020; Molica et al., 2020; Xiao, 2020).

Libyan medical students are exposed to high levels of psychological stress owing to civil war conflicts, resulting in a

**Significant at P < 0.05.*

higher prevalence of anxiety and depression. It is important to note that 294 of the medical students who answered the survey have been internally displaced owing to living in a conflict zone. These students have had to leave their homes and move to a relative's house or their families have had to find another place to live temporarily. This increases psychological stress; these students' families will be under higher financial pressure owing to them being forced to rent, and due to the fact that these students are at high risk of being kidnapped or killed and their home and belongings stolen or destroyed in the conflict.

A previous study conducted on Chinese college students during the COVID-19 outbreak demonstrated that 0.9, 2.7, and 21.3% had severe, moderate, and mild anxiety, respectively (Cao et al., 2020); this is lower than our study findings. However, Cao et al. (2020) focused on undergraduate students with no emphasis on the year of study, which varies according to our study findings, as it can play a role in terms of anxiety and depression levels; medical students in higher study years display greater stress and anxiety due to the increased work and study load (Chandavarkar et al., 2007). According to our study, having family members or friends infected with COVID-19 was not significantly associated with anxiety, which is not consistent with previous reports (Cao et al., 2020; Ren et al., 2020). A previous meta-analysis of 69 studies on anxiety among medical students found a pooled prevalence of anxiety of 33.8%, which is similar to our study; the study demonstrated a higher prevalence among Middle Eastern and Asian medical students, which might be due to cultural issues and the stigmatization of mental disorders (Quek et al., 2019).

Our study showed that depression symptoms were associated with the year of the study; those in a higher year of their studies demonstrated a higher prevalence. This is similar to previous studies in Nepal, India, Pakistan, and Thailand, which have also reported that students in higher academic years demonstrated a higher prevalence of psychological morbidities (Supe, 1998; Saipanish, 2003; Shaikh et al., 2004; Sreeramareddy et al., 2007).

Our study showed that 525 (21.6%) of the students were depressed, and suicidal ideation appeared in 552 (22.7%). A previous study in Vietnamese students, which was regarded to have a higher prevalence rate than previous reports, indicated a 15.2% prevalence of depression and 7.7% prevalence of suicidal ideation (Pham et al., 2019). In a recent study among 2,562 Saudi medical students with a similar gender distribution, a total of 15.9% were found to have moderately severe (PHQ-9 = 15–19) depressive symptoms, while 11.6% had severe (PHQ-9 = 20–27) depressive symptoms, which is similar to our results (Alharbi et al., 2018). In a study conducted in the United Arab Emirates, 32.1% of medical students showed evidence of psychiatric distress (Ahmadi et al., 2012). Using the depression, anxiety, and stress scale (DASS-21), another study on Syrian medical students found that the prevalence of depressive symptoms was up to 60.6% and that of anxiety 35.1%, which were higher than those in our study. They also found a higher prevalence among those with "insufficient" personal income (Al Saadi et al., 2017). In Iraq, prevalence of anxiety and depression of 62.5 and 52.1%, respectively, using the DASS-21 questionnaire, were reported (Rasheed and Hussein, 2019). Both Iraq and Syria have similar life stressors to those in Libya, with higher prevalence of anxiety and depression among medical students.

In a systemic review and meta-analysis of 167 cross-sectional studies and 16 longitudinal studies regarding medical students' depression and suicidal ideation, a prevalence of depression of between 9.3 and 55.9% was revealed across the studies. The pooled prevalence of suicidal ideation was present in 11.1% of the students among the included studies (Rotenstein et al., 2016) which is lower than our study where we found that 22.7% of participants have suicidal ideation.

The strengths of this study are in its adequate sample size and wide representation from 15 different universities and colleges around Libya. Moreover, this study focused on medical students' anxiety and depression during the COVID-19 pandemic, with special emphasis on several factors, such as internal displacement,

financial, and conflict-related factors that are relevant to the students' current state, with special circumstances regarding the civil war and ongoing conflict.

One of the limitations of this study is its cross-sectional design, which prevents the building of causal relationships. Another limitation is the predominance of the female gender in the study, which may affect the distribution of the results. Furthermore, there might be a selection and interview bias, as the medical students received the survey by email and social media. In addition, this study did not address other factors, such as family history of mental illness, nor other socio-demographic factors, such as emotional trauma.

CONCLUSION

Our study highlights that the mental health of medical students in Libya is at risk, especially under the stressful conditions of the civil war and COVID-19 outbreak. In addition to the COVID-19 pandemic, this can be attributed to several factors, including the year of study, age, psychological stress due to the civil war, living with family members or friends with COVID-19, internal displacement due to conflict, and living either with family or alone. These stressors may have long-term effects on their future careers as doctors, which necessitates combined efforts and determined actions to support medical students and provide help for their families. The government should implement strategies aimed at providing mental health support for students to improve healthcare outcomes and decrease the risk of suicide, training attrition, and long-term mental illness during this critical time.

Ahead of the Curve: Responses From Patients in Treatment for Obsessive-Compulsive Disorder to Coronavirus Disease 2019

Jennie M. Kuckertz[1,2], Nathaniel Van Kirk[1,2], David Alperovitz[1,2], Jacob A. Nota[1,2], Martha J. Falkenstein[1,2], Meghan Schreck[1,2] and Jason W. Krompinger[1,2]*

[1]Obsessive Compulsive Disorder Institute, McLean Hospital, Belmont, MA, United States, [2]Department of Psychiatry, Harvard Medical School, Boston, MA, United States

Alongside concern about the physical health impacts of the coronavirus disease 2019 (COVID-19) crisis, public health officials have also raised concerns about the potential for massive mental health impact. This has led many to wonder, how are individuals with obsessive-compulsive disorder (OCD), and especially those with contamination fears, doing in the era of COVID-19? We present data from eight patients in our residential treatment program for OCD who were admitted prior to any COVID-19 restrictions and continued in treatment at the facility during the pandemic. Much like the general population, our patients varied in the ways they were impacted by COVID-19, yet the majority experienced improvements in OCD symptoms despite the context. This is not to downplay the many ways in which our patients were personally affected by COVID-19. Rather our patients' relatively resilient responses mirror our program's treatment model, which emphasizes exposure and response prevention (ERP) within the complementary framework of acceptance and commitment therapy (ACT). The intention of this article is to challenge the notion that by definition this population will fare worse than the general public or that ERP cannot proceed effectively during this time. In contrast, we underscore that effective OCD treatment can and should continue in the era of COVID-19.

Keywords: obsessive compulsive disorder, anxiety, COVID-19, coronavirus, acceptance and commitment therapy, exposure and response prevention, resilience

INTRODUCTION

Coronavirus disease 2019 (COVID-19) was identified on December 31, 2019 and has become a global pandemic (World Health Organization, 2020) that has resulted in over 4 million positive cases and over 146,000 deaths in the United States alone (Centers for Disease Control and Prevention, 2020). Alongside physical health concerns, public health officials have raised concerns about the potential for massive mental health impact based on increased stress associated with fear of contracting/transmitting the virus and substantial changes to routine, financial ramifications, and social isolation (Holmes et al., 2020; Pfefferbaum and North, 2020; Yao et al., 2020). Initial data validate concerns regarding these negative mental health impacts among the general population (Ipsos MORI, 2020; Qiu et al., 2020), medical workers (Lu et al., 2020), college students (Cao et al., 2020), and individuals living in regions heavily impacted by COVID-19 (Liu et al., 2020).

This has led many to wonder, how are individuals with obsessive-compulsive disorder (OCD), and especially those with contamination fears, doing in the era of COVID-19? Myriad articles written by popular press and professional organizations have speculated about this topic and offered suggestions (Anxiety and Depression Association of America, 2020; Fontenelle and Miguel, 2020; International OCD Foundation, 2020; Rosman, 2020). The authors of the current article are clinicians and researchers at a residential treatment program for severe OCD. Frequently, we have heard comments from colleagues in the broader psychology and health fields such as "must be an interesting time to work with OCD," "your poor patients must be really struggling," or "how do you even do treatment right now when everyone has OCD?" The implication is that people with OCD are especially struggling to cope with the current COVID-19 realities, even for individuals currently in treatment.

To some degree, these assumptions are intuitive given that difficulty tolerating uncertainty (which is highly salient in this unprecedented global pandemic) is a hallmark feature of OCD (Obsessive Compulsive Cognitions Working Group, 2005) and 40–50% of individuals with OCD report concerns about germs or contamination (Pinto et al., 2008; Matsunaga et al., 2010). Moreover, existing literature suggests that obsessive-compulsive contamination and/or health anxiety symptoms are associated with greater anxiety about prior public health concerns among university-affiliated samples (Wheaton et al., 2012; Blakey et al., 2015; Blakey and Abramowitz, 2017).

However, the impact of the current pandemic on individuals with a diagnosis of OCD remains unclear. COVID-19 is unprecedented in modern history in its scope and impact on daily routine and behaviors (Callaway et al., 2020; Pew Research Center, 2020). Given recent public health directives to wash hands, sanitize items, and monitor symptoms frequently, it is reasonable to hypothesize that obsessive-compulsive symptoms might increase for individuals in the community who do not ordinarily engage in these behaviors. What is unclear is to what extent the current global pandemic results in a clinically meaningful exacerbation of OCD among individuals who already struggle with these symptoms in the absence of a pandemic. More importantly, in our minds, is the question of whether it is possible for individuals with OCD to cope adaptively (e.g., by engaging in treatment) during this time.

The assumption that all patients with OCD are uniquely struggling is discordant with our experiences working within a treatment context. We are not alone in our anecdotal impressions that many patients are doing well (Rosmarin, 2020) and that individuals who have engaged in treatment for OCD may be uniquely well-positioned to weather the COVID-19 storm with resilience (Morse, 2020). At the broader societal level, it has been noted that COVID-19 has the potential for positive impacts on mental health and wellbeing, including increased time for exercise, healthy eating, family, and friends (Delgado, 2020).

Given these mixed hypotheses about the impact of COVID-19 on the population we serve, we present both quantitative and qualitative data from eight patients in our residential treatment program. Given the unforeseen nature of this crisis, we did not (nor could we have) systematically design the optimal research methodology to study this question. We acknowledge that ours is not necessarily a representative nor random sample, as we were required to sharply reduce our census, and discharge decisions were based on geography, patients' desires to remain in treatment, and perceived ability to benefit. Nonetheless, rather than leave to speculation, our goal was to bring the empirical data that we do have to bear on the question of how patients in residential treatment for OCD have responded to the ongoing pandemic.

As such, we present data from patients who were (1) admitted prior to COVID-19 restrictions (January 6, 2020–February 24, 2020) and had the experience of our program per usual, and (2) continued in the program throughout a number of COVID-19 impacts (discharged April 7, 2020–May 22, 2020), including a no-visitor policy, being required to stay on unit, mask requirements for patients and staff, changes to meals and their delivery, significant reduction in census to maintain social distancing, and news of confirmed positive COVID-19 staff cases. Typical programming included 2–4 h daily of exposure and response prevention (ERP), four groups daily based on cognitive-behavioral and acceptance and commitment therapy (ACT), and meetings with a behavior therapist (2–3x/week), a family therapist (1x/week), and a psychiatrist (1x/week). Average length of stay was 83.9 days (SD = 17.2, range = 58–106). Patients completed weekly measures of OCD severity (Yale-Brown Obsessive Compulsive Scale, YBOCS; Goodman et al., 1989), quality of life (Quality of Life Enjoyment and Satisfaction Questionnaire, QLES; Endicott et al., 1993), and worry (Penn State Worry Questionnaire-Abbreviated, PSWQ-A; Crittendon and Hopko, 2006). Patients also completed the Dimensional Obsessive–Compulsive Scale at admission to characterize symptom presentation(s) (Abramowitz et al., 2010). Data were collected *via* a larger project that received institutional review board approval and for which patients provided informed consent.

HOW HAVE PATIENTS IN RESIDENTIAL TREATMENT FOR OCD FARED IN THE ERA OF COVID-19?

Mean YBOCS at admission was 23.62 (SD = 6.82, N = 8), corresponding to moderate to severe OCD. **Figure 1** displays patient-reported OCD severity, quality of life, and worry across treatment and suggests that most individuals experienced OCD symptom improvement despite the context of COVID-19. Changes in quality of life and worry were variable across and within patients. Follow-up data were available for five patients (M = 36.4 days after discharge, SD = 8.7, range = 35–49) and generally suggested stability of treatment effects (**Table 1**).

To further support our descriptive, visual, and qualitative data, we examined slopes of each indicator using mixed models to provide quantitative, group-level measures of effect. Mixed models are advantageous for examining longitudinal data in small samples relative to other analytic methods because they maximize power (Muth et al., 2016) and were examined using *nlme* in R (Pinheiro et al., 2019). Similar to individual-level

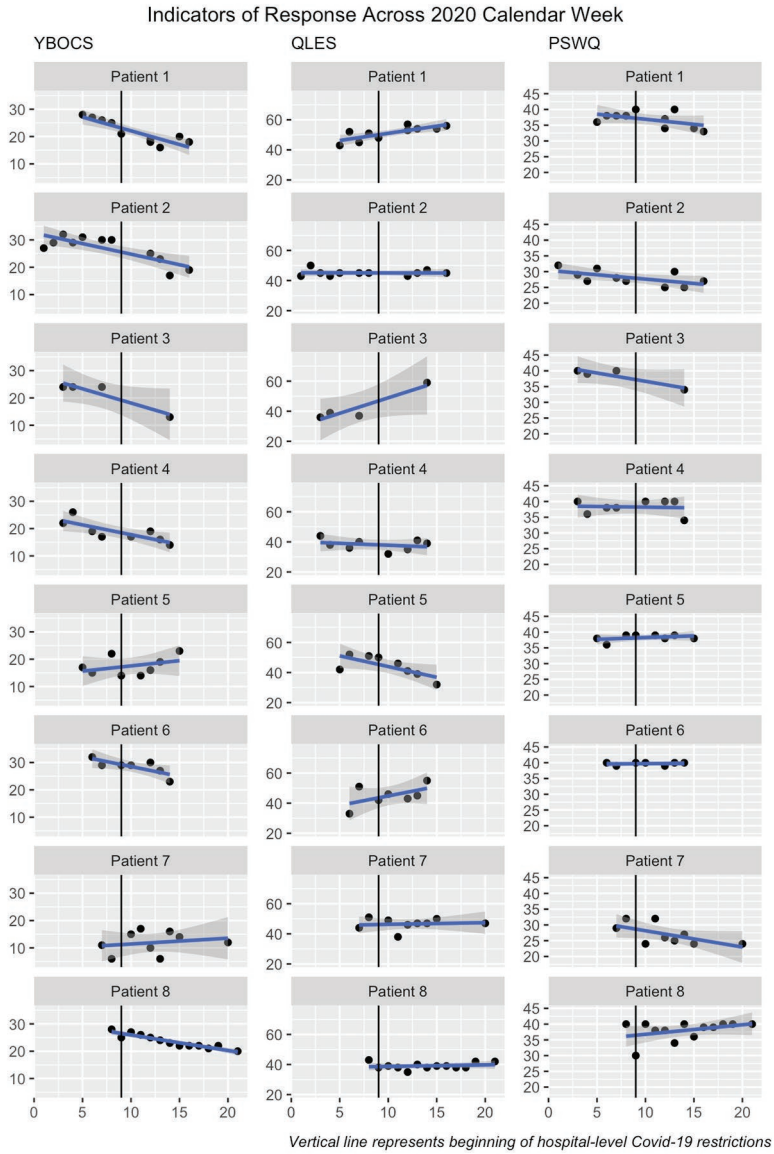

FIGURE 1 | Indicators of response across 2020 calendar week. YBOCS, Yale-Brown Obsessive Compulsive Scale; QLES, Quality Of Life Enjoyment and Satisfaction Questionnaire; PSWQ, Penn State Worry Questionnaire-Abbreviated. Data were visualized with *ggplot2* in R (Wickham et al., 2016).

visualization, these group-level analyses indicated that patients' OCD symptoms declined [$B = -0.50$, SE = 0.15, $t(64) = -3.42$, $p = 0.001$]. On average, there were no changes in quality of life [$B = 0.30$, SE = 0.30, $t(64) = 1.02$, $p = 0.313$] or worry [$B = -0.14$, SE = 0.09, $t(63) = -1.47$, $p = 0.147$].

To provide a rough context for how patients in our program respond in the absence of a pandemic and to account for seasonal effects on mental health (Tan et al., 2017), we examined the same indicators among patients ($N = 10$) who admitted and discharged in the comparable 2019 calendar weeks. Mean YBOCS at admission was 27.50 ($SD = 6.59$). Mixed models indicated that patients' OCD symptoms declined [$B = -0.70$, SE = 0.18, $t(95) = -3.93$, $p < 0.001$]. On average, there were no changes in patients' quality of life [$B = 0.24$, SE = 0.15, $t(90) = 1.56$, $p = 0.122$] but worry did decrease [$B = -0.38$, SE = 0.07, $t(87) = -5.06$, $p < 0.001$].

INDIVIDUAL CASE VIGNETTES

To contextualize individual-level data (**Table 1**; **Figure 1**), we briefly describe each patient's treatment trajectory and response to COVID-19.

Patient 1

This patient presented with symmetry and exactness concerns, perfectionism, harm obsessions, and need to understand. For years, they had avoided phone calls or videoconferencing because

**indicates primary symptom domain.*

YBOCS, Yale-Brown Obsessive Compulsive Scale; QLES, Quality Of Life Enjoyment And Satisfaction Questionnaire; PSWQ, Penn State Worry Questionnaire-Abbreviated; DOCS, Dimensional Obsessive-Compulsive Scale; comprises four categories. Category 1: Concerns about germs and contamination [shaded due to potential relevance to coronavirus disease 2019 (COVID-19)]. Category 2: Concerns about being responsible for harm, injury, or bad luck. Category 3: Unacceptable thoughts. Category 4: Concerns about symmetry, completeness, "just right." BAS, baseline; END, endpoint; FU, follow up. DOCS are presented for baseline only.

of fears of not being able to "control the content." The increasing emphasis on using phone/videoconferencing for treatment amid the pandemic was both highly triggering for this patient and provided motivation to address this issue. This patient reported increased anxiety when staff and patients were required to wear masks, as it triggered their end-of-the-world obsessions, but they were able to implement appropriate coping skills and reported feeling happy about socializing with peers despite masks. By discharge, the patient was able to consistently use audio/video communication for treatment and socially, reporting feeling happy that they were able to connect with their support system in these ways.

Patient 2

This patient presented with contamination symptoms around exposure to everyday chemicals that may alter their existence. The patient expressed little concern about contracting COVID-19 although found that the requirement to increase use of hand sanitizer and soap provided a push toward exposure, as these substances were triggers. The patient reflected that they noticed their parent, who does not have OCD, engaging in behaviors that appeared reassurance seeking and ruminative, and found it interesting that they were able to provide feedback to their parent about the function of these behaviors. This patient continued to make treatment progress before and during the onset of COVID-19 changes.

Patient 3

This patient presented with harm obsessions, perfectionism, scrupulosity, social anxiety, and eating disordered symptoms around food and exercise. The onset of COVID-19 elevated both normative and OCD worries, but also provided opportunities for fuller engagement with treatment goals. This patient's employer was affected by the pandemic, and they reported worrying about how coworkers would pay bills. Upon learning that a unit staff member tested positive, the patient experienced anxiety about not knowing who the staff member was (due to privacy policies) and about potential exposure to that staff member. The patient was anxious about receiving pre-packaged meals and not being able to go to the gym, but was able to be more flexible around these behaviors. Their clinicians noted that the patient remained fully engaged in treatment despite these increased anxieties and spent more time thinking about how to engage in activities with meaning and enjoyment.

Patient 4

This patient presented with harm obsessions and contamination fears resulting in vomiting. Additionally, not-just-right experiences, superstitious obsessions, and agoraphobia symptoms were endorsed. As their ultimate feared consequence within the contamination realm centered on illnesses causing vomiting, COVID-19 was not significantly triggering (beyond the universal anxiety associated with navigating the pandemic). As the pandemic progressed and unit restrictions intensified, the patient was unable to continue public transportation exposures. Even as these restrictions were implemented, they continued to make significant progress and refocused their exposures to target symptoms around vomiting, harm, and food-related obsessions.

Patient 5

This patient presented with concerns around perfectionism, intrusive thoughts, and contamination. The patient reported COVID-19 related stressors and increases in anxiety throughout the pandemic, including feeling hyper-aware of physical symptoms, worry that their partner would be less available due to pandemic-related increased work hours, learning that coworkers had been laid off, and having family members with the virus become seriously ill. The patient reported that these concerns caused them to feel distracted, cry, and experience difficulty sleeping. Nonetheless, throughout this time, exposure coaches rated the patient as highly engaged in perfectionism-related and interoceptive exposure exercises.

Patient 6

This patient presented with fears of rejection, intrusive thoughts, emetophobia, and panic symptoms. When the program reduced patient census due to COVID-19 restrictions, the patient expressed sadness and increased panic due to their closest peers discharging and concern that they would not have people with whom to connect and practice being vulnerable. They described feeling overwhelmed by the impact of COVID-19 on their community, including family members becoming ill. Nonetheless the patient identified positive ways to engage with family and valued activities to maintain structure following discharge and generally remained focused on treatment.

Patient 7

This patient presented with primary skin picking disorder in the context of family stressors along with a variety of "not just right" experiences. The patient exhibited an increase in skills and a decrease in skin picking over the first 3 weeks in treatment. The patient and treatment team were beginning to plan for exposures in the patient's home, but these were paused due to COVID-19 restrictions. Given this limitation and throughout various COVID-19 related changes, this patient expressed concern that they may not receive optimal treatment and considered discharging and returning post-COVID-19 yet ultimately decided to stay. The patient discharged 1 week prematurely due to exhibiting potential symptoms of COVID-19. Overall, the patient made good progress despite setbacks during stressful events and notably completed home-based exposures *via* a newly-developed virtual treatment program following discharge.

Patient 8

This patient presented with harm and contamination symptoms, including fear of bodily fluids and contracting disease. The patient progressed through treatment relatively fluidly despite COVID-19 related changes to their plan. For example, the patient discontinued exposures of brushing against people in crowded areas and shifted instead to similar imaginal exposures. Rather than resisting hand washing following exposure to household surfaces, the patient practiced washing their hands for 20 s and then moving forward to other activities. The patient's therapist noted that the patient "does not seem overtly concerned about the coronavirus" even after another member of the patient's treatment team tested positive. The patient mentioned feeling as though the social connection and activities provided through the program structure were helpful in managing symptoms.

CONCLUSION

Much like the general population, our patients with OCD varied in the ways they were impacted and responded to emerging COVID-19 related events. For some individuals, COVID-19 actually provided opportunities or motivation to more fully engage in exposure (Patients 1, 2) or other treatment goals (Patient 3). At the same time, some patients did encounter COVID-19 related exacerbation of symptoms (Patient 5) or required modifications to their treatment plan due to increased restrictions (Patients 4, 7, and 8). Most commonly, however, patients experienced COVID-19 related stressors due to general societal, familial, and economic consequences of a global pandemic (Patients 3, 5, 6, and 7). For these reasons, it is perhaps unsurprising that patients did not on average experience a significant reduction in worry during COVID-19 (in contrast to treatment effects for 2019 data).

Overall, our data do not support the notion that our patient population uniquely and universally struggled in the face of COVID-19. This is not surprising to us as clinicians. Common refrains we heard echoed from patients at the peak of COVID-19 disruptions were "this is what we've been training for!" and "we have other things that we're worried about." Typically said in a lighthearted way, these statements are illustrative of how our patients have responded: with appropriate in-group humor, fostering a "we're all in this together" attitude, with resilience and acceptance of the present realities. This is not to downplay the ways our patients were personally affected by COVID-19 nor their corresponding experiences of anxiety, fear, and sadness, or the fact that COVID-19 can exacerbate OCD symptoms when aligning with one's obsessional content.

Our patients' responses may mirror our program's treatment model, which emphasizes ERP within the complementary framework of ACT (Twohig et al., 2018). The emphasis in ACT is on having inner experiences without trying to control or push them away (Twohig, 2009). Instead, we can choose to engage in value-driven behaviors despite the context of difficult thoughts and feelings (Twohig, 2009). Through ERP, our patients learn to intentionally approach situations that trigger anxiety and uncertainty with curiosity and openness, with an overarching clinical goal to foster resiliency and flexibility. We have seen our patients embrace this idea even (especially) in the era of COVID-19 in how they utilize their time in treatment and plan for return home amid ongoing restrictions.

There has been much discussion of potential silver linings of COVID-19 at the societal level (Delgado, 2020), and this was true for some of our patients, such as increased opportunities for exposure to avoided situations. Data on the extent to which silver linings have come to fruition in the general public has been mixed (Gallup, 2020). While our patients reported mixed impacts, it is notable that we did not observe massive or consistent declines in quality of life. Most patients did see continued improvements in OCD symptoms, underscoring that effective OCD treatment can and should continue despite COVID-19 (Krompinger et al., 2020).

We appreciate that questions about how our patients are doing during COVID-19 typically stem from a place of caring and concern. So too, however, must we be aware of stigma and implicit assumptions that our patients with OCD may fall apart or cease to function adaptively during this time. It is important to acknowledge the resilience our patients possess, and recognize that the treatment principles patients must master to overcome their symptoms uniquely position

them to cope with situations of unprecedented uncertainty. By acknowledging these facts, we challenge the potential effects of stigma, such as relegating those with OCD to the "sick" or "fragile" role.

It is important to note that our patients were engaged in intensive treatment and thus received significant support and in-person socialization. For some patients, their initial targeted avoidance behaviors (i.e., hand washing) were now prescribed by the CDC and as such, adaptations made to their plans on the fly were thoughtful and in keeping with the underlying principles of ERP. Thus, our setting provides an optimal context and we do not mean to imply that our findings generalize to all individuals with OCD. Rather, we challenge the notion that by definition this population will fare worse than the general public or that ERP treatment cannot proceed effectively because "everyone has OCD."

This pandemic is not over, and continued research on patient longer-term responses is being conducted by our group and others. Meanwhile, we recommend that clinicians continue to encourage individuals with OCD to seek treatment. Given the benefit of social support from other individuals with OCD, we also encourage people with these symptoms to access any number of clinician-led or peer-led support groups available online. The International OCD Foundation[1] is a good place to start.

Adversity History Predicts Self-Reported Autonomic Reactivity and Mental Health in US Residents During the COVID-19 Pandemic

Background: The spread of the COVID-19 virus presents an unprecedented event that rapidly introduced widespread life threat, economic destabilization, and social isolation. The human nervous system is tuned to detect safety and danger, integrating body and brain responses via the autonomic nervous system. Shifts in brain-body states toward danger responses can compromise mental health. For those who have experienced prior potentially traumatic events, the autonomic threat response system may be sensitive to new dangers and these threat responses may mediate the association between prior adversity and current mental health.

Method: The present study collected survey data from adult U.S. residents (n = 1,666; 68% female; Age M = 46.24, SD = 15.14) recruited through websites, mailing lists, social media, and demographically-targeted sampling collected between March and May 2020. Participants reported on their adversity history, subjective experiences of autonomic reactivity, PTSD and depression symptoms, and intensity of worry related to the COVID-19 pandemic using a combination of standardized questionnaires and questions developed for the study. Formal mediation testing was conducted using path analysis and structural equation modeling.

Results: Respondents with prior adversities reported higher levels of destabilized autonomic reactivity, PTSD and depression symptoms, and worry related to COVID-19. Autonomic reactivity mediated the relation between adversity and all mental health variables (standardized indirect effect range for unadjusted models: 0.212–0.340; covariate-adjusted model: 0.183–0.301).

Discussion: The data highlight the important role of autonomic regulation as an intervening variable in mediating the impact of adversity on mental health. Because of the important role that autonomic function plays in the expression of mental health vulnerability, brain-body oriented therapies that promote threat response reduction should be investigated as possible therapeutic targets.

INTRODUCTION

On January 21, 2020, the Centers for Disease Control and Prevention announced the first confirmed case of the 2019 Novel Coronavirus (2019-nCoV) in the United States (1). Following this initial case, the virus spread rapidly throughout the country. Due to the drastic global spread of the virus the World Health Organization labeled the outbreak as a pandemic on March 11, 2020 and a national emergency was declared in the U.S. on March 13 (2, 3). The spread of the COVID-19 virus is an unprecedented event that rapidly introduced the threat of loss of life, severe illness, unemployment, economic destabilization, and social isolation. The danger, uncertainty, and social seclusion all have a potential to jeopardize well-being and mental health, with preliminary data and projections pointing to elevated rates of mental illness and distress (4, 5). Research, health policy, and intervention implementation all require information on factors that impact mental health vulnerability and resilience during this time (6) as well as identifying mechanisms through which mental health is challenged.

The human nervous system is tuned to detect safety and danger, integrating the body and brain through the autonomic nervous system [ANS, (7–9)]. The ANS is crucial for coordinating brain and body functions in safe contexts and promoting defensive bio-behavioral reactions during threat (10–14). The ANS forms efferent (motor) and afferent (sensory) connections that are integrated throughout the brainstem, spinal cord, and body organs. These circuits promote maintenance and reactivity in a range of physical functions such as cardiac output, sweating, breathing, and digestion. Shifts in physiological states toward danger-responses inhibit safety-related functions throughout the body. These shifts, particularly in the long term, can compromise emotional and physical health, influencing cognitive and emotional processes through pathways that connect higher level brain regions with the brainstem (15, 16).

The polyvagal theory describes how the structural and functional organization of human threat response systems are rooted in phylogenetic heritage (7, 8, 16, 17). The emergence of mammals was marked by the integration of ANS pathways with circuits that regulate social communication, forming a neuroanatomical social engagement system that dampens defense responses via the ventral vagal pathway of the parasympathetic nervous system and promotes affiliative social interactions. As proposed by the theory, danger detection can trigger withdrawal of the social engagement system, which can promote responses that include mobilization and immobilization (e.g., shut down). Mobilization states, in the absence of the active social engagement that down-regulates defenses, provide a neural platform for fight and flight behaviors. These mobilization states can contribute to chronic anxiety or irritability. Immobilization states, in turn, provide a platform for withdrawal and depression. Both defensive strategies have adaptive value for protecting the individual from certain types of threat, but interfere with co-regulation and feelings of safety.

Dampened parasympathetic activity is associated with depression, anxiety, and post-traumatic stress disorders (18–21). Although there are many external influences on the ANS, the most direct evidence supporting a causal association between the ANS and mental health come from vagal nerve stimulation (VNS), which uses an electrical current to stimulate vagal afferent pathways that lead from the periphery to the brainstem. There is now substantial evidence that vagal nerve stimulation can improve depression symptoms (22, 23) and modulate anxiety and fear (24, 25), supporting a causal connection between autonomic signaling and emotional well-being.

Prior experience with adversity may sensitize a nervous system toward more pronounced mental and physical health changes in response to danger (15, 26–28). In humans the ANS is developmentally sensitive to safety and threat cues and highly responsive to environmental conditions (29–31). This sensitivity promotes a potential mechanism for how adverse experiences may re-tune nervous systems and alter threat responses to future dangers. Thus, the individual's autonomic state might function as an intervening variable determining whether cues of threat are buffered or function as potent disruptors.

Children and adults with a history of childhood maltreatment are more likely to have blunted parasympathetic activity (32, 33). Dampened parasympathetic activity is associated with post-traumatic stress disorders (19), and can be seen in adults with a maltreatment history even when they do not meet clinical diagnostic criteria for PTSD (27, 32). Evidence for a causal pathway between child maltreatment and autonomic regulation has been demonstrated through randomized intervention studies. In one study, children living in Romanian orphanages with access to physical needs but lacking in emotional caregiver connection exhibited low parasympathetic activity and less flexibility in response to challenges, but those who were randomized into foster care that provided greater emotional interpersonal connection developed autonomic activity much like their peers who had never been institutionalized (34). In a recent study of children referred to Child Protective Services for maltreatment, children developed better parasympathetic flexibility in response to challenges when their caregivers were randomized into a parenting sensitivity intervention compared to peers in a control condition (35).

Taken together, theory and empirical evidence reviewed above supports the possibility that prior adversity could help shape autonomic reactivity in response to threats, which may increase worry in response to danger, and the risk of developing PTSD and depressive symptomology. Those with a prior adversity history are at risk for higher threat-response autonomic activity at rest and stronger responses to threatening challenges (36–38). Recent longitudinal data from a cohort study show that stressful life events measured prior to the pandemic are predictive of emotional distress in young adults (39). The COVID-19 combination of life threat, economic destabilization, and social isolation create a particularly challenging environment for the nervous system, placing individuals at risk of mental and physical problems and exacerbation of pre-existing conditions (40).

Using a combination of social media recruitment and targeted online panels data collection, this cross-sectional survey study sought to examine the relations between prior adversity, autonomic reactivity, mental health, and concerns about the coronavirus during the first months of the pandemic

among U. S. residents (March–May 2020). The specific aim was to examine whether self-reported autonomic reactivity mediates the relationship between prior adversity and current depression/PTSD symptomatology and worry during the COVID-19 pandemic. Based on prior literature, we hypothesized that self-reported autonomic reactivity would be related to previous adversity, current mental health, and worry about COVID-19, and that it would be mediate the relationship between these variables.

MATERIALS AND METHODS

Procedure

The protocol was approved by Indiana University's Institutional Review Board. All participants provided informed consent for the study. Data collection was conducted online from March 29 to May 13, 2020. The study recruited from a general population with inclusion criteria being that participants must be 18 years or older. Recruitment was conducted via social media postings on Twitter, Facebook, Instagram, Reddit, and email lists. Additional recruitment oversampling for male, low income, and non-Caucasian responders in the U.S. was conducted via Qualtrics Panels. Qualtrics Panels consist of respondents who have signed up to participate in online surveys in exchange for incentives including cash, airline miles, and gift cards and can be targeted by demographic categories. Participants who completed the survey through Qualtrics Panels were paid according to their compensation agreement with the service. Paid commercial online panel data has been found to have similar scale internal reliability estimates and effect sizes between variables compared to conventional sampling techniques (41). In the United States, samples recruited by Qualtrics are most demographically similar to a national probability sample compared to other online sampling services (42).

The study landing page, which was linked directly from recruitment advertisements, was accessed 5,240 times. Of these, 3,817 individuals consented to participate. Data quality analysis was conducted by automated checks for poor quality responses and manual inspection. Responses with large sections of identical responses for any one survey section were flagged and checked for plausibility, internal consistency, comparison to item response patterns in prior studies. Responses that did not meet these requirements or had a completion time faster than 25% of the median completion time were excluded.

Measures

Previous Adversity

The Adverse and Traumatic Experiences Scale (43) was created to inquire about a range of adverse and traumatic experiences that had been included in other measures including the ACES (44), Trauma History Questionnaire (45), Life Events Checklist for DSM-5 (46), and Brief Trauma Questionnaire (47). Thus, the measure asks about childhood adverse experiences, childhood maltreatment, other person maltreatment, life-threatening situations, sudden deaths of close ones, and personal health situations. To test study hypotheses, adverse experiences relating to physical health were excluded because of the elevated risk of serious illness due to COVID in those with prior medical conditions. Thus, respondent-reported prior adverse events of maltreatment, life-threatening situations, and sudden deaths of close ones were summed to create an adversity score (range: 0–19).

Self-Reported Autonomic Reactivity

The Body Perception Questionnaire Short Form [BPQ-SF; (48, 49)] was used to measure self-reported experiences of reactivity in organs and tissues that are regulated by the autonomic nervous system. The BPQ-SF has been found to have good psychometric properties, convergent validity with similar measures, and consistent factor structure across samples [(50); Kolacz et al., in preparation; Cerritelli et al., under review]. The combined autonomic reactivity subscale assesses the typical experience of the reactivity of functions above the diaphragm (e.g., sweat in armpits) and gastrointestinal functions (e.g., constipation, indigestion) on a 5-point Liker-type scale (ranging from "never" to "always"). Raw scores were transformed into T scores based on previously collected norms (49). Higher scores on the subscale are indicative of destabilized autonomic reactivity and associated with lower parasympathetic activity, higher resting heart rate, and less parasympathetic and sympathetic flexibility in response to a challenge (Kolacz et al., in preparation).

Post-traumatic Stress Disorder Symptoms

PTSD symptoms were measured using the PTSD Checklist-Civilian Version (51), a 17-item self-report measure assessing level of re-experiencing, avoidance, and hyperarousal related to experiencing a traumatic event. It has been found to have good internal stability, test-retest reliability, convergent validity, and temporal stability (52). The items were developed to correspond to DSM-IV-TR criteria for PTSD (53) and measure problems in response to stressful life experiences over the past month using a five-point Likert-type scale (0 = not all, 1 = a little bit, 2 = moderately, 3 = quite a bit, 4 = extremely). On the PCL-C, endorsement of at least one re-experiencing item, at least three avoidance items, and at least two hyperarousal items is suggestive of symptoms that may meet PTSD diagnosis (54).

Depression Symptoms

The Patient Health Questionnaire-2 was used as a depression screener (55, 56). The instrument inquires about frequency of depressed mood and anhedonia over the past 2 weeks using a 4-point Likert-type scale (0 = not at all, 1 = several days, 2 = more than half the days, and 3 = nearly every day). The scores for the two items are summed to determine a total score, with a score of 3 or greater suggesting that the individual should be assessed further to determine whether depressive disorder criteria is met.

COVID-19-Related Worry

Respondents reported on their extent of worry about becoming infected with the COVID-19 virus, seriously ill due to the virus, unable to access important necessities such as a food and medication, unemployed (i.e., losing their jobs), and less financially stable. For each item, the participants reported their level of worry via a 4-point Likert-type scale (0 = not worried, 1 = a little worried, 2 = somewhat worried, and 3 = very worried).

Data Analysis

Analysis was conducted in R 3.6.2 (57). Continuous variables were examined for group differences using Welch's unequal variances *t*-test, a more robust alternative to Student's *t*-test for groups that may have unequal variances or sample sizes (58); categorical variables were examined with $\chi 2$ tests; and ordinal variables with Mann-Whitney-Wilcoxon tests. Cohen's d was used to determine standardized mean difference, a measure of effect size of differences between groups.

Formal mediation analysis was conducted using path analysis and structural equation modeling using the Lavaan package (59). Mediation models are statistical tests that assess whether the association between an independent and dependent variable can be attributed to the effect of a third variable (60–62). In mediation analysis, the strength of mediation is represented via the indirect effect (the product of the coefficient of the independent variable on the mediator and the mediator on the outcome variable). The direct effect is the association of the independent variable on the dependent variable, adjusting for the effect of the hypothesized mediator. The total effect is the sum of the direct and indirect effects.

Models were estimated using diagonally-weighted least squares. The full weight matrix was used to compute robust standard errors, and the test statistic was mean- and variance-adjusted. Indirect and total effect confidence intervals were calculated using bias-corrected adjusted bootstrap percentiles with 5,000 draws. Compared to other mediation estimation methods, this method has been found to have superior power for detecting true effects with accurate Type I error rates (63). Mediation was supported if the bootstrapped 95% confidence interval around the indirect effect did not include 0. Total effects were examined for evidence of divergence of direction between direct and indirect effects, which may weaken, nullify, or reverse the indirect effect. Binary endogenous variables were modeled using probit link functions. Age and gender were included as exogenous variables to adjust model estimates.

Model fit was evaluated using the root mean squared error of approximation [RMSEA; (64)], the Tucker-Lewis Index [TLI; (65)]; and the Comparative Fit Index [CFI; (66)]. Based on recommendations from Hu and Bentler (67), good model fit was evidenced by RMSEA values near or below 0.06 as well as CFI and TLI values near or above 0.95. When model fit was poor, modification indices were cautiously examined to determine whether freeing certain parameters would improve model fit. Modification indices provide data-driven information on the amount that model fit would improve if a single parameter restriction were lifted from the model. Given that modification indices are susceptible to capitalizing on chance characteristics of the data (68), decisions based on modification indices were used sparingly and applied only when the resulting model change could be supported by theory.

RESULTS

The final sample size, excluding incomplete responses (n = 995), poor-quality data (n = 303 from the paid panel recruitment, n = 2 from the social media recruitment), and demographic criteria (e.g., non-US citizen; n = 851) was 1,666 (See **Supplementary Materials** for a detailed consort diagram). Demographic variable descriptive statistics are reported in **Table 1**. Survey respondents ranged from 18 to 88 years of age (M = 45.87; SD = 16.17) and were slightly oversampled with regard to females, high yearly household income (>50% reporting $60 k or more), and higher levels of education (44.5% holding a graduate degree).

Unspecified	2 (0.1%)

Autonomic reactivity T scores had similar distributional features to those reported in previous studies (M = 48.07, SD = 10.15, Range: 33.23–83.45) (49, 50). The mean number of prior adverse events was 5.93 (SD = 4.86; range: 0–19). Respondents reported high levels of worry about the negative effects of COVID-19, with the highest levels of worry relating to infection, serious illness caused by the virus, and loss of financial stability (**Table 2**). Of the respondents, 93.7% reported at least a little worry about 1 or more threats associated with the virus,

TABLE 2 | COVID-19-related worry response distributions.

COVID-19 worry variable	Not worried (%)	A little worried (%)	Somewhat worried (%)	Very worried (%)
Becoming infected with COVID-19 virus	17.54	35.80	29.55	17.12
Becoming seriously ill because of coronavirus	22.56	34.72	25.87	16.85
Being unable to get important necessities	36.93	26.75	21.87	14.46
Being unable to get necessary medications	44.80	24.26	18.20	12.73
Losing job	49.12	18.47	14.48	17.92
Becoming less financially stable	23.00	26.49	23.42	27.09

27.8% met symptom criteria for post-traumatic stress disorder, and 28.7% met symptom criteria for depression.

Pearson and point-biserial correlations for continuous and binary variables are presented in **Table 3**. Age had a very small negative association with number of prior adversities ($r = -0.07$). In addition, age had a negative relation with self-reported autonomic reactivity ($r = -0.23$) and more advanced age was associated with a lower probability of depression and PTSD symptoms ($r = -0.26$ and -0.27, respectively). Higher numbers of previous adverse events were associated with higher values of autonomic reactivity ($r = 0.60$, $p < 0.0001$). Respondents with depression symptoms had more prior adverse experiences (No symptoms M = 5.07, SD = 4.10; Symptoms M = 8.10, SD = 5.84; $t_{(664.49)} = 10.317$, $p < 0.0001$, Cohen's d = 0.65). Those who had PTSD symptoms likewise had more prior adverse experiences (No symptoms M = 4.72, SD = 3.67; Symptoms M = 9.07, SD = 6.17; $t_{(590.11)} = 14.465$, $p < 0.0001$, Cohen's d = 0.98). Respondents who met depression criteria reported more destabilized autonomic reactivity [No symptoms M = 45.18, SD = 8.99; Symptoms M = 55.28, SD = 12.37, $t_{(686.98)} = 16.201$, $p < 0.0001$, Cohen's d = 1.00]. Likewise, destabilized autonomic reactivity was also greater in those who met PTSD criteria (No symptoms M = 44.56, SD = 8.05; Symptoms M = 57.13, SD = 12.45, $t_{(616.82)} = 20.17$, $p < 0.0001$, Cohen's d = 1.33). Household income was not associated with number of adverse experiences (rho = 0.01, $p = 0.77$) or autonomic reactivity (rho = −0.05, $p = 0.05$). There were significant but small negative associations of household income and education with depression (rho = −0.10, $p < 0.001$; rho = −0.05, $p = 0.03$, respectively) and PTSD symptoms (rho = −0.10, $p < 0.001$; rho = −0.07, $p = 0.01$, respectively).

Younger respondents expressed more worry about loss of access to necessities, loss of access to medication, loss of job, and loss of financial stability due to the coronavirus (age and worry item rho = −0.21, −0.18, −0.30, −0.24, respectively; all $p < 0.001$) but there were no associations of age with worry about contracting the virus or becoming seriously ill because of it (rho = −0.02, $p = 0.39$; rho = 0.03, $p = 0.29$; respectively).

TABLE 3 | Means, standard deviations, ranges, and correlations with confidence intervals.

Variable	1	2	3	4
1. Age				
2. Prior adversities	−0.07** [−0.12, −0.02]			
3. Autonomic reactivity	−0.23** [−0.27, −0.18]	0.60** [0.57, 0.63]

5. PTSD symptoms (Binary)	−0.27** [−0.31, −0.22]	0.40** [0.36, 0.44]	0.51** [0.47, 0.55]	0.54** [0.50, 0.57]

*Values in square brackets indicate the 95% confidence interval for each correlation coefficient. *p < 0.05. **p < 0.01.*
Correlations between continuous variables are calculated using Pearson's correlation coefficient and those including binary variables are point-biserial correlations.

COVID-Related Worry Measurement Model

Modeling began with establishing a COVID-19 worry using a reflective measurement model. In this model, each worry indicator has a unique influence independent of others and is also influenced by a general worry latent factor (69). Modification indices supported the need for free co-variances between (a) worry about infection and worry about becoming seriously ill and (b) worry about losing one's job and becoming less financially stable (i.e., these paths were not constrained to 0). These appeared to reflect the added correlation of infection-related and income-related worries and could thus be justified as modifications to the model. When these covariances were included, the measurement model fit the data well ($\chi 2 = 12.264$, df = 7, CFI = 1.000, TLI = 1.000; **Figure 1A**).

Model Building

Modeling proceeded by conducting individual tests of mediation for each outcome variable–PTSD symptoms, depression symptoms, and COVID-19-related worry.

First, joint variable distributions of adversity history, self-reported autonomic reactivity, and PTSD symptoms were examined. Formal testing supported the mediation of autonomic reactivity between adversity history and PTSD symptoms (standardized indirect effect = 0.340 [95% CI: 0.291, 0.390], standardized total effect = 0.532 [95% CI: 0.462, 0.602]; **Figure 1B**). Second, key variable relations with depression symptoms were examined. Formal testing supported the mediation of autonomic reactivity between adversity history and depression symptoms (standardized indirect effect = 0.293

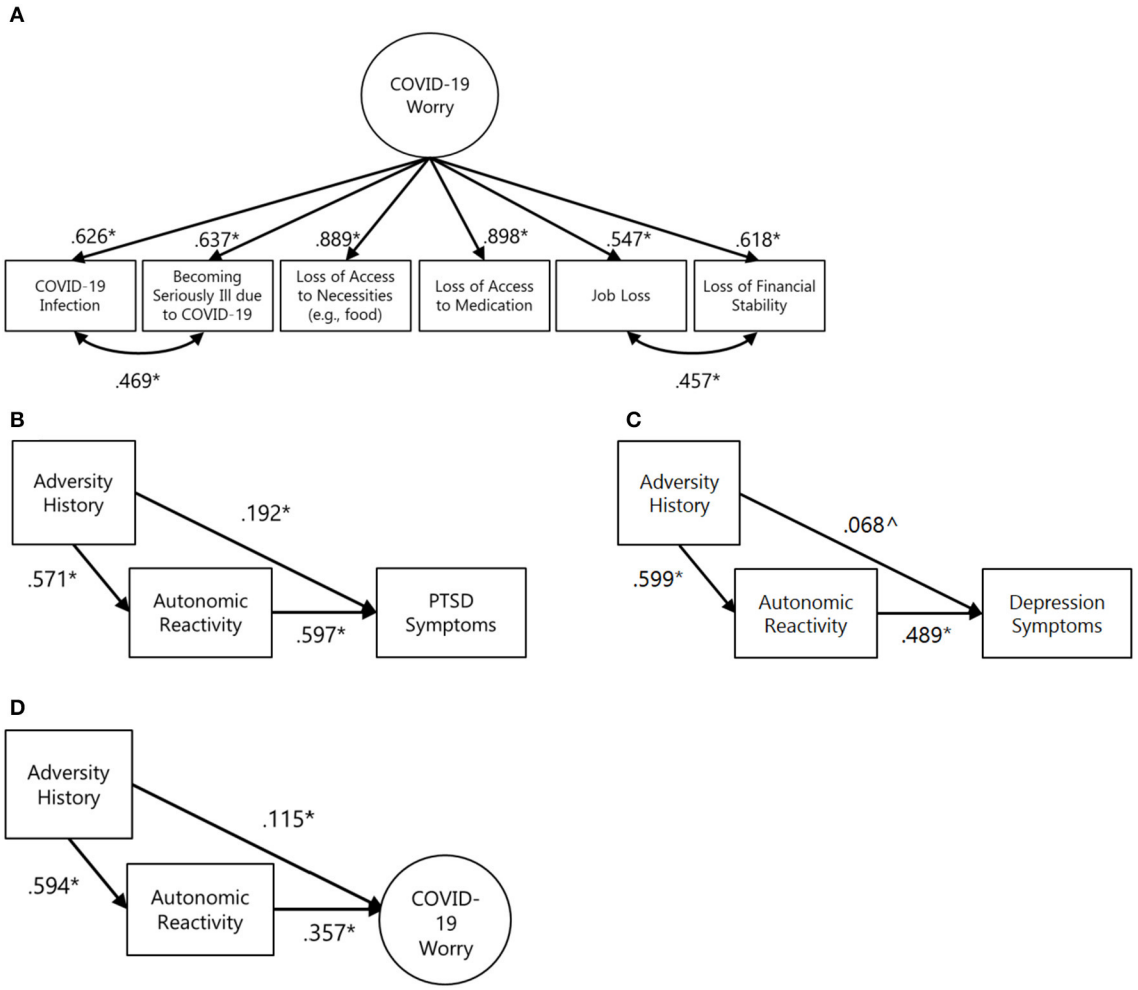

FIGURE 1 | COVID-19 worry measurement model and preliminary, unadjusted mediation models for individual predictors. In all figures: $^*p < 0.05$, $^p < 0.10$. **(A)** COVID-19 worry measurement model. Model fit indices: $\chi 2 = 12.264$, df = 7, RMSEA = 0.021 [90% CI: 0.000, 0.041] CFI = 1.000 TLI = 1.000 **(B)** Unadjusted mediation test for PTSD symptom outcome with standardized coefficients. Model fit indices not available due to model saturation. Standardized indirect effect = 0.340 [95% CI: 0.291, 0.390], standardized total effect = 0.532 [95% CI: 0.462, 0.602]. **(C)** Unadjusted mediation test for depression symptom outcome with standardized coefficients. Model fit indices not available due to model saturation. Standardized indirect effect = 0.293 [95% CI: 0.244, 0.342], standardized total effect = 0.361 [95% CI: 0.296, 0.429]. **(D)** Unadjusted mediation test for COVID-related worry outcomes with standardized coefficients. $\chi 2 = 27.045$, df = 17, RMSEA = 0.019 [90% CI: 0.000, 0.032] CFI = 1.000 TLI = 1.000. Standardized indirect effect = 0.212 [95% CI: 0.160, 0.266], standardized total effect = 0.327 [95% CI: 0.264, 0.385].

[95% CI: 0.244, 0.342], standardized total effect = 0.361 [95% CI: 0.296, 0.429]; **Figure 1C**). Third, key variable relations with COVID-related worry was examined. The extent of worry was positively associated with autonomic reactivity ($r = 0.357$). As above, formal testing supported the mediation of autonomic reactivity between adversity history and COVID-related worry (standardized indirect effect = 0.212 [95% CI: 0.160, 0.266], standardized total effect = 0.327 [95% CI: 0.264, 0.385]; **Figure 1D**).

The three mediation models were combined to test the independence of effects, with gender and age included as exogenous predictors of adversity history, autonomic reactivity, and all outcome variables. Due to small numbers of respondents who identified as non-binary or transgender ($n = 14$), only male and female effects could be included in the model. Model results are presented in **Figure 2**. All outcome variables were positively correlated, with the strongest association being between PTSD and depression symptoms ($r = 0.537$). Adjusting for age, gender, and the mutual associations between outcome variables, formal testing supported the mediation of autonomic reactivity in the link between adversity history and PTSD symptoms, depression symptoms, and COVID-19-related worry (**Figure 3**). Inclusion of household income in sensitivity analyses did not substantively affect the pattern of results.

DISCUSSION

This cross-sectional survey study focused on a large general sample of US residents and the factors that may influence patterns of mental health in response to the coronavirus pandemic. It examined the potential impact of adversity (i.e., childhood adversity/maltreatment, intimate partner

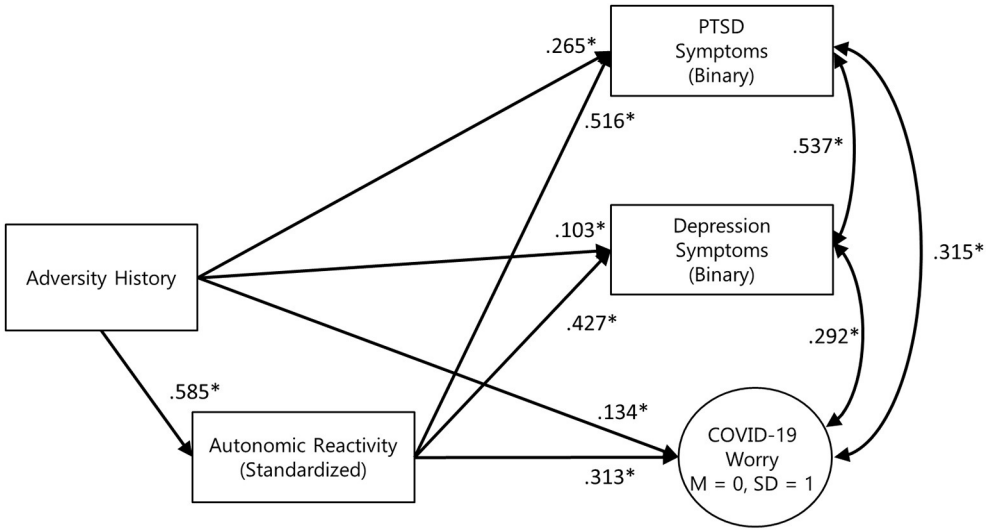

FIGURE 2 | Simplified final model diagram of the 3-outcome mediation model, adjusted for age and sex. Model fit indices: $\chi 2 = 216.853$, df = 37, RMSEA = 0.056 [90% CI: 0.049, 0.063] CFI = 0.994 TLI = 0.994. PTSD symptom standardized indirect effect = 0.301 [95% CI: 0.251, 0.354], standardized total effect = 0.558 [95% CI: 0.476, 0.631]. Depression symptom standardized indirect effect = 0.250 [95% CI: 0.202, 0.303], standardized total effect = 0.353 [95% CI: 0.283, 0.423]. COVID-19 worry standardized indirect effect = 0.183 [95% CI: 0.130, 0.237], standardized total effect = 0.318 [95% CI: 0.255, 0.383].

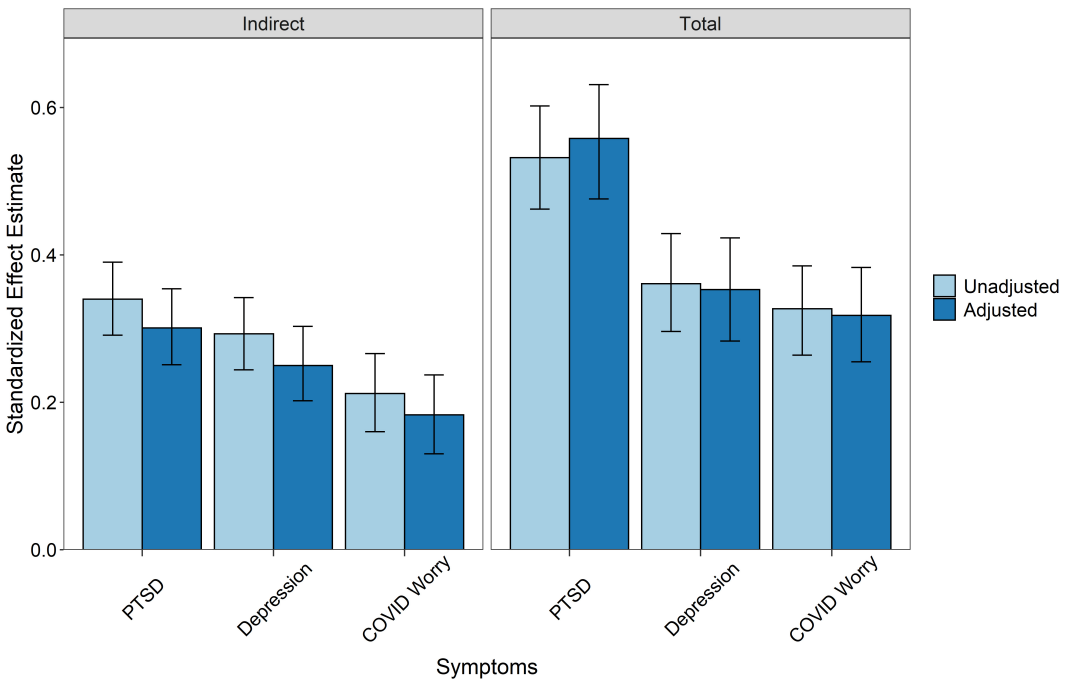

FIGURE 3 | Indirect and total effects from mediation models with 95% confidence intervals. Indirect effects represent the mediation strength of the adversity -> self-reported autonomic reactivity -> outcome pathway. The total effects are the sum of direct and indirect effects in the models. Unadjusted models are calculated using the paths between the three key variables only. Unadjusted estimates for the PTSD model: Standardized indirect effect = 0.340 [95% CI: 0.291, 0.390], standardized total effect = 0.532 [95% CI: 0.462, 0.602]. Unadjusted estimates for the depression model: Standardized indirect effect = 0.293 [95% CI: 0.244, 0.342], standardized total effect = 0.361 [95% CI: 0.296, 0.429]. Unadjusted estimates for the COVID-19 worry model: Standardized indirect effect = 0.212 [95% CI: 0.160, 0.266], standardized total effect = 0.327 [95% CI: 0.264, 0.385]. Adjusted models include all outcome variables with gender and age covariates. PTSD symptom standardized indirect effect = 0.301 [95% CI: 0.251, 0.354], standardized total effect = 0.558 [95% CI: 0.476, 0.631]. Depression symptom standardized indirect effect = 0.250 [95% CI: 0.202, 0.303], standardized total effect = 0.353 [95% CI: 0.283, 0.423]. COVID-19 worry standardized indirect effect = 0.183 [95% CI: 0.130, 0.237], standardized total effect = 0.318 [95% CI: 0.255, 0.383].

maltreatment, life-threatening events, and sudden losses) and self-reported autonomic reactivity. The results support the hypothesis that self-reported autonomic reactivity was related to previous adversity and current mental health. Destabilized autonomic reactivity scores were higher in respondents that reported experiencing more prior adverse events, and those who met the symptom criteria for depression and/or PTSD.

This study suggests that prior adversity history is a risk factor for mental health and worry during the COVID-19 pandemic, and that these effects are mediated by autonomic dysregulation. To our knowledge, this is the first study to examine the link between adversity history, autonomic reactivity, and a large-scale external stressor such as a pandemic. Adjusting for age, gender, and the mutual associations between outcome variables, formal testing supported the mediation of autonomic reactivity in the link between prior adversity and PTSD symptoms, depression symptoms, and COVID-19-related worry. These findings are consistent with Polyvagal Theory and previous research suggesting that individuals who experience adversity are at increased risk of developing chronic and sensitized threat responses to new challenges (27, 32). They are also consistent with research suggesting that autonomic dysregulation is a linking component that is found in a range of clinical conditions including anxiety (70), disorders of impulse control (71), borderline personality disorder (72), and PTSD (73). The mechanism in this study may also be related to neuroticism, a relatively stable tendency to respond to events with negative emotions and lability, which appears to increase risk of mental health disorders (74). Sensitized or chronic autonomic threat reactions may influence long term patterns of emotional responses toward negativity. There is some evidence of dampened parasympathetic regulation and sensitized physiological reactivity in those who fit a neurotic profile (75, 76) though this connection has been understudied in the context of adversity history and responses to prolonged external danger.

Although the current study does not focus on a clinical sample, the result suggesting that autonomic reactivity may be a mechanism linking adversity and psychological function may have implications for mental health intervention and prevention strategies. These results point to the brain-body threat-response circuits that impact physical, emotional, and cognitive function, suggesting that improving their regulation during a crisis may be a promising target for improving mental health and worry. Thus, it may be beneficial for research to examine how therapeutic strategies for dampening chronic threat responses and improving safety-related regulation as part of trauma interventions can help individuals whose nervous systems are biased toward mobilization and/or shut down. These safety-focused strategies could help with the stabilization that is needed prior to attempting other approaches, especially those involving exposure therapy.

Our results are consistent with clinical insights that individuals experiencing mental health symptoms may benefit from interventions with bottom-up approaches focused on the affect and feelings within the body [i.e., body-based or sensorimotor; (77)]. These approaches (e.g., sensorimotor psychotherapy and relaxation training) use interoception techniques (i.e., the noting of sensations, discomforts, pain, tension, pleasurers, and cues) to increase positive feelings toward physical sensations and help with integrating sensations and body regulation (78). Interventions including yoga (79), mindfulness-based stress reduction (80), and biofeedback (81) have been shown to reduce threat-responsive autonomic reactivity and have benefits for mental health. Additional research should explore their use as a therapeutic method or as part of a multi-method intervention to assist with coping during large scale crises such as the COVID-19 pandemic.

In addition, laboratory studies have shown that social connections can inhibit threat responses and promote affiliative safety states (82, 83). The social distancing and isolation strategies put in place by government mandates and individual decisions to reduce the spread for the COVID-19 virus may be detrimental if they decrease opportunities for co-regulation with others to reduce the impacts of threat response reactivity. This suggests that research into the promotion of opportunities for socioemotional connections during times of physical distancing is an important target to improve understanding of how clinicians can support coping mechanisms and help clients regulate threat responses.

Limitations

This study is not without limitations, including the use of social media for online data collection. To reduce the data bias, procedures were followed to evaluate data quality using a combination of attention checks and statistically or logically implausible response patterns. Given the social media sampling strategy, this study was not designed to assess nationally representative prevalence rates, though the relations between variables are consistent with prior literature based on objective measures, experimental methods, and prospective designs. The strength of the cross-sectional design selected for this study is the ability to rapidly collect data using validated measures to provide a picture of responses during the first months of the pandemic.

Another limitation relates to the use of self-report measures. Retrospective reporting of prior adverse events may induce bias both toward over- or under-reporting, which can contribute to decreasing reliability and validity of measurement (84) and bias the associations of self-reports compared to objective reports (85). However, the strengths of adversity self-reports include sensitivity for events that may not have been captured by prospective measures, such as the low documentation of sexual abuse in official records (85). In addition, the psychometric properties of the COVID-19 worry measure have not yet been examined in other datasets. The measure was created by a team of researchers and clinicians to address pressing needs at a time when no validated measure was available. The measurement model described in this study provides a starting point for additional psychometric study in the future. Follow up studies will need to examine test-retest reliability, validity, and whether the factor structure of worry is consistent across samples.

Further, due to single time point design it is unknown if the participants were already experiencing symptoms of PTSD, depression, and economic worry prior to the pandemic. Objective autonomic monitoring and prospective longitudinal designs are

needed to support the findings reported here, and to better establish temporal precedence. However, the results presented here are consistent with longitudinal data that show adverse experiences reported prior to the onset of the pandemic are a predictor of emotional distress (39). Thus, there is a need for prospective longitudinal research that allows for a better understanding about how changes in mental health relate to autonomic reactivity and regulation. Future research should also address the contributions of cognitive processes, such as posttraumatic growth and worldview, which are affected by adversity.

CONCLUSION

The autonomic nervous system (ANS) integrates brain-body threat responses. Prior adversity may sensitize individuals toward autonomic threat responses that increase risk of mental health and worry during crises such as the COVID-19 pandemic. In light of prior literature that shows the ANS to be sensitive to context and a useful therapeutic target, the results support the need for research on whether reduction of bio-behavioral threat responses and improvement of safety-related autonomic function could be effective treatment strategies, particularly during chronic, uncontrollable stressors.

Front. Psychol. 11:563876. doi: 10.3389/fpsyg.2020.563876

We conducted a rapid review and quantitative summary of meta-analyses that have examined interventions which can be used by individuals during quarantine and social distancing to manage anxiety, depression, stress, and subjective well-being. A literature search yielded 34 meta-analyses (total number of studies k = 1,390, n = 145,744) that were summarized. Overall, self-guided interventions showed small to medium effects in comparison to control groups. In particular, self-guided therapeutic approaches (including cognitive-behavioral, mindfulness, and acceptance-based interventions), selected positive psychology interventions, and multi-component and activity-based interventions (music, physical exercise) showed promising evidence for effectiveness. Overall, self-guided interventions on average did not show the same degree of effectiveness as traditional guided individual or group therapies. There was no consistent evidence of dose effects, baseline differences, and differential effectiveness of eHealth interventions. More research on the effectiveness of interventions in diverse cultural settings is needed.

Keywords: COVID-19, meta-analysis, self-guided interventions, depression, anxiety, culture, stress, subjective well-being

IMPACT STATEMENT

Social distancing measures are effective in reducing viral spread in the current COVID-19 pandemic but have been shown to increase mental health burdens. These collateral effects are affecting large numbers of individuals globally, requiring urgent attention because of the strains on mental health providers struggling to provide adequate support for people in need. Although there are many self-help guidelines available online and via social media, it is unclear how effective these are. We provide a quantitative review of evidence-based practices that can be used by individuals at home or in confined physical environments during social distancing and quarantine to manage anxiety, depression, and stress. Given the likely continuation of social

distancing measures in various parts of the world and shortages in mental health systems globally, our systematic review provides evidence on effective self-guided interventions, either as an initial stand-alone self-help intervention or while waiting for treatment.

INTRODUCTION

What strategies can an individual adopt to maintain good mental health and reduce anxiety and stress during quarantines and physical distancing? Quarantines are psychologically taxing (Brooks et al., 2020), yet quarantines and physical distancing are core behavioral strategies for containing the spread of communicable diseases such as COVID-19. Levels of depression, anxiety, and psychological stress tend to be significantly elevated and can reach clinical levels in both disease survivors as well as the general population during pandemics. For example, Reynolds et al. (2008) reported that over 40% of quarantined Canadians in their sample reported high levels of worry. In the context of the COVID-19 pandemic, Wang et al. (2020) found that 28% of Chinese respondents reported clinically relevant levels of anxiety. Across both studies, over 50% of the sample indicated moderate to high levels of stress. The long-term psychological consequences of quarantine can last for months or possibly years (Brooks et al., 2020; Ho et al., 2020). The current COVID-19 (SARS-CoV-2) pandemic is affecting individuals globally at an unprecedented scale. Although widespread physical distancing measures appears effective in mitigating the spread of COVID-19 (Milne and Xie, 2020), the psychological ramifications of social distancing may result in increased levels of mental health problems in the near-term future.

Public mental health resources are finite, and the mental health services currently available are unlikely to cope with the emerging demands (Dong and Bouey, 2020; Duan and Zhu, 2020; Xiang et al., 2020). Addressing mental health needs within a physical distancing context is critical, given the possibility of continued movement restrictions in the near future to combat repeated outbreaks of SARS-CoV-2 (Kissler et al., 2020). To bolster available mental health services, while also reducing the likelihood of virus transmission, there has been a recent drive to convert usual face-to-face mental health treatments into an online or tele-health format.

However, while such modifications are no doubt vital, they represent only one building block of an organized mental health response, particularly when dealing with a pandemic such as COVID-19. Furthermore, even with increased use of tele-health measures by mental health providers, the shortage of trained professionals coupled with the increased demand on public health services highlights the need for effective and evidence-based self-guided therapeutic interventions (Duan and Zhu, 2020). The "*World Health Organization Service Organization Pyramid for an Optimal Mix of Services for Mental Health*" highlights self-care approaches (actions taken by individuals to improve their well-being) as an essential component of optimal mental health care (World Health Organization, 2003). In order to promote resilience and to appropriately manage the emerging mental health impacts of the ongoing COVID-19 pandemic, it is necessary to identify effective self-guided approaches to manage the psychological demands experienced during such outbreaks. Self-guided interventions can provide a first point of intervention for concerned individuals to alleviate anxieties, stress and worries, decrease negative mood and depressive symptoms, and increase positive psychological functioning and subjective well-being, either as a stand-alone intervention or while waiting for treatment. Although there are many self-help guidelines available online and via social media, it is unclear how effective these are and how well they are grounded in scientific evidence.

The goal of our rapid review is to provide a broad summary of the current evidence drawn from published meta-analyses in order to evaluate the effectiveness of self-guided therapeutic practices which can be implemented by individuals on their own, including during physical distancing and quarantine measures. We focused on published meta-analyses of randomized controlled trials (RCT) or experimental studies that evaluate the effectiveness of psychological interventions and strategies for a range of psychological outcomes. In particular, we focus on increasing subjective well-being (including life satisfaction, quality of life, happiness), and decreasing anxiety, depression, or stress as key outcomes. Critically, we screened all meta-analyses identified by our search parameters, but only summarize evidence from those meta-analyses which included self-guided conditions which can be performed by individuals alone without the guidance of trained health professionals. Our meta-analysis is more inclusive in scope because previous meta-analyses have: (a) typically focused on either a specific type of intervention or compared a small number of interventions without considering the wider range of possible interventions that might be beneficial; or (b) did not specifically consider the relevance and evidence of self-guided practices that could be performed by individuals alone. Thus, our primary aim is to provide a comparative summary of the available evidence of diverse psychological strategies that can inform recommendations by public health workers and psychologists, as well as be made available to the larger public. The COVID-19 pandemic affects populations of all nations, but interventions are often conducted with Western, industrialized and individualistic samples (Henrich et al., 2010), requiring more attention to cultural differences in effectiveness. We therefore evaluated whether the meta-analyses included in this review reported differences in treatment effectiveness for individuals from different cultural backgrounds. We focus on interventions that might be applicable in the current pandemic (and beyond), but explicitly stress that our data is not based on interventions conducted during the current COVID-19 pandemic. In order to provide actionable advice, we provide an electronic supplement containing selected self-guided exercises based on evidence gathered in this review. These exercises and tasks were selected with attention to possible applications across different cultural and economic contexts.

METHOD

We performed a PsycInfo and MedLine search on March 22, 2020 to identify meta-analyses that have summarized RCTs or experimental studies that report the effectiveness of interventions on anxiety, depression, stress, or subjective well-being in human

populations. The exact search terms and their combination are listed in **Appendix A**. The inclusion criteria for our review were: (a) quantitative meta-analysis of RCTs or experimental studies; (b) conducted with general populations, clinical or non-clinical samples, or samples selected for anxiety or depression symptoms; (c) the sample was on average 18 years or older; (d) measures of anxiety, depression, stress, or subjective well-being were included; (e) the meta-analysis included interventions that are self-guided or could be used by individuals without supervision or guidance by a trainer, therapist, or mental health professional; and (f) reported sufficient information on effect sizes. Where available, relevant moderator conditions were also extracted for further analysis. We decided to include anxiety and depression clinical samples due to the reported increase of anxiety and depression during quarantines (Brooks et al., 2020). The exclusion criteria for our review were: (a) clinical or patient populations other than individuals or groups with clinical anxiety and depression symptoms; (b) meta-analyses of group-based interventions; (c) meta-analyses of individual therapies or interventions led by or supervised/assisted by another person; (d) meta-analyses that did not clearly report on conditions in criteria a-c; (e) meta-analyses focusing exclusively on children or adolescents; (f) systematic reviews; (g) meta-analyses of cross-sectional or correlational studies; and (h) not published in a peer-reviewed English language journal. Regarding group and clinician-led interventions, we included meta-analyses if the authors tested delivery and application effects and found no significant differences between self-guided and other applications. If a meta-analysis examined those differences and reported differential effects for self-guided interventions, we only included those effect sizes relevant for self-guided interventions.

We identified a substantial number of meta-analyses which examined the effectiveness of specific interventions, particularly for contemporary therapeutic approaches such as mindfulness and acceptance and commitment therapy (e.g., Hayes et al., 2012). Using all eligible meta-analyses may mean that identical primary studies might be included in a series of meta-analyses, leading to potential double-counting and duplication of effect sizes that would bias the overall patterns. To overcome this problem, we adopted the following strategies. First, we screened meta-analyses in a reverse temporal order, starting with the most recent meta-analyses per category. We then identified overlap in included primary studies between subsequent meta-analyses per outcome variable. If there was a 50% overlap or larger between two meta-analyses for a specific outcome variable, we included only the meta-analysis with the larger sample size. We still examined smaller meta-analyses to check if they reported moderator analyses of interest for our purposes, particularly the effectiveness of self-guided vs. other-guided or group interventions and differences in effectiveness between different cultural samples. As not all meta-analyses provided estimates for each of the outcomes of interest in this review, we repeated this process for each outcome variable. See **Figure 1** for a PRISMA diagram of the selection process.

META-META-ANALYSIS APPROACH

We present the average effect size and 95% confidence interval as reported in the original meta-analyses in the form of a forest plot. The most common effect sizes are variations of the standardized mean difference (typically d or g), therefore, we use these metrics for plotting the effects. If no confidence interval was reported, only the mean effect size is displayed.

However, this visual display does not easily allow a statistical summary of the overall effect sizes. Therefore, we converted standardized mean differences into r and then z-transformed r (Rosenthal, 1991). As expected, the transformed effect size and the original effect size correlated $r = 1.0$. Inverse variance weights were calculated from sample sizes. If only the overall sample size was available, we used the average sample size per study to estimate sample sizes for subgroups. The average effect sizes per intervention category were computed using rma with REML estimation in the metafor package in R (Viechtbauer, 2010). We report the unstandardized regression weights.

RESULTS

Participant Characteristics

Our sample of meta-analyses included 34 meta-analyses (total number of studies $k = 1{,}390$, $n = 145{,}744$). The majority of meta-analyses included general population samples, including working adults (meta-analysis $k = 16$). The second largest sample group were mixed general population and clinical samples (meta-analysis $k = 11$). Purely clinical samples were included in 4 meta-analyses and students were the primary population in 3 meta-analyses. All but one meta-analysis (Dickens, 2017) exclusively focused on adult populations. Only 5 meta-analyses explicitly reported and tested cross-cultural differences.

Qualitative Review of Published Meta-Analyses

We used two approaches to evaluate the relative effectiveness of self-guided interventions. First, we used Cohen (1988) effect size benchmarks to specify small ($d = 0.2$), medium ($d = 0.5$), and large ($d = 0.8$) effect sizes of standardized mean differences. This first allows us to assess the overall effectiveness of self-guided interventions compared to control interventions (typically, waitlist, or active control groups). Second, we compared the overall effect sizes of self-guided interventions against effectiveness benchmarks of traditional clinician-guided psychotherapy for reducing depression symptoms (Cuijpers et al., 2020). The overall effect size of traditional clinician-guided psychotherapy on depression was $g = 0.72$ ($k = 385$), with Cognitive-Behavioral Therapy (CBT) showing an effectiveness of $g = 0.73$ ($k = 205$); Behavioral Activation Theory $g = 1.05$ ($k = 21$), and third-wave therapies (including Acceptance and Commitment Therapy [ACT] and Mindfulness-Based Interventions [MBI]) an effectiveness of $g = 0.85$ ($k = 19$).

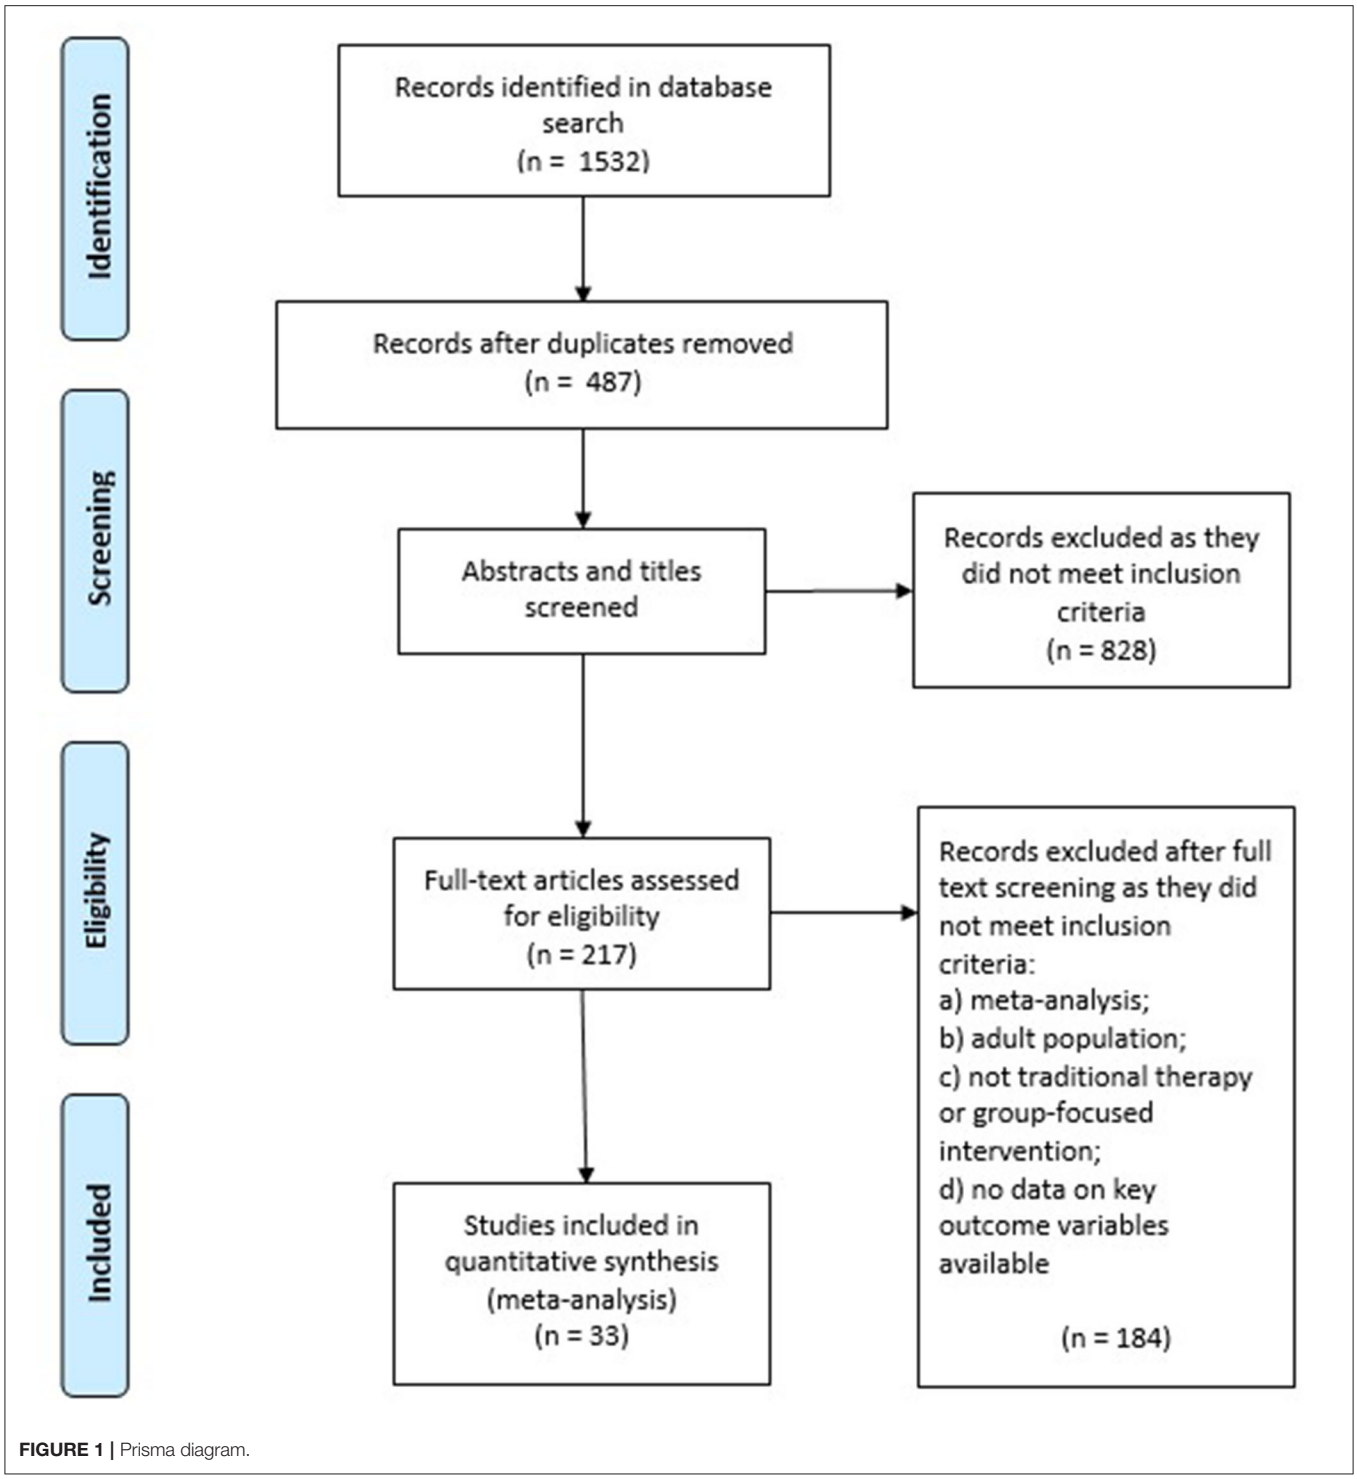

FIGURE 1 | Prisma diagram.

Effectiveness Across Types of Self-Guided Interventions

Table 1 shows an overview of the meta-analyses included in this review. The large majority of psychological intervention meta-analyses that were eligible to be included in our review consisted of meta-analyses of clinical psychology therapy-derived interventions ($k = 17$), which encompass self-guided CBT, ACT, and MBI, as well as diverse Positive Psychology-based interventions ($k = 8$).

TABLE 1 | Overview of meta-analytical findings.

Article	Population	Type of interventions	Control groups	Data quality	Data base *n* (*k*)	Evidence of effectiveness of self-guided interventions	Effect sizes	Dose effects	Base line effects	Cultural differences
Blanck et al. (2018)	Primarily student	Mindfulness (guided; audio-tapes)	CT and RCT with active and inactive controls	Tulder Quality Assessment scale mean = 5.59 (SD = 1.56); 10 studies had high quality, 5 studies judged low quality (out of 18); Evidence of publication bias (funnel plot, Egger regression)	$n = 1,150$ ($k = 18$)	No significant difference between guided and self-administered interventions	Anxiety: $g = 0.39$ [0.22, 0.56] (Overall compared to inactive), $g = 0.27$ [0.03, 0.50] (Overall compared to active); Depression: $g = 0.41$[0.19, 0.64] (Overall compared to inactive), $g = 0.27$[−0.04, 0.58] (Overall compared to active)	Practice time and duration of individual sessions did not show significant effects	NA	NA
Cavanagh et al. (2014)	General population	Self-help mindfulness and acceptance-based interventions	RCT with active and inactive control	Jadad score: on average medium quality; publication bias for anxiety, but not depression (funnel plot)	$n = 2,286$, ($k = 15$)	Guided interventions show larger effect (*post-hoc* analysis)	Anxiety: $g = 0.34$ [0.10, 0.57], Depression: $g = 0.37$ [0.19, 0.56]	Self-help interventions: The mindfulness and/or acceptance components resulted in a significantly higher level of mindfulness/acceptance skills and significantly lower levels of anxiety and depressive symptoms than control conditions, with small to medium effect sizes	NA	NA
Chu and Mak (2020)	Clinical and general population	Mindfulness (including meditation, Loving-kindness)	RCT with active and inactive control	RCTs showed medium quality on average. Higher-quality studies showed significantly smaller ES's. Evidence of publication bias (Egger regression)	$n = 912$ ($k = 11$, RCT's only)	Online studies showed higher ES than group (but small number of valid comparisons)	SWB (Satisfaction with life): $g = 0.53$ [0.26, 0.80] (RTCs)	NA	No difference between clinical and general populations	No significant difference between regions (North America; Europe/Australia; Asia; other)
Conn (2010)	General population	Physical activity	Experimental studies (including quasi-experiments and pre-post comparisons)	Random assignment shows significantly smaller effects	Control group designs: $n = 1,081$ ($k = 22$); Pre-post design: $n = 3,420$ ($k = 45$)	Individual vs. group training not significantly different	Depression: $d = 0.52$ [0.28; 0.77] for control group designs; $d = 0.47$ [0.38; 0.56] for pre-post designs	home exercise less effective than fitness center; more training per week less effective; shorter trainings more effective	NA	NA
Cregg and Cheavens (2020)	Clinical and general population	Gratitude	RCT with active and inactive control	Cochrane: majority of studies was classified as medium to high risk of bias; bias rating did not significant moderate ES overall (studies where participants were aware of condition had larger pooled ES compared to blinded/insufficient information studies); all outcomes are adjusted for unreliability. Possibility of publication bias (larger ES with smaller *n*)	$n = 3,675$ ($k = 27$)	No difference between online vs. offline activities	Anxiety: $g = -0.16$ [−0.38, 0.05]; Depression: $g = -0.17$ [−0.24, −0.10] (outliers excluded)	Duration (days, weeks) and compliance do no moderate ES	Level of depression does not moderate ES	NA

TABLE 1 | Continued

Article	Population	Type of interventions	Control groups	Data quality	Data base *n* (*k*)	Evidence of effectiveness of self-guided interventions	Effect sizes	Dose effects	Base line effects	Cultural differences
Cuijpers et al. (2011)	Clinical samples	Self-guided interventions (mainly CBT)	RCT with active and inactive control	Cochrane: acceptable level of bias (but no blinding); no evidence of publication bias (Egger regression)	n =1,362 (k = 7)	Self-guided interventions are effective compared to control; personal contact vs. complete self-help did not moderate effect size	Depression: d = 0.28 [0.14; 0.42]	NA	NA	
Curry et al. (2018)	General population	Kindness (other focused; excluding loving-kindness)	Experimental studies	No quality rating; no evidence of publication bias (funnel plot)	n = 4,045 (k = 27)	NA	SWB: d = 0.28 [0.16, 0.41]	NA	No differences between socially anxious and other populations	NA
Davies et al. (2014)	Clinical and non-clinical samples	Multicomponent online interventions	RCT with active and inactive control	Cochrane: Moderate quality on average	n = 1,480 (k = 17)	NA	Inactive control: Anxiety: g = −0.56 [−0.77; −0.35]; Depression: g = −0.43 [−0.63; −0.22]; Stress: g = −0.73 [−1.27; −0.19] Active control: Anxiety: g = −0.18 [−0.98; 0.62]; Depression: g = −0.28 [−0.75; −0.20]; Comparison intervention: Anxiety: g = −0.10 [−0.39; −0.18]; Depression: g = 0.33 [−0.43; 1.09]	NA	NA	NA
de Witte et al. (2019)	General population	Music activities and music therapy	RCT with active and inactive control	Quality rated and no evidence of publication bias (funnel plot)	n = 6,800 (k = 79)	No significant difference between music therapy and self-guided music activities	Anxiety: g = 0.55; Stress: g = 0.51	No effect of frequency or duration	No differences between surgery, non-medical, or polyclinical procedures	No difference between Western or Non-Western samples
Deady et al. (2017)	General population	eHealth (8 CBT; 1 ACT, 1 self-help emails)	RCT with active and inactive control	Downs and Black checklist: Fair to good quality; no evidence of publication bias (Egger regression)	n = 4,522 (k = 10)	NA	Anxiety: d = 0.31 [0.10; 0.52]; Depression: d = 0.25 [0.09; 0.41]	NA	No difference between general and indicated/selected populations	NA
Dickens (2017)	General population (including children)	Gratitude	Experimental (including quasi-experimental), comparing gratitude to neutral, negative, and positive intervention	NA. Evidence that negative interventions (focusing on hassles etc.) produce significantly larger ES	n = 3,351 (k = 38)	NA	Gratitude vs. Neutral: Depression: d = 0.13; SWB (life satisfaction): d = 0.17; Stress: d = 0.04; Gratitude vs. Positive: Depression: d = 0.02; SWB (life satisfaction): d = 0.03; Stress: d = −0.03	NA	NA	NA
Firth et al. (2017)	Clinical and non-clinical samples	eHealth	RCT with active and inactive control	Cochrane: most show lack of blinding; No evidence of publication bias (funnel plot)	n = 3,414 (k = 18)	eHealth interventions with "in-person" (i.e., human) compared to without feedback had small, non-significant effects on depressive symptoms; in-app feedback applications showed slightly greater ES compared to no in-app feedback; self-contained smartphone apps showed slightly larger ES compared to non-self-contained interventions (p = 0.07)	Inactive control: Depression: g = 0.56 [0.38; 0.74]; Active control: g = 0.22 [0.10; 0.33]	Length (in weeks) showed a trend to reduce effectiveness	Mild-to-moderate depressive groups showed larger improvement; no significant ES for samples with major depressive disorder, bipolar disorder, and anxiety disorders (but possible lack of power)	NA

(Continued)

TABLE 1 | Continued

Article	Population	Type of interventions	Control groups	Data quality	Data base *n* (*k*)	Evidence of effectiveness of self-guided interventions	Effect sizes	Dose effects	Base line effects	Cultural differences
Frattaroli (2006)	Clinical and general population	Expressive writing	RCT with neutral or waitlist control	Mean quality rating = 2.94 (scale 0–4); higher quality studies show smaller psychological health effect (strongest impact for participant expectation of study benefit); larger *n* was associated with weaker effects (possible publication bias)	$n = 8,533$ ($k = 112$)	Larger ES when expressive writing was conducted at home and in private settings	Anxiety: $r = 0.03$ [−0.09; 0.19]; Depression: $r = 0.04$ [−0.11; 0.16]; SWB: (Satisfaction with life) $r = 0.03$ [0.01; 0.08]; Stress $r = 0.02$ [−0.02; 0.08]	Trend for larger ES with more than 3 sessions; no effect of length of disclosure or spacing of sessions	Studies with participants with a history of trauma or stressors did not moderate ES; writing about more recent trauma showed stronger effect	No effects for proportion of ethnic minorities
Heekerens and Eid (2020)	General population	Positive psychology intervention (best-possible-self intervention)	RCT with active control group	Cochrane:	$n = 4,462$ ($k = 34$)	NA	Depression: $g = -0.09$ [−0.23; 0.06]; SWB (Life satisfaction): $g < 0.01$ [−0.09; 0.09]	NA	NA	NA
Hendriks et al. (2018)	Clinical and non-clinical samples	Positive psychology interventions	RCT with active and inactive control	Cochrane: mean quality score 1.79 on 0–6 scale	n= 3,009 ($k = 28$)	Self-guided interventions showed no effect (compared with group studies, but difference not significant)	Anxiety: $g = 0.95$ [0.28; 1.61]; Depression: $g = 0.62$ [0.19; 1.05]; SWB: $g = 0.48$ [0.24; 0.72]	Longer interventions showed larger ES	No significant difference	Non-western samples only
Hendriks et al. (2020)	Clinical and non-clinical samples	Positive psychology interventions	RCT with active and inactive control	Cochrane: 26% (13 studies) had high quality, average study $M = 3.2$ on 0–6 scale; Low quality studies show higher effect than moderate quality studies; funnel plot and Egger regression show some inconsistent evidence of publication bias	$n = 6,141$ ($k = 50$)	No statistically significant difference between individual, self-help, and group studies	Anxiety: $g = 0.35$ [0.23; 0.48]; Depression $g = 0.32$ [0.13; 0.51]; SWB: $g = 0.34$ [0.18; 0.50]; Stress: $g = 0.35$ [0.03; 0.66]	Inconsistent duration and session effects	No difference between clinical and general populations	Non-Western samples show significantly larger ES compared to Western samples
Huang et al. (2018)	Students	Diverse interventions	RCT with active and inactive control	CONSORT rating: moderate compliance	$n = 3,602$ ($k = 51$)	Easy to disseminate interventions (less guidance, etc.) showed smaller effects	Anxiety overall: $g = 0.48$ [−0.62; −0.34]; For mixed/other interventions: $g = -0.84$ [−1.19, −0.49]; CBT $g = -0.39$ [−0.55; −0.22]; Mindfulness–based: $g = -0.49$ [−0.84, −0.15]; Depression overall effects: $g = -0.60$ [−0.74, −0.46]; For mixed/other interventions: $g = -0.76$ [−1.19, −0.32], CBT: $g = -0.59$ [−0.72, −0.45]; Mindfulness-based: $g = -0.52$ [−0.88, −0.16]; Attention/perception modification: $g = -0.46$ [−1.06, 0.13]	Longer interventions showed larger ES	NA	Effects for depression vary by region (in order of effectiveness): Asia > Australia > North America > Europe; no effects for anxiety
Karyotaki et al. (2017)	Clinical samples	self-guided internet-based CBT	RCT with active and inactive control	Cochrane: overall low risk of bias (but no blinding); evidence of publication bias (Egger regression)	$n = 3,876$ ($k = 16$)	Self-guided interventions are effective compared to control; adherence increases effectiveness	Depression: $g = 0.27$ [0.17, 0.37]	No significant effect for treatment duration	No baseline effects	NA

TABLE 1 | Continued

Article	Population	Type of interventions	Control groups	Data quality	Data base *n* (*k*)	Evidence of effectiveness of self-guided interventions	Effect sizes	Dose effects	Base line effects	Cultural differences
Kirby et al. (2017)	General adult population	Compassion-based interventions (incl. loving kindness)	RCT with active and inactive control	Cochrane: most studies show low quality (blinding, reporting, attrition); funnel plot suggested weak evidence of publication bias	$n = 1,285$ ($k = 20$)	NA	Anxiety: $d = 0.49$ [0.30–0.68]; Depression: $d = 0.64$ [0.45–0.82]; SWB: $d = 0.51$ [0.30–0.63] (relative to waitlist); Anxiety: $d = 0.42$ [0.19; 0.64]; Depression: $d = 0.62$ [0.44-0.80]; SWB: $d = 0.48$ [0.28–0.67] (active control).	NA	NA	NA
Koydemir et al. (2020)	General population	Positive psychology interventions	RCT with active and inactive controls	No quality rating; Funnel plot suggests some publication bias	$n = 16,085$ ($k = 68$)	No statistically significant difference between self vs. trainer guided interventions; technologically assisted interventions significantly less effective than traditional interventions	SWB: $d = 0.22$	Duration effects significant (longer duration more effective)	NA	NA
Ma et al. (2019)	University Students	Mindfulness training and ACT	RCT with active and inactive control	Cochrane: 20% of studies showed high risk of bias (but study quality was not a significant moderator); evidence of publication bias (smaller n shows stronger effect)	$n = 2,472$ ($k = 22$)	Method of delivery had no significant effect	Depression: $g = 0.52$ [0.39, 0.65]	Weekly delivery more effective than more frequent training, inconsistent effects of duration (in weeks)	Indicated MBIs showed stronger effects than universal MBIs, but no difference with selective MBIs	NA
Malouff and Schutte (2017)	Clinical and general population	Optimism training (mostly best possible self and self-compassion)	RCT with active and inactive control	Funnel plot suggests some positive bias	$n = 3,319$ ($k = 29$)	Online studies showed weaker effect than in-person interventions	SWB (Optimism): $g = 0.51$ [0.36, 0.66] (waitlist control) SWB (Optimism): $g = 0.23$ [0.09, 0.37] (active control)	In-person intervention hours showed negative effect on ES (longer sessions less effective)	No difference for healthy vs. identified problem sample	NA
Massoudi et al. (2019)	Clinical population (anxiety, depression)	eHealth	RCT with active control group	Cochrane: Low risk of bias for 46.7% of trials, with high risk for 29.5%. No evidence of publication bias (symmetric funnel plot)	$n = 4,183$ ($k = 14$)	NA	Depression: $g = -0.19$ [−0.31, −0.06]	NA	NA	NA
O'Connor et al. (2018)	Clinical and non-clinical samples	eHealth third wave treatments (9 ACT, remainder mixture of CBT, mindfulness and others)	RCT with active and inactive control	Cochrane: moderate level of bias; bias is associated with larger ES; weak evidence of publication bias overall (funnel plot)	$n = 3,176$ ($k = 21$)	Therapist guidance did not significantly moderate ES	Inactive control: Anxiety: $g = 0.32$ [0.09, 0.56]; Depression: $g = 0.52$ [0.26, 0.77] Active control: Anxiety: $g = 0.31$ [0.07, 0.54]; Depression: $g = 0.29$ [0.14, 0.44] Comparison intervention: Anxiety: $g < 0.01$ [−0.16, 0.17]; Depression: $g = -0.02$ [−0.18, 0.15]	Number of intervention sessions did not moderate ES	No statistical difference between clinical vs. non-clinical populations	NA

TABLE 1 | Continued

Article	Population	Type of interventions	Control groups	Data quality	Data base *n* (*k*)	Evidence of effectiveness of self-guided interventions	Effect sizes	Dose effects	Base line effects	Cultural differences
Panteleeva et al. (2017)	General population	Music listening	RCT with active and inactive control	CONSORT rating: Low quality on average	$n = 792$ ($k = 21$)	NA	Anxiety: $d = -0.30$ [−0.55, −0.04]	NA	NA	NA
Pavlacic et al. (2019)	Clinical and general population	Expressive writing	Experimental (including pre–post studies)	No evidence of publication bias, but low power in *post-hoc* power analyses	$n = 1,581$ ($k = 53$)	NA	SWB (Quality of Life): $d = -0.01$ [−0.16, 0.13]	*Post-hoc* analyses suggest that short term intervals show positive ES, longer time intervals show negative ES (but low power)	NA	NA
Reinhold et al. (2018)	General population (no PTSD diagnosis)	Expressive writing (emotional, personal topic)	RCT with active and inactive control	Cochrane analysis: quality not correlated with ES; removed one study with incorrect reporting	$n = 4,009$ ($k = 39$)	NA	Depression: $g = -0.09$ [−0.15, −0.02]	Higher number of writing sessions and specific writing topic (vs. general) showed higher ES	No effect of clinical vs. non-clinical samples, depression score at pre-test	NA
Slemp et al. (2019)	Working adults	Mindfulness-based work interventions (ACT included; yoga excluded)	Intervention based (including quasi-experimental)	Down and Black: overall poor quality. No effect of data quality on ES; evidence of publication bias (Egger regression)	$n = 6,044$ ($k = 119$)	Self-guided interventions where as effective as other guided interventions ($p = 0.077$)	Anxiety: $d = 0.58$ [0.37, 0.79]; Depression: $d = 0.42$ [0.24, 0.59]; Stress: $d = 0.47$ [0.35, 0.58]	No dose effects for duration (weeks) or number of sessions	NA	NA
Spijkerman et al. (2016)	General population	Online administered MBIs	RCT	Jadad scale and Cochrane: most studies (k =10) medium quality; Evidence of publication bias (funnel plot)	$n = 2,360$ ($k = 15$)	For stress: interventions supported by therapists produced larger effects than online only interventions; no differences found for anxiety, depression and well-being.	Anxiety: $g = 0.19$ [−0.06, 0.43] (Self–help only); $g = 0.22$ [0.05, 0.39] (Overall) Depression: $g = 0.29$ [0.03, 0.55] (Self-help only); $g = 0.29$ [0.13, 0.46] (Overall); Stress: $g = 0.19$ [−0.01, 0.38] (Only self-help); $g = 0.51$[0.26, 0.75] (Overall); Well-being: $g = 0.31$ [0.11, 0.52] (Self-help only); $g = 0.23$[0.09, 0.38] (Overall)	For stress: more sessions had stronger effect (when excluding outliers, this effect disappears)	No differences between general and groups with psychological problems	NA
Stratton et al. (2017)	Working adults	eHealth interventions (CBT, mindfulness, stress management)	RCT with waitlist control	Down and black ratings; evidence of publication bias (funnel plot, Egger regression)	$n = 2,922$ ($k = 23$)	Guided eHealth interventions show higher ES than unguided ones	Overall effects – Anxiety: $g = 0.21$; Depression: $g = 0.25$; Stress: $g = 0.30$	NA	Targeted populations (compared to untargeted) showed stronger ES overall (mainly driven by target effects for Stress Management on stress outcomes; no effect for CBT interventions)	NA
Strohmaier (2020)	Clinical and general population	MBCT/MBSR and other Mindfulness-based practices	RCT with active or inactive controls	Cochrane: Only five studies showed low risk of bias	$n = 15,971$ ($k = 203$)	No significant effects of the number of face-to-face sessions or contact hours	Compared to inactive controls: Anxiety: $d = -0.49$ [−0.59, −0.38]; Depression: $d = -0.60$ [−0.70, −0.50]; Stress: $d = -0.73$[−1.00, − 0.46] (Post–program). Compared to active controls: Anxiety: $d = -0.16$ [−0.26, −0.05]; Depression: $d = -0.20$ [−0.30, −0.11]; Stress: $d = -0.32$ [−0.61,−0.04]	Immediately post-program no dose response differences, but at 1–4 months follow-up shows inconsistent dose effects (e.g., home practice, intensity, facilitator contact)	No effect of baseline differences	NA

TABLE 1 | Continued

Article	Population	Type of interventions	Control groups	Data quality	Data base *n* (*k*)	Evidence of effectiveness of self-guided interventions	Effect sizes	Dose effects	Base line effects	Cultural differences
Vonderlin et al. (2020)	Working adults	Mindfulness work interventions (at least 2 h; at least 50% mindfulness practice; ACT and yoga included)	RCT with active and inactive control	Cochrane: low risk of bias; some evidence of publication bias for stress (funnel plot)	n = 5,161 (k = 56)	No effect of method of delivery (self-guided/online vs. in-person delivery)	SWB (Life satisfaction): g = 0.68 [0.24, 1.12]; Stress: g = −0.66 [−0.88, −0.44]	Program attendance hours increased SWB (but not duration in weeks)	NA	NA
Weisel et al. (2019)	General population	Multicomponent mobile health apps	RCT with active and inactive control	Cochrane: 53% (10/19) exhibit bias in at least three domains	n = 3,681 (k = 19)	Standalone smartphone apps	Anxiety: g = 0.43 [0.19; 0.66]; Depression: g = 0.34 [0.18, 0.49] (overall) Anxiety: g = 0.49 [0.27, 0.71]; Depression: g = 0.41 [0.24-0.59] (waitlist control)	Follow-up assessments were not examined	NA	NA
Yang (2018)	Clinical groups	Computer-Mediated Support Groups	RCTs and one-group pre-test post-test design	Possibility of publication bias (funnel plot, Egger regression)	n = 7,582 (k = 43)	Presence vs. absence of facilitator did not moderate ES	Depression: d = 0.32 [0.22; 0.43]	Group size was significant: larger online groups less effective	NA	NA

If no 95% confidence intervals are included, they were not reported in the original meta-analysis.

Self-guided therapy-derived interventions

A large number of studies used therapy-derived interventions including CBT, MBI, and ACT, and showed small to medium effect sizes for reducing anxiety, depression, and stress. Effects for subjective well-being in some analyses showed moderate to large effect sizes (Chu and Mak, 2020; Vonderlin et al., 2020). When compared to active control groups instead of non-active controls or waitlist groups, effect sizes typically diminished but remained statistically significant (e.g., Deady et al., 2017; O'Connor et al., 2018). Overall, the self-guided effect sizes tended to be lower than the effectiveness of traditional clinician-guided therapies, but clearly showed an effectiveness over and above active control groups (e.g., Spijkerman et al., 2016; Stratton et al., 2017). Other meta-analyses found no difference for self-guided compared to clinician-guided interventions (e.g., in general: Spijkerman et al., 2016; O'Connor et al., 2018 found no difference for anxiety and depression). Based on these meta-analyses, self-guided therapy-derived interventions are recommended to improve well-being during isolation.

Positive psychology-based interventions

Positive psychology-based interventions are typically focused on positive functioning, including interventions focusing on optimism, gratitude, or kindness. There is a somewhat older literature on expressive writing (Pennebaker, 1997) which we included here for convenience purposes. Overall, the effect sizes of positive psychology-based interventions were typically small and appear even more strongly affected by the type of control group than therapy-derived interventions (for a particularly striking example, see Dickens, 2017). Some of the positive psychology gratitude interventions differ by the focus of the intervention: either self- or interpersonally-oriented gratitude. These differences appear to be similarly effective (e.g., Cregg and Cheavens, 2020). Cregg and Cheavens (2020) found online compared to off-line applications equally effective, whereas Koydemir et al. (2020) reported greater effectiveness of non-technologically mediated interventions. Hendriks et al. (2020) reported that web-based interventions were as effective as online positive psychology apps. Expressive writing interventions showed the smallest effect sizes overall in this group, whereas compassion and kindness-based interventions showed moderate effect sizes in some meta-analyses (Kirby et al., 2017). Based on these meta-analyses, expressive writing interventions are the least effective, whereas gratitude, especially compassion-based interventions, could be recommended to improve well-being during quarantine and isolation.

Other activity-based interventions

Other activity-based interventions comprised a broad category including various physical exercise, arts, and music-based activities. Physical exercise showed weak effects overall in improving subjective well-being, with slightly larger effects for reducing depression (Conn, 2010). Music-based interventions also showed weak to moderate effects in reduced anxiety and stress levels (Panteleeva et al., 2017; de Witte et al., 2019). Therefore, activity-based interventions, including music and

physical exercise, show small to moderate effects and could be recommended to improve mental health during isolation.

Multicomponent online and app-interventions

Multicomponent online and app-based interventions showed small to moderate effects, with diminished effects when compared to standard therapeutic interventions (see for example, O'Connor et al., 2018). Overall, their effectiveness was considerably smaller than similar non-online interventions (e.g., Malouff and Schutte, 2017) or standard in-person therapies. The relative effectiveness of online only compared to smartphone-based apps remains unclear (Firth et al., 2017; Weisel et al., 2019), and thus no clear guidance is available.

Dose Effects

Dose effects, or the extent to which people are practicing or using a specific activity, are important to consider when recommending self-guided practice. These might include total practice time, or duration of individual interventions. Several meta-analyses examined the effectiveness of interventions at different dose levels. For therapy- derived interventions, Blanck et al. (2018) and O'Connor et al. (2018) found no dose effects for self-guided CBT-based interventions. In contrast, Firth et al. (2017) reported a reduction (although not statistically significant) in the effectiveness of longer-term smartphone-based interventions, whereas Huang et al. (2018) reported greater effectiveness of longer ACT and CBT-based interventions on depression. Strohmaier (2020), Spijkerman et al. (2016, after removing outliers), and Slemp et al. (2019) found no difference in dose effects for MBI-based interventions. Focusing on life satisfaction, Vonderlin et al. (2020) reported greater life satisfaction was correlated with higher number of mindfulness-based practice hours, whereas Ma et al. (2019) reported inconsistent dose effects for mindfulness-based interventions in students, with a slight increase in effectiveness for weekly practices compared to more frequent sessions.

Positive psychology interventions also showed inconsistent dose effects. Hendriks et al. (2020) reported inconsistent patterns for interventions of more or less than 8 weeks for different outcome variables. Similarly, for expressive writing exercises, the dose effects are inconsistent across the studies that reported them (Frattaroli, 2006; Malouff and Schutte, 2017; Reinhold et al., 2018). For physical exercise, a meta-analysis by Conn (2010) found that home-based unsupervised exercise was less effective than unsupervised exercise in fitness centers. The same meta-analysis also suggested that shorter training overall might be more effective in improving depressive symptoms. de Witte et al. (2019) reported no significant dose effects for music interventions. Examining the overall pattern, dose effects appear inconsistent and no clear guidance is available about optimal levels of practice.

Baseline Effects and Applicability for Clinical Populations

One important concern in recommending self-guided interventions is whether these interventions are applicable for populations experiencing clinically relevant symptoms. In particular, a specific intervention may show no effect or an adverse effect in clinical populations, making the intervention unsafe for such populations. Hence, we investigated whether meta-analyses examined baseline effects of anxiety, depression, or stress on effectiveness, or directly compared the effectiveness between clinical and non-clinical populations.

Among therapy-derived interventions, several meta-analyses found no significant baseline effects or difference between clinical and non-clinical samples (Spijkerman et al., 2016; Deady et al., 2017; O'Connor et al., 2018; Strohmaier, 2020). For positive psychology interventions, several meta-analyses also found no difference between clinical and non-clinical samples (Frattaroli, 2006; Reinhold et al., 2018; Cregg and Cheavens, 2020; Hendriks et al., 2020). Only Pavlacic et al. (2019) reported larger effect sizes for groups with a Post-Traumatic Stress Disorder (PTSD) diagnosis compared to non-PTSD groups. No difference between clinical (labeled socially anxious) and non-clinical populations was found for kindness-based interventions (Curry et al., 2018). Taken together, this suggests that therapy- derived and positive psychology interventions in general could be recommended to populations irrespective of their depression or anxiety levels or clinical diagnosis status. For music interventions, de Witte et al. (2019) reported no differences between different populations in terms of effectiveness. For generic smart-phone applications (including a large number of clinical therapeutic approaches), Firth et al. (2017) reported that effectiveness of these apps was better for individuals diagnosed with mild-to-moderate levels of depression, but groups diagnosed with major depressive disorder, bipolar disorder, and anxiety disorder showed no significant improvement when using these applications. However, these sample sizes were typically small and might have been too small to show the effectiveness of these eHealth apps. Overall, clinical status or level of anxiety or depression do not exert a strong influence on the effectiveness of these self-guided interventions. This is encouraging news to support the widespread recommendation of these self-guided interventions in general, in the absence of immediate clinical guidance or supervision.

Cross-Cultural Applicability

The current COVID-19 pandemic is affecting all countries. For this reason, we also examined the extent to which the interventions might be applicable and effective in different cultural regions. Unfortunately, only a small number of meta-analyses ($k = 5$) attended to possible cultural differences in the effectiveness. Chu and Mak (2020) found no significant differences in mindfulness-based interventions between world regions and de Witte et al. (2019) comparing the effectiveness of music interventions reported no differences between Western and non-Western samples. In contrast, Hendriks et al. (2020) compared positive psychology interventions and reported larger effect sizes in non-Western compared to Western samples. However, it is unclear whether these comparisons might be confounded by other study characteristics. An earlier meta-analysis by Hendriks et al. (2018) only focused on non-Western interventions and reported low quality studies. Overall, it is noteworthy that there are relatively few high-quality studies

available that have examined the effectiveness of self-guided psychological interventions in samples beyond Western Europe, North America, and Australia.

Contextualizing the Evidence-Base Against Excluded Intervention Types

We were unable to include any studies that exclusively looked at yoga or meditation because meta-analyses of these studies always included group settings or guidance by a trainer or clinician. Based on our inclusion criteria, we were unable to include them in our review. However, the evidence from recent meta-analyses suggests that these interventions are effective for anxiety, depression, and broader mental and physical health (see for example, Sedlmeier et al., 2018; Zoogman et al., 2019) and clinical network meta-analyses attest to their safety and effectiveness (Chen and Shan, 2019). A further advantage of these types of interventions is that they seem to show higher effectiveness in non-Western populations (e.g., Zoogman et al., 2019). Given the wide availability of online yoga and meditation sessions/apps and the overall effectiveness of guided yoga and meditation sessions *in situ*, we could cautiously recommend the practice of yoga and meditation for improving mental health during quarantine and social distancing conditions.

Meta-Meta-Analysis of the Effectiveness of Self-Guided Interventions

Figures 2–5 show the effect sizes and confidence intervals (if reported) from the meta-analyses (we converted r coefficients reported in Frattaroli, 2006 into d). We recoded effect sizes for anxiety, depression and stress so that positive numbers indicated a positive change (improvement) for the experimental group compared to the control group. As **Figures 2–5** demonstrate, most meta-analyses showed an advantage of the intervention compared to the control group, but the type of control group appeared to impact the observed effect size.

After converting standardized mean differences to z-transformed r, the average effect size r was comparable across the four outcome variables, for anxiety $r = 0.19$ (95% CI: 0.14, 0.24; $k = 31$); depression $r = 0.17$ (95% CI: 0.13, 0.20; $k = 45$); subjective well-being $r = 0.19$ (95% CI: 0.13, 0.25; $k = 25$), and stress $r = 0.19$ (95% CI: 0.11,0.26; $k = 17$). Effect sizes computed for comparisons with active control groups yielded smaller effects, but this difference was only significant for depression ($Q\,[1] = 5.70$, $p = 0.017$, $R^2 = 0.096$).

When examining differences between types of interventions, we used therapeutic approaches (CBT, ACT, and MBI) as the reference category. For positive psychology interventions, we separated gratitude and expressive writing interventions from other positive interventions. Due to the small number of effect size summaries available, we included activity-based interventions (exercise, music) with other/multicomponent interventions. For anxiety, we found a significantly larger effect for mixed, multicomponent and other interventions compared to CBT and ACT ($b = 0.19$ [95% CI: 0.05–0.55]; $p = 0.009$). For subjective well-being, we found a trend for mindfulness interventions to show larger effect sizes compared to CBT ($b = 0.16$ [95% CI: $= 0.02$ -0.34], $p = 0.086$). For depression, we first controlled for active control group comparisons (see the results reported above). Expressive writing exercises had a significantly smaller effect size on average compared to CBT/ACT based interventions ($r = -0.15$ [95% CI: -0.29 to -0.00], $p = 0.017$). We did not find statistically significant differences in the effectiveness of different interventions for stress.

DISCUSSION

Our rapid review of available meta-analyses demonstrated that there are a number of evidence-based self-guided interventions that can be used by individuals at home to manage depression, anxiety, stress, and well-being during stay-at-home orders, lockdown, and quarantine. Overall, self-guided interventions are better at improving psychological health compared to no intervention (e.g., waitlist controls) and, to some extent, active controls (e.g., comparable treatments). In particular, self-guided therapy-derived interventions (including CBT, ACT, and MBI), mindfulness-based practices, positive psychology interventions, and activity-based interventions (e.g., physical exercise, music listening) appear effective in reducing anxiety, depression, stress, and in increasing subjective well-being compared to both active and inactive control groups. However, dose effects were largely inconsistent. Therefore, we cannot recommend specific intervals or durations for any of the intervention categories. Baseline effects were largely absent, implying that even individuals with elevated stress or psychological problems can use these practices at home without supervision, however we strongly recommend contacting health professionals if an individual is experiencing distress.

The unique context created by social distancing and quarantine necessitates reflection on the way self-guided interventions might be used. Although expressive writing interventions showed effectiveness compared to control groups, effectiveness was consistently lower compared to CBT and ACT-based interventions. Expressive writing about concerns or worries (including detailed reflections of difficult or traumatic events) may not be appropriate without adequate clinical support or guidance (Reinhold et al., 2018), especially when acutely experiencing negative emotional symptoms. Hence, we do not recommend these exercises for individuals to perform unsupervised at this current time of elevated collective worry and distress (see Wang et al., 2020).

Overall, self-guided activities included in these meta-analyses appear effective, but not as effective as in-person or group-based interventions. Therefore, these activities can be useful as a first line of psychological support during stay-at-home and lockdown periods, but they could not and should not replace more guided clinical interventions (either via telehealth or once in-person sessions become available again). Given the current strain on the mental health system and the likelihood of further restrictions in the near future, it is important to provide widely available evidence-based practices to avoid negative collateral

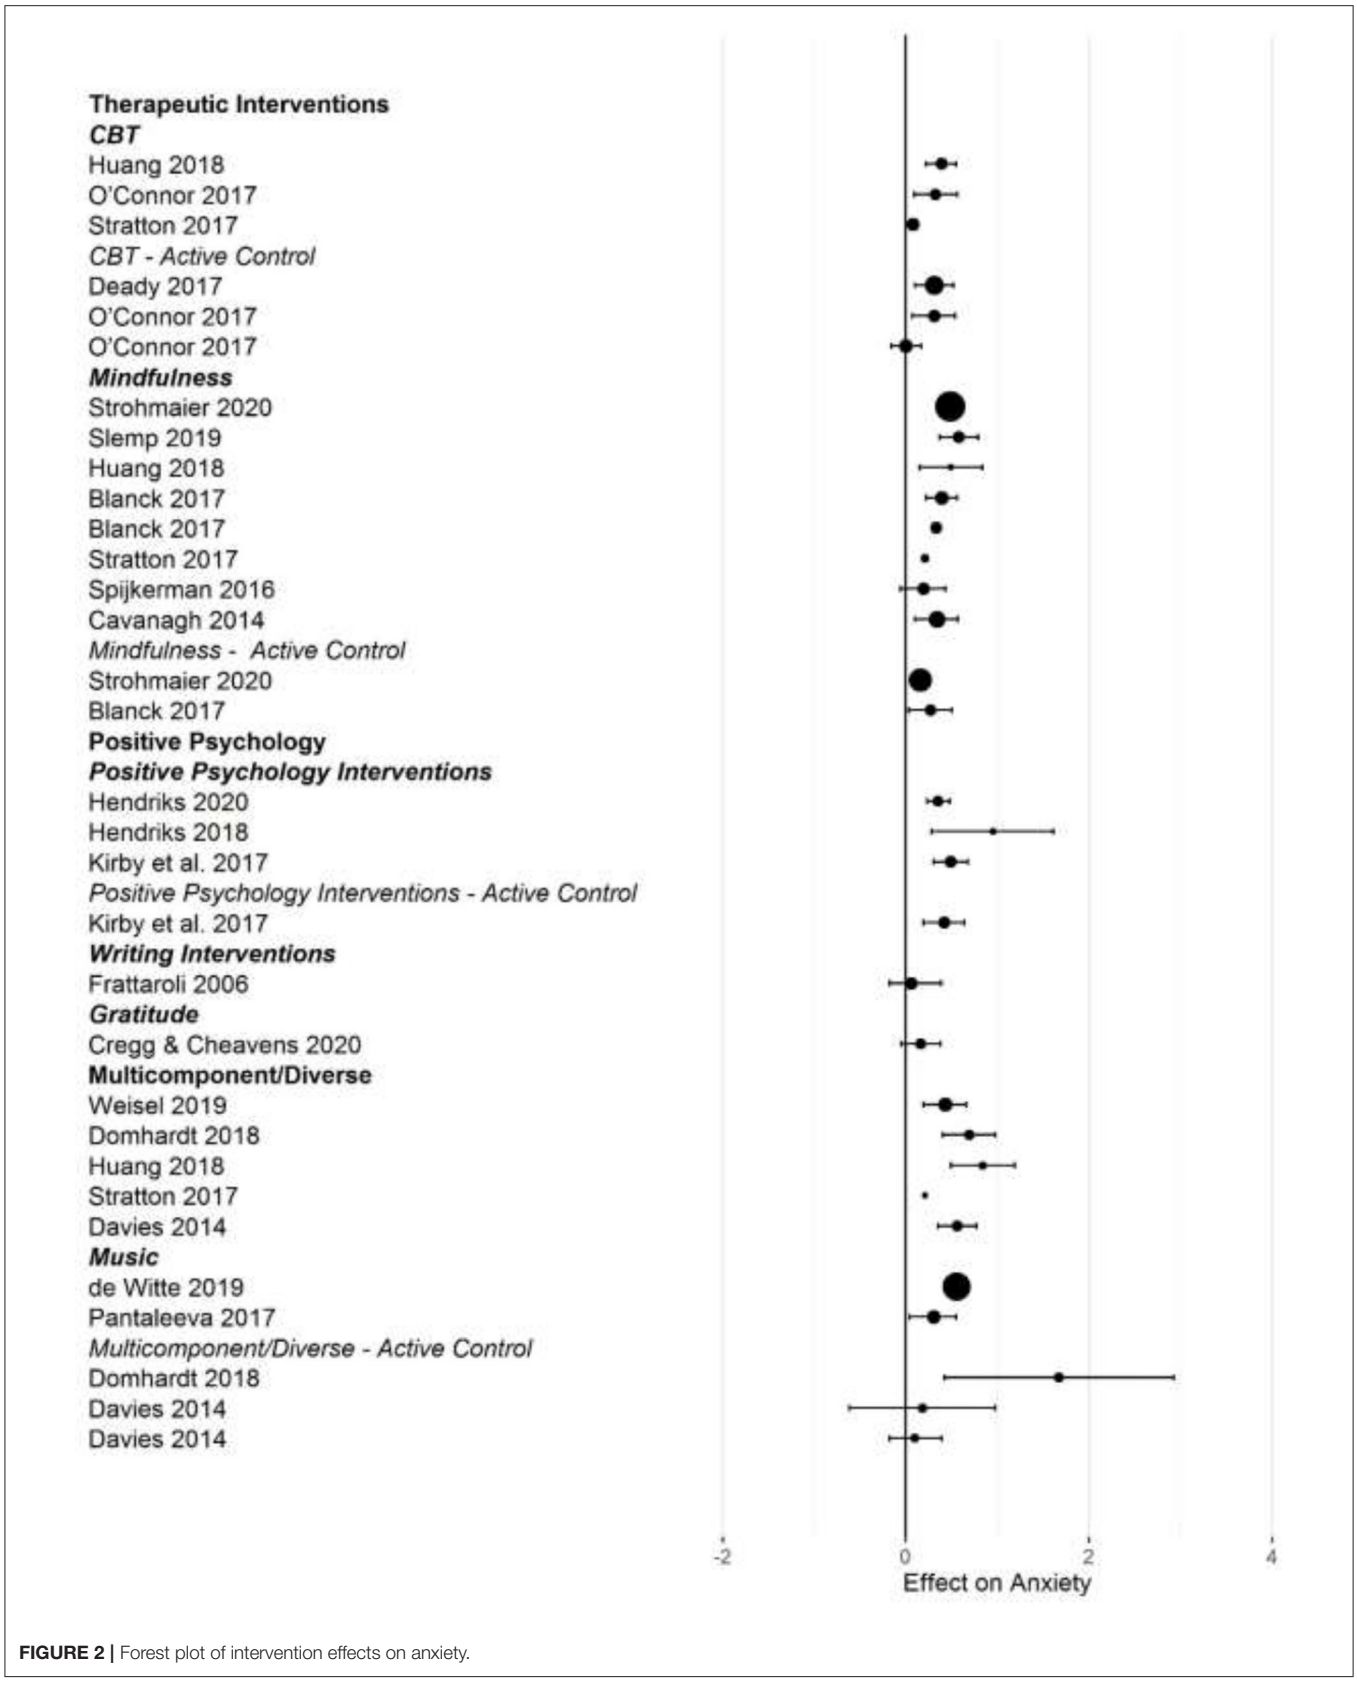

FIGURE 2 | Forest plot of intervention effects on anxiety.

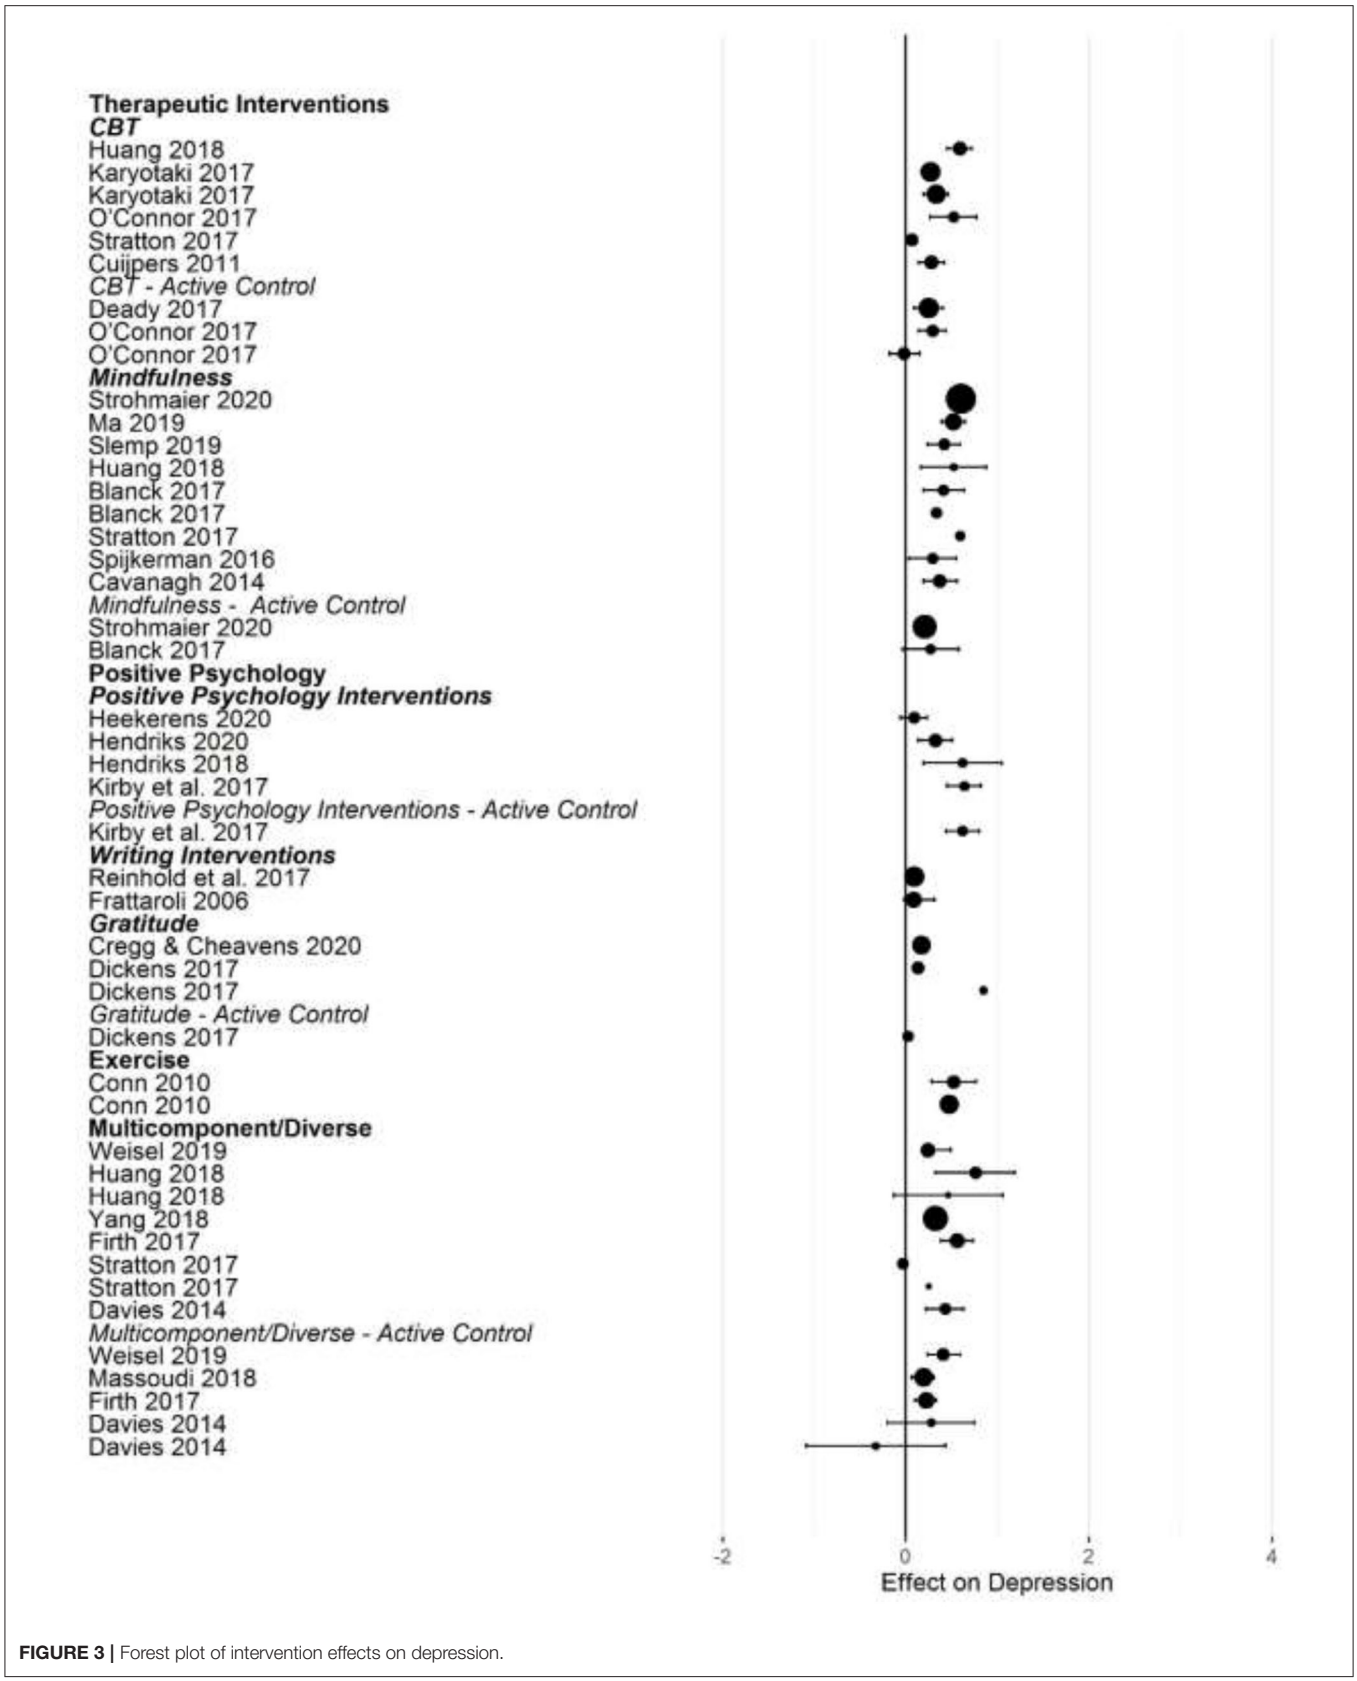

FIGURE 3 | Forest plot of intervention effects on depression.

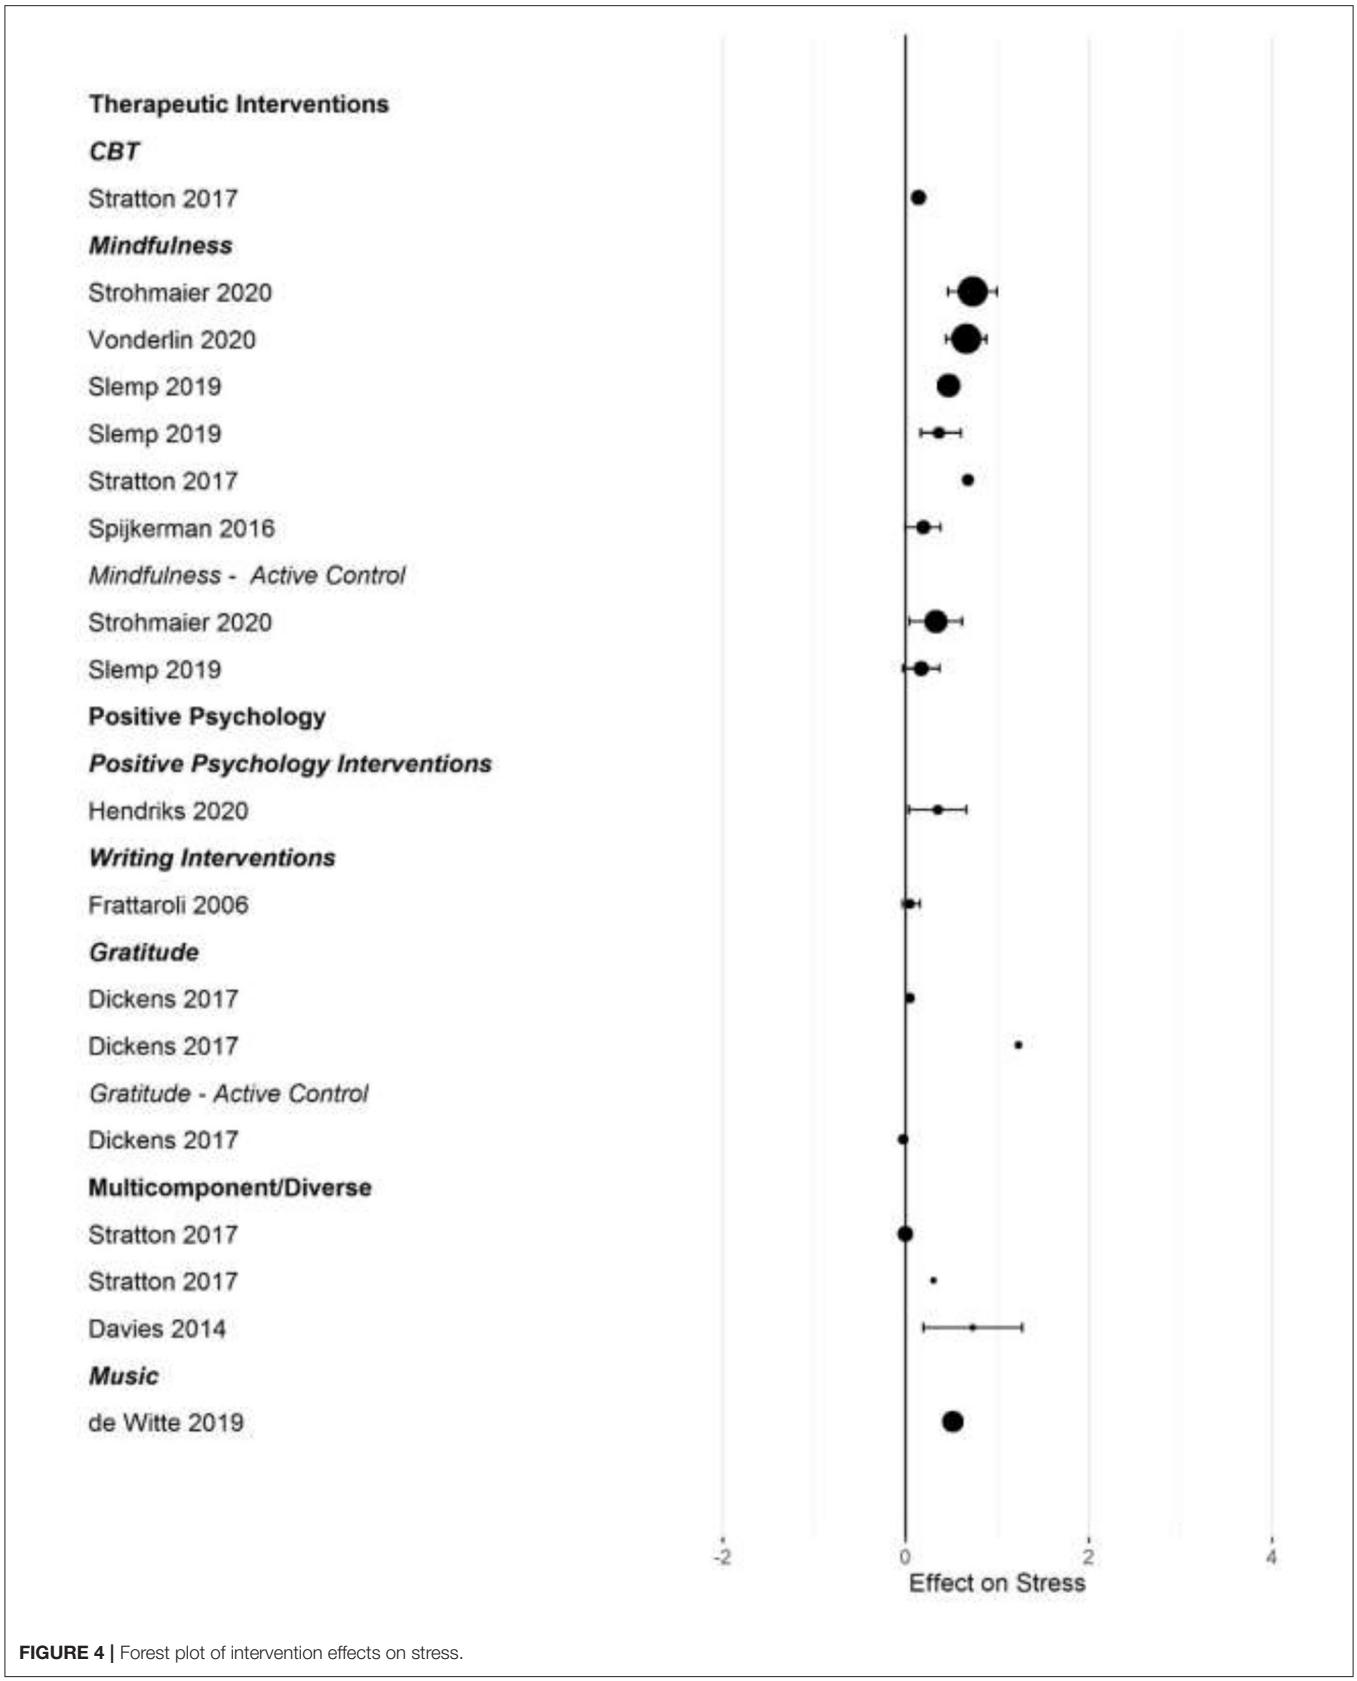

FIGURE 4 | Forest plot of intervention effects on stress.

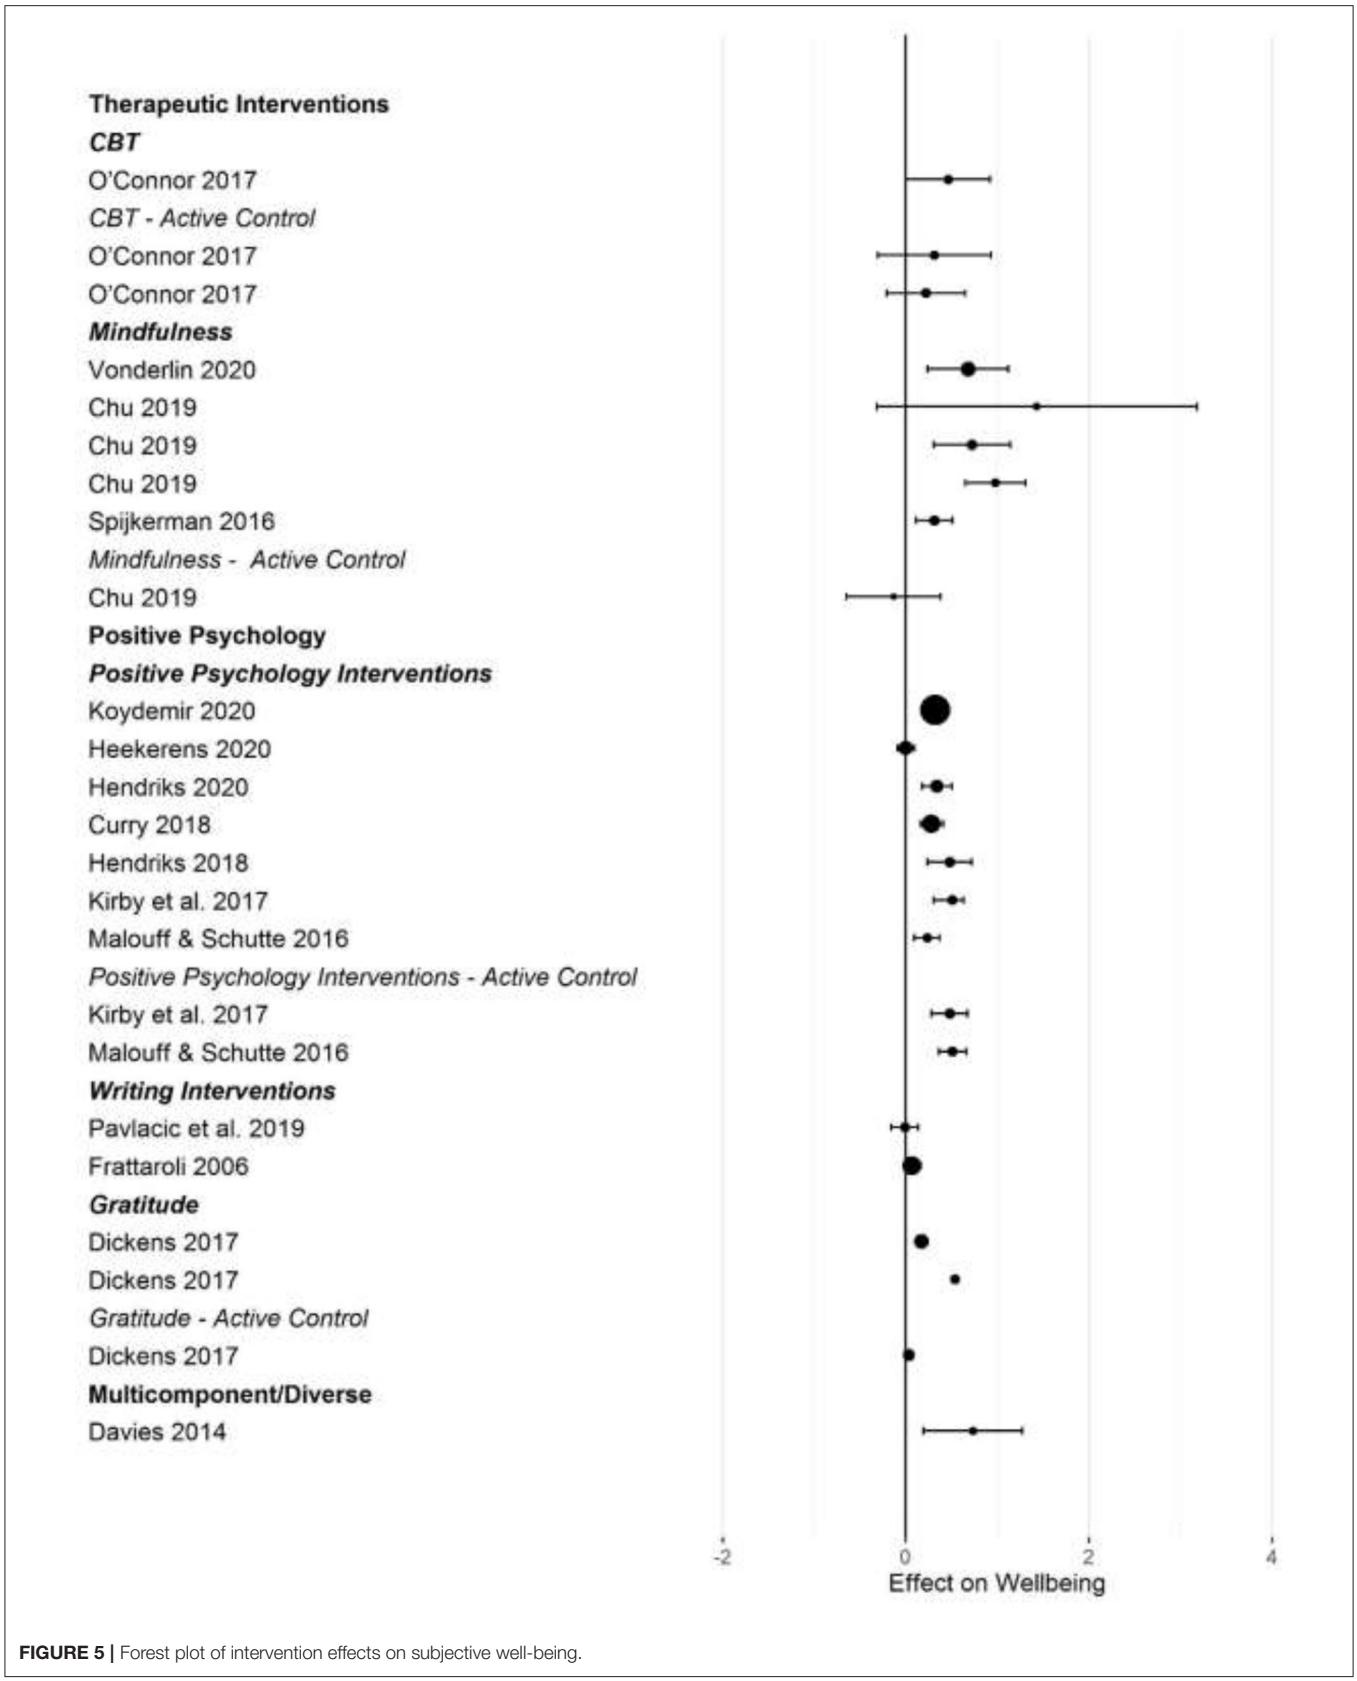

FIGURE 5 | Forest plot of intervention effects on subjective well-being.

effects on mental health at the population level (see Brooks et al., 2020; Duan and Zhu, 2020). This review provides an overview of best-practice self-guided interventions conducted prior to the pandemic that can be recommended and implemented at large scale to help and support populations at risk of mental health problems. However, self-guided interventions need to be complemented by further investment and strengthening of traditional mental health care support.

At the same time, the review clearly highlights blind spots in our understanding of evidence-based practices. More highly controlled research on self-guided and home-based interventions is needed to inform public health decision-making during pandemics that require quarantine and social distancing over potentially long periods of time. What are the ideal levels of compliance for self-guided mental health interventions beyond an initial lockdown period and how can mental health be maintained? When should self-guided interventions first be implemented or recommended to populations at risk and how long should these practices be maintained after the immediate lifting of more restrictive lockdowns? What are the effects of repeated lockdowns: should recommended self-guided interventions be switched or rotated? The meta-analyses summarize studies that were not specifically geared toward evaluating interventions that are focused on home practices during lockdown.

We isolate three main limitations of the current evidence-base to guide future research. A first gap, especially in the current context of global pandemic, is the lack of attention to culturally transferable interventions. Most studies have been conducted with samples from high-income, highly educated, and mainly Western nations. Given the greater population density and living arrangements in non-Western environments, these conditions may make effective mental health interventions even more urgent. We need further national and international multi-center research that includes diverse groups of participants to better understand whether interventions developed for autonomous individuals socialized into societies that emphasize individuality and self-reliance are as applicable and as effective in more community oriented contexts (Smith et al., 2013). A second major concern of current distancing measures which we were unable to address here is the potential for a negative impact on social relationships. The current lockdown measures require greater interpersonal skills, both in terms of living together with others in closed spaces for extended periods of time as well as maintaining contact with others outside the immediate social "bubble." The current evidence is clearly geared toward the individual as the focus of the intervention, with little emphasis on social relationships (although gratitude interventions might be the single major exception). Thus, we need more evidence of the effectiveness of social interaction interventions. A third limitation is that our evidence is based on interventions that were conducted prior to the current pandemic. It is unclear whether the effectiveness of self-guided interventions is equally effective under the specific conditions of a pandemic. The baseline effects that we report make us cautiously optimistic about the continuing effectiveness of these interventions, even in conditions of increased overall stress and anxiety. A meta-analysis of controlled studies during the current pandemic would be highly beneficial.

Finally, it is worth considering the broader role of psychologists in responding to the COVID-19 pandemic. A major concern for individuals, groups, organizations, and nations is the economic impact of the current pandemic. The mental health impact of quarantine is more dramatic for lower income groups (see Reynolds et al., 2008). The medium and long-term negative economic impact of COVID-19 on the larger population, and especially financially and economically more vulnerable populations also needs greater attention from psychologists. Psychologists need to collaborate with economists and others involved in economic decision-making to consider options to support people to upskill and create new employment opportunities which help to alleviate this financial worry.

In summary, the current evidence suggests that a number of self-guided interventions suitable for at-home practice during lockdown and physical distancing are effective to for improving mental health. Specifically, we recommend interventions based on cognitive behavioral therapy, mindfulness, and acceptance-based activities, selected positive psychology activities, physical exercise, and music as useful first-line mental health interventions. However, these activities are not as effective as in-person and group based therapeutic interventions, and so they should not replace clinician-guided interventions for individuals and groups in need. Many of these interventions are now available via smartphone and web-based applications. In order to provide broad access to such evidence-based interventions to mitigate the negative side-effects of social distancing measures, this article includes an online supplement with selected exercises and further information to help individuals cope with the mental health challenges of physical distancing and quarantine.

DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. This data can be found at: https://osf.io/fpx4s/.

AUTHOR CONTRIBUTIONS

RF conceptualized the study and wrote the first draft. RF, TB, JK, MZ, KR, AR, and LG conducted the literature search and data extraction. RF, JK, and TB conducted the analyses and created the visualizations. DW coordinated the activity material collation. DW, TN, BI, and MC collated and summarized the activity material. PM provided feedback and advice. All authors approved the final version.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fpsyg.2020.563876/full#supplementary-material

The COVID-19 outbreak has seen people in many countries asked to radically modify their way of life in compliance with sweeping safety measures. During the current crisis, technology is turning out to be key, in that it allows practitioners to deliver psychological services to people who would otherwise be unreachable. However, professionals cannot solely rely on their traditional modes of practice, in that different methods are required to bring to light the needs of those affected by the emergency. People are being overwhelmed by a cascade of unusual and unexpected events that are putting a strain on their everyday routines and usual meaning-making systems; ongoing challenges to their employment and financial status will likely divert personal resources away from psychological well-being. We therefore argue that psychologists should also consider the needs of the general population. Among those who may require help–aside from the main targets of psychological intervention, such as healthcare personnel and COVID-19 patients and their relatives–specific attention should be paid to those who are not at the center of the crisis. We suggest that this large segment of potential users may benefit from a non-medical approach focused on the promotion of meaning-making processes. Indeed, the disruptive nature of the current situation hinders sense-making and threatens to undermine psychological balance and well-being, at an individual as well as at a societal level. The present article proposes a methodological perspective based on the reconstruction of meaning-making processes (sense of coherence, predictability, metaphors, narratives). Specifically, psychological interventions should promote personal and collective resources with a view to: "normalizing" current distressful experiences (i.e., acknowledging that such reactions are normal in light of the present situation); widening the observational field, taking relational contexts into account, and promoting an understanding of distressful experiences as coping strategies; fostering meaning-making/reconstruction processes through the use of appropriate metaphors and narratives; promoting a sense of coherence. We present two clinical vignettes to illustrate how these principles might be applied in practice. In conclusion, the exceptional psychological challenges posed by the COVID-19 pandemic require practitioners to adopt a broad and flexible perspective on clinical intervention.

INTRODUCTION

The recent coronavirus disease (COVID-19) outbreak has seen people in many countries asked to radically modify their everyday behaviors in compliance with sweeping safety measures introduced by European, Asian, and American governments. It is well documented that having to cope with infectious outbreaks places a considerable strain on people's lives[1] (see Brooks et al., 2020; Pfefferbaum and North, 2020). During the COVID-19 crisis, entire populations have suddenly found themselves struggling with an invisible enemy that can potentially strike anyone and may only be confronted by forgoing–although temporarily–the company of significant others and enduring severe reductions in living space and personal freedoms.

In view of the above, it is our opinion that scholars should extend their research focus beyond those "in the frontline," such as healthcare personnel, COVID-19 patients, and their relatives, to investigate the impact of the emergency on the public at large, given that "emotional distress is ubiquitous in [populations affected by public health emergencies]–a finding certain to be echoed in populations affected by the COVID-19 pandemic" (Pfefferbaum and North, 2020, p. 1). Indeed, recent works have pointed up the need to study the "psychological effects of the COVID-19 pandemic across the whole population and in specific vulnerable groups" (Holmes et al., 2020, p. 10) in light of the clearly adverse effects of quarantining on psychological well-being (Brooks et al., 2020) and long-lasting stressors related to the outbreak (Sood, 2020).

The negative effects of forced and prolonged mass quarantining include boredom, loneliness, social disconnectedness, a sense of lack of meaning, relationship breakdowns, anger, avoidance behaviors, unhealthy behaviors, and abnormal emotional reactions (Brooks et al., 2020; Holmes et al., 2020; Pfefferbaum and North, 2020). The unavailability of routine assistance due to the closure of businesses and institutions can further amplify the impact of the crisis, potentially affecting large sectors of the population: consider, for example, families with schoolchildren, persons living alone, elderly persons and their caregivers, unemployed persons, those on a low income, people in unstable social conditions, homeless persons, and other vulnerable categories (see World Health Organization, 2020). It is also likely that the pandemic will have enduring psychological consequences on an unprecedentedly global scale in the later stages of mass home confinement (when freedom of movement has been at least partially restored) and over the long-term aftermath of the lockdown. A recent survey by the American Psychological Association (2020) revealed that the pandemic has altered all aspects of personal and family life, from health and work to education and exercise. Parents of children under 18 are among the categories most affected by pandemic-related stress. The emergency has upset daily routines (during both the initial lockdown and the ongoing phase of gradual resumption of normal activity),[2] severely impinging upon personal as well as family and interpersonal projects and drastically modifying habitual modes of interaction at both the familial and social levels.

The nature of the disease itself prompts significant uncertainty about the future. People's concerns can be many and varied, spanning fears for their occupational and financial status during the recovery phase; anxiety surrounding new behaviors that the epidemiological situation may require them to adopt in the interests of their personal safety (such as novel modes of interacting with strangers, alternative workplace procedures or leisure-time activities, etc.); worry that a new wave of disease may hit the world, or that we may have to live with the virus for a long time to come. It is likely that such sources of distress will wield a profound effect on community mental health, although not necessarily in terms of diagnosable disorders.

Policy makers and psychological scientists thus need to be keenly aware of the wide-ranging psychological impact of the pandemic if they are to design targeted psychological surveillance and intervention strategies for helping people to cope with it (see Higgins, 2020).

Accordingly, this paper presents a possible perspective on addressing COVID-induced forms of distress–which are often subtle and elusive, but, nevertheless, worthy of attention–in people who are not at the center of the crisis, that is to say, those impacted by safety measures but not necessarily directly affected by COVID-19. First, in the "Critical Issues for the Delivery of Psychological Assistance During the COVID-19 Outbreak" section, we acknowledge the key role of technology in providing access to, or ensuring the continuity of, psychological services to this population. We also flag conceptual issues with interventions–whether technologically mediated or face-to-face–that are strongly rooted in the biomedical model and draw on a symptom-centered approach. While recognizing the importance of taking symptoms into account in all clinical intervention contexts, we argue that symptom-centered approaches may be of limited benefit when applied to forms of distress whose diagnostic status is unclear (or inexistent).

We therefore suggest that a broader perspective on psychological intervention is needed. In the "Making Sense of COVID-19: Routine, Predictability, Narrative, Sense of Coherence, and Resilience" section, we explore the link between COVID-19-related distress and the disruption of meaning, going on to outline key theoretical aspects of the meaning-making process, such as routine, predictability, narratives, sense of coherence, and resilience. Then, in the "Enhancing Processes of Meaning Making About COVID-19 in the General Population" section, we describe a multipronged perspective on psychological intervention, whose main features are coherent communication strategies, the de-pathologization of distressful reactions to the pandemic, a widening of the field of observation from individuals to their relational contexts, and the negotiation of suitable personalized metaphors for enhancing psychological well-being. In the "Clinical Vignettes" section, we present two

[1]There is evidence that pandemics may also have positive effects, such as strengthening individual resilience, increasing levels of social cohesion, and fostering positive concern about mental health (Perrin et al., 2009; Pfefferbaum and North, 2020).

[2]The disruption of previous routines and the need to adjust to new ones represent a major source of stress for 74% of American parents.

clinical vignettes to practically illustrate how our proposed perspective might be applied in practice. Finally, in the "Concluding Remarks" section, we conclude by summarizing the broad criteria that we believe should inform intervention targeting COVID-19-induced psychological issues.

CRITICAL ISSUES FOR THE DELIVERY OF PSYCHOLOGICAL ASSISTANCE DURING THE COVID-19 OUTBREAK

The situation in countries that have implemented mass home confinement in response to the COVID-19 outbreak raises serious mental health concerns. However, policy makers dealing with large-scale public health challenges typically overlook recommendations to supplement physical health interventions with mental health programs (Perrin et al., 2009). Due to the perception that physical assistance is more crucial or urgent, and the awareness that enormous financial, political, and even communication resources are required to address the epidemiological aspects of pandemics, the psychological impact of the emergency may only receive attention at a later stage. Clearly, this has major implications for people's mental health and the availability of psychological assistance, compounding the critical factors that already routinely hinder access to mental health services.

Under normal conditions, a high proportion of people suffering from mental health problems do not receive care. It is well documented that the barriers to seeking treatment are attitudinal rather than structural. In other words, people are more frequently hindered from looking for help by their own thoughts and beliefs than by practical obstacles to accessing psychological services (such as a lack of financial resources, transportation, or availability). In a World Health Organization (WHO) study conducted by Andrade et al. (2014) in 24 countries, people with mental health issues reported not seeking treatment for two main reasons: 1. They wished to handle the problem independently. 2. Their self-perceived need for treatment was low, associated with the expectation that the problem would get better on its own. Now, in a pandemic scenario where the greatest emphasis is understandably laid on physical protection and the implementation of effective safety measures, it is likely that such attitudinal barriers may impact even further on people's willingness to ask for psychological assistance, at least in the initial stages of the emergency. We further hypothesize that a crisis like the COVID-19 pandemic will lead individuals to increasingly focus on ongoing challenges to their employment and financial status, and that this can easily lead them to divert personal resources away from caring for their mental health. Such a dynamic may be exacerbated by two concurrent factors. First, media and government communications about the risks associated with the pandemic and the safety measures to be adopted are frequently perceived as inadequate, alarming, and even contradictory (see Brooks et al., 2020), while the style, approach, and content of media and government communications can accentuate perceptions that some issues are more urgent than others, thus influencing the focus of people's attention. Second, growing recourse to drugs for stress-related symptoms may favor the adoption of shallow solutions to complex problems (Ao, 2020; Pesce, 2020). Furthermore, while the sample in the above-cited study by Andrade and colleagues was assessed using a DSM-IV-based diagnostic approach, in the current pandemic, people may suffer from forms of distress that are not strictly ascribable to traditional psychopathology or that fall below the diagnostic threshold and are therefore less immediately recognizable. Hence, during a pandemic, a lack of psychological surveillance is likely to become a major problem due to the combined effects of all these factors. There is a severe risk that people's psychological needs will remain unexpressed and untreated.

In a scenario like the present emergency, the use of technology to provide psychological assistance is turning out to be key, as the only viable way to overcome the necessary barrier of obligatory physical distancing. This last-mentioned concept has very recently replaced that of social distancing (Gunnell et al., 2020), in acknowledgment of the distinction between social connections and physical connections, and reflecting the fact that the former may be ensured by technological devices, while the latter are generally precluded during large-scale sheltering in place.

Although it is beyond the scope of this article to analyze in depth the use of technological devices for psychological purposes, we should note the undoubted advantages of deploying technology during an infectious outbreak. First, research has documented the efficacy of mental health services mediated by technological devices[3] in targeting psychiatric disorders across a range of populations and settings (Bashshur et al., 2016; Hubley et al., 2016; Ebert et al., 2018; Shore et al., 2020). Second, the deployment of technology is generally accepted and positively evaluated by clients (Bashshur et al., 2016; Hubley et al., 2016). Third, through the use of technological devices, psychological assistance can be made virtually available to all those who need it, including persons living in isolated regions or those whose liberty of movement is most severely restricted. Fourth, technology-based intervention is financially advantageous for clients, practitioners, and healthcare institutions alike (see Bashshur et al., 2016). Finally, technological mediation may mitigate the shame and stigma associated with attending psychological services, thus facilitating access to mental health assistance (Ebert et al., 2018). In sum, the psychological community has a duty to avail of technology to efficaciously deliver psychological interventions to the population at large. However, despite the huge potential offered by the online medium, certain limitations of most of the technologically mediated psychological services currently on offer should be noted. As Bashshur et al. (2016), as well as Ebert et al. (2018), have pointed out, mediated services are generally designed and delivered in keeping with standard cognitive behavior therapy (CBT) principles. In other words, due to the features of technological devices and the type of interaction that they

[3]A variety of labels are used in the literature to indicate these practices: telemedicine applied to mental health, telepsychology, mediated services, Internet- and mobile-based intervention.

typically support, these services most frequently target changes in specific behaviors and thoughts and are therefore particularly suited to treating specific psychopathological conditions such as, for example, panic disorders, and PTSD (Bashshur et al., 2016; Hubley et al., 2016). However, telepsychology is a multifaceted and evolving area comprising multiple kinds of services with diverse features. To simplify somewhat, one main type of intervention is closely modeled on face-to-face interaction: the practitioner/client relationship (whether in the area of counseling, education, psychotherapy, supportive intervention, etc.) is merely transferred to a different (technological) medium. Another group comprises more focused interventions, including interactive self-help lessons, virtual or augmented reality exposure-based techniques, serious games, avatar-led sessions, and others.

Both types of intervention–whether or not directly based on CBT principles–tend to be symptom centered, that is to say, they target discrete, well-defined symptoms,[4] using current diagnostic systems such as the DMS-5 (American Psychiatric Association, 2013) and the ICD-11 (World Health Organization, 2018).[5] There is ample evidence that this approach is rooted in a biomedical model of clinical intervention that has influenced clinical psychology more profoundly than is commonly believed (Henriques, 2002; Deacon, 2013; Frances, 2013; Castiglioni and Laudisa, 2015). Analogously to its treatment of bodily ailments, the biomedical model conceptualizes forms of mental distress as diseases, that is to say, as clusters of interconnected and concurrent symptoms (with diagnostic status) that form a single framework of disease (Hucklenbroich, 2017). It consequently emphasizes the development and delivery of disorder-specific treatments (Deacon, 2013), such as manualized interventions, behavior protocols, and skills training.

Now, what aspects of the biomedical model might turn out to be problematic when addressing the distress caused by the COVID-19 pandemic and its direct and indirect consequences? In answer, let us focus on two conceptual features of this model.

First, as stated above, it presupposes a sort of isomorphism between bodily problems and mental problems. Mental health issues are understood as forms of dysfunction, that is to say, as problematic (i.e., prejudicial) deviations from normal, physiological functioning. Thus, mental symptoms are viewed as signals that something is going wrong inside the individual: sources of distress are viewed as endogenous, while external factors only influence the expression of inner causes (see Slife et al., 2017). This perspective strongly favors biological explanations for mental health issues (Henriques, 2002; Deacon, 2013; Johnstone and Boyle, 2018).

Second, the biomedical model frames mental problems as relatively context independent, where context is understood as the social, situational, relational, and local conditions or circumstances in which a particular phenomenon occurs (see VandenBos, 2015). In principle, from a biomedical perspective, the diagnostic process may be conceptualized in two ways: as a part-whole explanation, whereby all symptoms are manifestations or components of the disease, or as a causal explanation, whereby all symptoms of a disease are connected by a causal chain (Hucklenbroich, 2017). In both cases, the conceptual resolution, although different in degree, is narrower in focus, centering on a sort of *micro-context* whose elements are internal to the individual (such as personality traits, reinforcement histories, cognitions, etc.) and proximal to the cluster of symptoms (hence generally biological in nature) (see Slife et al., 2017). This is because if symptoms are envisaged as impersonal displays of a discrete disease (see Hucklenbroich, 2017), understanding and diagnosing mental health issues will be seen as relatively independent of other specific situations or circumstances pertaining to the broader context where these issues have arisen (see Bradford, 2010; Jacobs and Cohen, 2010). This *meso*/*macro-context*, whose elements are distal to the cluster of symptoms and interpersonal in nature, thus becomes marginal to understanding an individual's distress. In sum, such an approach "assigns a secondary role to the social world as a source of 'triggers' or 'stressors' and offers a particular construction of the person, often as biologically different and vulnerable (. . .)" (Johnstone and Boyle, 2018, p. 90).

Hence, symptom-centered approaches grounded in the biomedical model bear methodological as well as practical implications when addressing mental health issues arising due to infectious outbreaks. On the one hand, they fail to acknowledge that forms of distress they label as mental problems might be better understood as coping strategies–although painful and onerous in terms of emotional resources–deployed to face extraordinary environmental circumstances (Bentall, 2009; Herman, 2015). They therefore risk overlooking or underestimating the active stance that an individual must adopt in order to cope responsibly with pandemic-related issues. On the other hand, symptom-centered approaches focus heavily on the disability associated with the problem under scrutiny, that is, the impairment interfering with the individual's ability to function in one or more key life domains (VandenBos, 2015). This emphasis may hinder the development and leverage of personal, familial, and social resources for dealing with distressing experiences; on the contrary, it may amplify the shame, guilt, and stigma often experienced in relation to mental health problems (Bentall, 2009; Deacon, 2013).

[4]In the interests of epistemological clarity, let us here summarize our perspective on "symptoms" throughout this paper: Far from viewing them as mere "facts," we conceptualize symptoms (and their diagnosis) as–at least in part–theoretical constructs. Indeed, "one of the major conclusions from the philosophical analysis of science after the demise of logical empiricism in the second half of the 20th century has been that there is no such thing as notions of 'experience', 'fact', 'evidence', and the like (including 'symptom'), which are *not* theoretically informed. In the wake of the tradition begun by philosophers and historians of science such as Hanson and Kuhn, a common place of contemporary philosophy of science is that any piece of scientifically relevant 'evidence' is, in fact, *theory laden* (Hanson, 1958), that is to say, it is meaningful only when viewed as part of a theoretical framework" (Castiglioni and Laudisa, 2015, p. 4). Nevertheless, in light of the specific aims of this paper, we do not set out here to make a systematic critique of the traditional diagnostic approach.

[5]We acknowledge that the weaknesses attributed to the biomedical model certainly extend beyond the boundaries of CBT and indeed concern many models of psychological intervention. However, we also note that most of the interventions offered during the pandemic–whether face-to-face or technologically mediated–have been based on CBT principles, given the core features of this approach (i.e., symptom centeredness, focus on rapid interventions, replicability of interventions, quantifiability of results, etc.). These features make the CBT model particularly apt to be chosen for intervention in emergency situations such as the COVID-19 pandemic.

This said, a caveat is in order here. We are not suggesting that symptom-centered approaches are to be rejected. We acknowledge that the treatment of symptoms is a key component of all clinical interventions targeting specific manifestations of distress. Furthermore, symptoms may be conceptualized as the "tip of the iceberg," so to speak, in that they often offer access to a client's needs and system of meanings. Indeed, symptoms are frequently the reason individuals decide to request a clinical consultation in the first place, as well as the conduit linking the client's needs with the clinician's competence. Hence, a careful clinical assessment of symptoms is a key component of any psychological intervention, regardless of the practitioner's clinical orientation.

Rather, we contend that: 1. Symptom-centered techniques (whether technologically mediated or not) may prove inadequate when used as stand-alone interventions, encouraging a mechanistic reading of complaints and treatment that is exclusively aimed at bringing about the remission of symptoms. 2. They may be unhelpful in cases of milder and/or blurred symptomatology, or manifestations of distress that do not fully meet any given set of diagnostic criteria (see Deacon, 2013). These considerations are relevant to the COVID-19 emergency insofar as we may reasonably assume that the most common sources of distress during infectious outbreaks do not necessarily give rise to classical mental health conditions, in terms of either intensity of distress (i.e., milder and/or subtle forms of distress may be the norm) or quality of subjective experience (i.e., they will likely generate new ways of coping with novel stressors).

We therefore argue that the marked influence of the biomedical model on most psychological practices–including those that are technologically mediated–risks undermining psychological responses to the challenges posed by the COVID-19 outbreak to the population at large.

MAKING SENSE OF COVID-19: ROUTINE, PREDICTABILITY, NARRATIVE, SENSE OF COHERENCE, AND RESILIENCE

As described above, the COVID-19 pandemic is generating a set of long-lasting triggers that are highly disruptive of the processes by which people usually make sense of their lives. It poses serious challenges, at a variety of levels, to the systems we all use (both individually and socially) to construct a meaningful sense of the world we live in and even of ourselves. Within the constructivist paradigm[6] (Neimeyer and Mahoney, 1995; Raskin and Bridges, 2002; Neimeyer, 2009), meaning construction is seen as the most central factor in human psychological life, a key to understanding both typical and atypical mental functioning.

Meaning making is a complex and multilayered process that includes cultural, linguistic, social, familial, and psychological (cognitive and emotional) components, among others. Together, these elements give rise to a *lived*, *dynamic sense of intentionality* and *selfhood*. Given the nature and variety of its constituents, meaning is never entirely individually constructed: it is something that we both "make and find" (Shotter, 1993, p. 77). In the specific domain of mental suffering, Guidano (1991, pp. 56–60) defined psychopathology as a "science of meaning," proposing that "personal meaning organization" shapes the meaning-making process that undergirds the development of self, lending coherence and stability to personal identity (citation omitted for anonymous peer review, Castiglioni et al., 2014). Hence, most forms of mental distress derive from a disruption (or interruption) to meaning making.[7] For example, in depression (one of the consequences of the COVID-19 pandemic viewed as most likely and harmful by WHO), "depressed persons often report that *they feel disconnected from the world*, that it appears as an *empty place deprived of all meaning*" (Jacobs, 2013, p. 2, italics added).

As long documented in the literature (Kelly, 1955; Bruner, 1990, 1991), there is a close (psycho)logical link between routine, predictability, and meaning. The disruption of everyday routines renders the world unpredictable, thus interfering with sense making, a process that according to Kelly (1955) relies on the ability to "predict and control events." In circumstances such as these, *time*–one of the core dimensions of human life–is deeply impacted: the *present* is "suspended" (a phenomenon that applies particularly to the confinement phase of managing the pandemic); the *past* no longer provides the wherewithal to interpret the current situation; the *future* becomes unpredictable, and all capacity for forward planning is arrested, given that most aspects of everyday reality have become fuzzy and unrecognizable, causing disorientation and the inability to act (a phenomenon that is typical of the current recovery phase).

The multifaceted process of meaning making described above organizes and expresses itself through metaphors and narratives. *Metaphors* serve to provide us with an idea of something that is hitherto unknown to us by associating it with an object we already

[6]By "constructivist paradigm" we mean a sort of broad theoretical "umbrella" encompassing a range of theories, which in, some cases, are different, and "rival" to each other (Kuhn, 1962-1970). Attempting to analyze the differences between the positions of individual scholars would mean initiating a huge and potentially never-ending epistemological debate. Such an analysis would fall far outside the scope of this paper. The present article, whose specific focus is the impact of the COVID-19 pandemic, is generally informed by the constructivist perspective. For each of the main points in our argument, we cite the authors whose work we consider most salient. All the scholars whose work we draw on may be viewed as belonging to the "extended family" of constructivism, in all its different varieties and with all its different nuances. This should be sufficient–for the specific purposes of the present work–to ensure the overall epistemological coherence of our proposed perspective, leaving the analysis of the different constructivist positions to other works (see for example, to limit the field to clinical psychology: quotations omitted for anonymous peer review; Neimeyer and Mahoney, 1995; Castiglioni and Faccio, 2010; Castiglioni, 2011). Importantly, the key constructs on which we have based our perspective display a degree of commonality. Specifically, they share the following common points, which may be viewed as alternative to the premises of the biomedical model: (a) a focus on the importance of meaning-making processes; (b) an emphasis on the "embeddedness" of such processes in social/relational contexts.

[7]From a "general" constructivist standpoint, we might say that mental distress arises when one feels that one's usual system of meanings has become useless, unavailable, or unsound for the purposes of making sense of one's current situation. Hence, the existing meaning-making system is "interrupted" or "suspended" before it has been possible to elaborate a sufficiently satisfactory "alternative type of construction" (whether by extending/further modifying the old one or by replacing it with a new one): no viable sense making (whether personal or "social") appears to be currently possible (Kelly, 1955; Feixas et al., 2009).

know (Battistelli, 2020), a function that bears similarities to the process of "anchoring" described by Moscovici et al. (2001) in his theory of social representations.[8]

Narratives are stories, based on metaphors, that convey the meaning of events in our lives over time (Polkinghorne, 2004; Squire et al., 2014); they thus offer a useful guide to interpreting and dealing with unfamiliar phenomena. "Narrative is a form of discourse that links events together across time, and thus, it can display the temporal dimension of human existence. Narrative form captures the notion that human lives are 'becomings' or journeys in which actions and happenings occur before, after, and at the same time as other actions and happenings" (Polkinghorne, 2004, p. 58).

Due to their discursive nature, narratives are constructed in and through social interaction. Neimeyer and Sands (2011) described how people organize the "seamless flow of life events," including negative happenings, into meaningful episodes that reflect personally significant themes, and then seek validation for this framework of meaning in the course of relating to others. From a narrative point of view, individuals construct a life story that is uniquely their own, yet unavoidably shaped by the social discourse of their specific cultural context.

The ability to construct meaningful and consistent narratives that illuminate and explain what is happening, at the individual, familial, and societal levels, appears to be a fundamental (pre)requisite for coping with any situation we may be presented with. Narratives, metaphors, and the set of meanings they convey, all contribute to establishing our *sense of coherence*.

The construct of sense of coherence (SOC), first proposed by Antonovsky (1993, 1987, 1979), offers a helpful framework for integrating personal and contextual factors. SOC is a stable universal construct that applies to all genders, social classes, and cultures (Sagy and Antonovsky, 2000; Eriksson and Lindström, 2005). It may be defined as a global predisposition reflecting the degree to which an individual feels pervasively, lastingly, and dynamically confident that internal and environmental stimuli are structured, predictable, and explainable (*comprehensibility*); that resources are available to meet the demands posed by these stimuli (*manageability*); and that such demands are challenges meriting investment and engagement (*meaningfulness*). Accordingly, sense of coherence would appear to be a key factor in our ability to deal with traumatic events such as the COVID-19 emergency and its direct and indirect aftereffects (Kimhi et al., 2010; Veronese et al., 2013; citation omitted for anonymous peer review).

There is no doubt that the COVID-19 pandemic, which is unprecedented in recent Western history, is a quintessential instance of the "unknown": one that defies all our usual sense-making systems, challenging our "sense of coherence." It thus requires the construction of new meanings, as well as of new routines, metaphors, and narratives, or–at the very least–a major revisiting or re-adaptation of existing ones.

As expressed by Prime et al. (2020, p. 9) in a "hot-off-the-press" paper on family well-being during COVID-19, "in recent weeks, families have encountered social disruption; family illness; and, for many, death and grief. They will experience the highest levels of adaptation when they are able to 'make sense' of the disaster by incorporating the events into their existing worldview, or by modifying their views, in a way that promotes health, togetherness, and a sense of coherence."

Significantly, Prime and colleagues view the *family* as playing a key role in the process of meaning (re)construction, given its status as the crucial point of intersection between the individual and social dimensions. They propose a conceptual framework based on systemic and ecological models of human development and family functioning, in which they link the social disruption (public health emergency, financial turmoil, job losses) caused by COVID-19 to family–and particularly child–adjustment, through a cascading process involving family caregivers, family (sub)systems, and family processes (Prime et al., 2020). A key construct in their work is "family resilience," a construct first developed by Walsh (1998, 2015), who–in a critique of the individualistic "deficit model"–reinterpreted the concept of resilience (traditionally viewed as an exclusively individual trait) according to insights drawn from systemic family therapy. "Walsh (1998, 2015) seminal work on family belief systems in fostering resilience highlights three critical areas in which family beliefs will be implicated in the response to COVID-19: (a) meaning making of adversity, (b) fostering a positive outlook, and (c) transcendence and spirituality" (Prime et al., 2020, p. 9).

Despite its novel status, COVID-19 presents some similarities to other traumatic events such as natural disasters, catastrophes, terrorist attacks, wars, and traumatic loss (Prime et al., 2020), all situations that elicit major distress (Veronese et al., 2010) found that, in a context of ongoing warfare and protracted political violence, the capacity to attribute sense and coherence to uncertainty promoted a sense of efficacy and power. Hence, the ability to construct meaning in uncertain and traumatic conditions may be expected to enhance psychological well-being and quality of life, mitigating the direct and indirect effects of trauma caused by adverse conditions. Furthermore, clinical theory on traumatic loss (Hooghe et al., 2012; Neimeyer et al., 2014; Procaccia et al., 2018 citation omitted for anonymous peer review) suggests that family systems and their crucial role in meaning-making processes contribute to a more advanced ability to make sense of adverse events.

The study of narratives can further our understanding of the processes through which family members maintain or construct a sense of resilience following a shared loss or, as in the case of the current pandemic, a prolonged adverse situation. This is borne out by the finding that mourners who succeeded in gradually integrating their bereavement into their meaning systems report fewer symptoms of complicated grief over the longer term (citation omitted for anonymous peer review; Holland et al., 2010; Procaccia et al., 2018).

Naturally, all of the factors in meaning making just outlined can be influenced, and potentially significantly reinforced, by the use of technological media. As observed in the "Critical Issues for the Delivery of Psychological Assistance During the COVID-19 Outbreak" section, new digital technologies can facilitate the

[8]Within this theoretical framework, Moscovici examined the process whereby scientific theories are translated into, and permeate, "common-sense" knowledge.

work done in clinical settings; more generally, they can enhance people's everyday interaction with others. For example, they can enable routines to be maintained that might otherwise be interrupted due to physical distancing requirements, or they can serve to convey and amplify narratives and metaphors, bringing them to the attention of wide audiences, and they can even offer a "laboratory" for the creation of new meanings.

In light of this background, how may the key coping factors we have just described be enhanced to equip the broader population for dealing with COVID-19?

ENHANCING PROCESSES OF MEANING MAKING ABOUT COVID-19 IN THE GENERAL POPULATION

One of the first areas requiring intervention is *communication strategy*. As argued by many (Brooks et al., 2020; Holmes et al., 2020), in a situation like the COVID-19 pandemic, all official and media communications should be clear, consistent, and brief, especially those concerning the practical rules to be followed in the interest of avoiding infection and accelerating recovery from the public health and economic crises. In practice, conflicting messages delivered by media and government agencies in many countries have posed an additional challenge to the sense of coherence of the general population, especially in terms of the perceived *comprehensibility* and *manageability* of the pandemic (Antonovsky, 1996; citation omitted for anonymous peer review, Veronese et al., 2013). With regard to comprehensibility, inconsistent information about the nature of COVID-19 undermines the perception that the phenomenon is predictable and explainable. With regard to manageability, confusing communications have prompted serious doubts about the technical and practical resources available to address the pandemic and its consequences.

Second, clinical intervention should foster the *normalization* of psychological reactions to the pandemic. It seems reasonable that–up to a certain degree–fear, anxiety, depressive mood, sorrow, preoccupation, disappointment, insomnia, lessened or increased appetite, inability to concentrate, and many other distressful reactions should be viewed as natural responses to the exceptional triggers generated by the COVID-19 emergency. As argued by Horwitz and Wakefield (2007, p. 9) in relation to depressive symptoms arising in response to adverse events, "such reactions, even when quite intense due to the severity of the experience, are surely part of normal human nature." It is therefore difficult to justify the current overreadiness to pathologize many "negative" reactions to detrimental stimuli (see Schimmenti et al., 2020; Venuleo et al., 2020). Of course, individuals can react very differently, in terms of both intensity and type of response, depending on a multitude of factors, including previous mental disorders, disadvantaged circumstances, economic difficulties, membership of discriminated-against minority groups, and so on (Johnstone and Boyle, 2018; Prime et al., 2020), and some reactions may be perceived as more "appropriate" than others with respect to society's standards of "normal." In any case, we, here wish to flag the risk of what Frances (2013) has termed diagnostic hyperinflation, a phenomenon that entails the medicalization of *ordinary* life. In the context of the current situation, an increase in distress and requests for psychological support should be generally viewed as an appropriate and proportional response to *extraordinary* circumstances that have altered virtually all aspects of everyday life. Thus, an uptick in demand for psychological services might even be seen as desirable, to the extent that it likely reflects self-awareness on the part of those undergoing distress. At the same time, initial psychological assistance should be characterized by *active listening*, with a view to allowing the client's needs to emerge and be expressed. As argued elsewhere (citation omitted for anonymous peer review, Castiglioni and Laudisa, 2015) in relation to depressive symptoms, throughout the diagnostic process, practitioners should take careful account of the traditional distinction between "endogenous" syndromes, arising in the absence of any apparent external reason, and "reactive" ones, triggered by negative external circumstances.

A third aspect, which is closely interconnected with the second, concerns the crucial importance of *widening the observational field* from individuals to their familial and social–relational contexts (Watzlawick et al., 1967; Bateson, 1972) if we are to fully understand the origins and nature of clients' suffering and contribute to the effective resolution of their difficulties. As argued above, the biomedical model tends to be a-contextual, limiting its observational (and diagnostic) focus to the individual. This is due to its implicit correlation with the so-called "deficit model." The latter posits that "psychopathology is the result of dysfunction and distress, which are attributed to some deficiency within the individual. Thus, the onus is on the individual to enact certain changes to reduce distress and dysfunction and consequently improve mental health" (Anglin and Polanco-Roman, 2017, p. 998). In contrast with this predominantly "illness-oriented" biomedical-deficit perspective, more health-oriented paradigms (Antonovsky, 1996; Seligman et al., 2005) emphasize the importance of promoting well-being by focusing both on individuals' personal strengths and on the resources available to them in their contextual environments, such as the earlier-cited factor of family resilience. The outcomes of previous research on war settings by one of the present authors (citations omitted for anonymous peer review, Veronese et al., 2010, 2012, 2013) suggest that clinical intervention should be designed to reinforce components of positive functioning rather than to "rectify" behaviors, patterns of thinking, or emotions perceived as maladaptive. In keeping with the methodological principle of widening the field of observation, clinical efforts should be directed at increasing clients' "social capital," in terms of maximizing and leveraging cohesion at the levels of family, networks of friends, and community. Used to this end, participatory frameworks and action research models can facilitate and enhance therapeutic interventions focused on symptoms (Razer et al., 2009; Smith and Romero, 2010). Overall, the emphasis should be on fostering well-being and strengthening positive coping factors, with a view to obtaining stronger outcomes in uncertain situations without short-term solutions (Nguyen-Gillham et al., 2008; Hunt, 2010).

Group intervention offers a valuable means of targeting this goal. We suggest that the formation of *ad hoc* peer groups–whose meetings could be physical and/or technologically mediated and would be led by a specialized psychologist, at least in the earlier stages–may be key in this regard. Such groups–by sharing their emotional experiences surrounding the pandemic and activating the members' personal resources–would counteract the sense of meaninglessness and disconnectedness induced by the decrease in the quality and quantity of interpersonal interactions imposed by the COVID-19 emergency. Indeed, the very fact of taking part in a group promotes a sense of being connected to others, which is crucial in the current scenario where individual behaviors are interdependent (in terms of the mutual observance of safety measures), yet people have far fewer opportunities to interact with one another (due to lockdown arrangements and physical distancing rules). Among their intrinsic therapeutic factors, groups can inspire hope, given that they "invariably contain individuals who are at different points along a coping-collapse continuum" (Yalom and Leszcz, 2005, p. 5): hence, mutual interaction among group members may itself instill the hope of future improvements. Furthermore, groups may foster a normalizing outlook on the personal issues and distressful experiences generated by the pandemic: the discovery that many issues and experiences are shared with others could prompt the members of the group to broaden their definition of "normal" (for examples of group interventions fostering meaning-making processes, see Breitbart et al., 2010; Lund et al., 2017). A particularly interesting format recently developed in the context of the COVID-19 pandemic is W I I Thrive,[9] a group-centered approach aimed at enhancing human dignity and well-being with integrity. Within this framework, individuals are encouraged to form peer groups with a view to connecting with and supporting each other and discussing the challenges of adaptive living, on the basis of a shared set of ideas, values, and practices (G. R. Henriques, personal communication, 28 May 2020).

Finally, spirituality, in terms of either religious beliefs and rituals or a sense of "connectedness" to nature, art, beauty, etc., has been identified as an additional key resource for coping, healing, and fostering personal, familial, and group resilience (Delgado, 2007; Walsh, 2010; Prime et al., 2020). In brief, active social and personal engagement with spiritual and/or religious experiences may contribute to maintaining an adequate sense of coherence, and thus to coping better with psychological distress caused by the COVID-19 pandemic and the resulting socioeconomic crisis (Drageset et al., 2008).

Fourth, interventions aimed at restoring and fostering well-being should focus on processes of *meaning construction*, drawing on *metaphors*, and *narratives* that orient clients in coping with the pandemic and its long-term consequences. Let us consider the "metaphor of war" as an example of this kind of meaning-making process, bearing in mind that the performative power of communication and language enables us to "do things with words" (Austin, 1962).

Throughout this paper, we have more than once drawn a parallel between how people may be affected by the COVID-19 pandemic and the impact on individuals and communities of ongoing armed conflict. It is not by chance that one of the figures most widely used in the media (as well as in everyday conversations among people) to describe the current health emergency has been the war metaphor: we are engaged in a war against an "invisible enemy" (the virus), a war that has its own soldiers, prisoners, heroes, martyrs, traitors, victims, and fallen. Vedovelli (in Milesi, 2020) has critiqued the pervasive use of this metaphorical device, arguing that it risks generating a climate of suspicion, closures, barriers, and clashes. On the contrary, Battistelli (2020), while recognizing the potential insidiousness of the "pandemic as a war" metaphor, has pointed to its effectiveness in conveying a notion of serious threat to people's safety, health, and lives, thus spurring us to join forces in combatting the disease. In Vedovelli's view, social communications should be aimed, on the one hand, at making the "inexpressible" (the invisible enemy) understandable through the *logos* of scientific discourse and, on the other, at generating and supporting social relations. The debate between these two scholars illustrates how different metaphors give rise to different narratives and sets of meanings, potentially orienting the way in which we experience, interpret, and deal with the pandemic.

Of course, in our opinion, other metaphors could be viable, too. For example, the metaphor of the journey (Polkinghorne, 2004), which portrays us as currently traveling over very rough terrain with no reliable map, or the bereavement metaphor (Neimeyer et al., 2011), whereby, as a community, we have joined together to mourn our previous way of life, hoping that a new alternative will soon emerge, or the "man-as-scientist" metaphor (Kelly, 1955), according to which we all strive to predict and gain control of events, for example, by researching the causes of this unprecedented phenomenon and studying new solutions for overcoming or managing it. However, the range of metaphors available in a certain cultural context are not infinite. Given that meaning-making processes are embedded in their social–cultural and historical contexts, to some extent, "the affective interpretation of the insurgence of the pandemic scenario, rather than depending on the inherent characteristics of COVID-19, reflects the patterns of affective meanings grounding the cultural milieu at the moment in which the interpretation was enacted" (Venuleo et al., 2020, p. 124).

All these metaphors produce different narratives and interpretations, which in turn may prompt different attitudes and behaviors. In the context of clinical intervention, the practitioner can negotiate suitable personalized metaphors with the client.

CLINICAL VIGNETTES

We now present two clinical vignettes with a view to practically illustrating–although in brief–some aspects of the clinical perspective outlined in the last section.

[9]W I I stands for "We" (referring to one's relationships with others), "I" (individuality and subjectivity), "It" (referring both to the natural world and human technological and scientific understanding of it). Thriving refers to a state of flourishing, optimal functioning, and fulfillment across all levels of analysis and time frames (see https://www.wiithrive.com/home).

The first vignette thematizes the normalization of distressful experiences generated by the COVID-19 pandemic and the value of widening the field of observation to include the client's present and past contextual environment.

> C., an only child, is a 49-year-old married woman with two children, one of whom displays difficult personality traits. She lives with her family in the suburbs of Milan. At the age of nine, she lost her father, a farmer, and spent her youth with her mother, a woman – then in her late forties – without a formal education. At the age of 20, she met her husband, whom she describes as "a strong man you can rely on." However, she has somehow always felt inferior to him: she still believes that she was lucky he "chose her, a simple country girl." She is now employed by a state-owned enterprise.
>
> During the COVID-19 home confinement, she discovered that she had been in contact with an elderly woman who later passed away due to coronavirus. As required by governmental regulations, C. reached out to the local health authority to report what had happened. She was very worried about her own health status and tried to gather information about the possible consequences of infection. She relayed that the health professionals she spoke with – first by phone and later in person – had displayed a highly detached attitude. In their interactions with her, they focused solely on what had happened during the brief contacts C. had had with the deceased woman and on the measures to be taken as a result. C. was clearly distressed by the situation but had the impression that her concerns were largely being ignored. When healthcare personnel finally called her home, she described their attitude as cold and "medical." The team's protective attire and scant verbal interactions with C. – while consulting frequently among themselves – all contributed to making her feel even more "psychologically distant" from the very people she was relying on to take care of her. C. began to believe that her worries were excessive and stopped "trying to make an emotional connection" with the health professionals, from whom she had initially expected a word of comfort. In the weeks following the in-home meeting, one of the team phoned her regularly once a week, but kept the conversation firmly focused on her observation of the confinement rules and on recording "objective parameters" (temperature, presence of breathing difficulties, etc.). C. shut down during these calls and only spoke to answer the questions put to her by the health worker. She began to think that her worries were "wrong" and unworthy of attention.
>
> Although she was developing an increasingly judgmental attitude toward herself, she also progressively felt the need to share what had happened with someone who would really listen to her. Her husband was not a candidate given that he tended to minimize and trivialize her emotional concerns.
>
> When she first met one of the authors for a consultation, her sense of being emotionally incompetent was evident. She stated that "normal people react differently," while she herself "couldn't stop crying during the lockdown, like a kid." At first, she was unable to connect the extraordinary nature of the disruption to her everyday routines with the emotional reactions that had followed. The habitual meanings underpinning her self-assessments ("You're just a country girl," "You don't know how the world works," "You must be wrong to feel or think this," and "Stop crying and complaining") continued to prevail over any objective evaluation of the situation. The aim of the initial sessions was to listen closely and nonjudgmentally to her account and help her to link her emotional reactions to what had actually happened: drawing out this connection was intended to normalize her experiences, making them more understandable and acceptable to her (see the *normalization criterion*). This required the clinician to adopt a widened perspective that encompassed the personal, familial, cultural, and social contexts in which the sources of the client's distress had come into play. In light of these contextual features, the clinician guided the client toward developing a more comprehensive understanding of her life conditions. He did so by encouraging the client to view her thoughts and emotions as reactions to (internal and external) stimuli, rather than as manifestations of an inner and immutable deficit (see the *criterion of widening the observational field*). The practitioner also sought to enhance the client's awareness that these reactions had been strongly influenced by her personal history by fostering the construction of an alternative narrative framework, and specifically the view that the client had attempted to cope with an unprecedented series of unpredictable events based on the personal resources she felt she could count on. Such resources were deeply rooted in her own proximal and distal history and profoundly influenced the ways available to her for dealing with the events of the pandemic: the clinician noted that she could not have reacted any differently, given the exceptional nature of the events and the (personal, psychological, familial, social) resources at her disposal. To this end, he made connections between C.'s history and her present concerns. The clinician also made extensive use of a metaphorical analogy, drawing from the client's personal history. Because the client's mother had been bitterly critical toward her and excessively demanding considering her daughter's age ("an inflexible schoolmistress," in the shared language of the therapy), the client was continuously at risk of adopting the same attitude toward herself, and focusing exclusively on performance ("You should have done better!") rather than taking into account the unfavorable conditions she had been obliged to face ("I could not have behaved or thought differently, considering that. . ."). This negotiated and reiterated metaphor helped the client to develop a strong sense of kindness toward the much-criticized little girl that she had been and to transfer this to a considerable extent to her "adult-self." This, in turn, fostered the development of a nonjudgmental, positive attitude toward herself and her emotional life more generally, helping her

to make new sense of the difficulties she had encountered in the process of coping with the pandemic (see the *criterion of fostering meaning-making processes through the use of narratives and metaphors*).

The second vignette, while also confirming the importance of contextual factors, touches more specifically upon the role of community resilience and the mitigating effects of experiencing connectedness and transcendence.

F., an only child, is a 39-year-old single woman who has been living in Milan for the past 10 years. Her family is wealthy and highly cultured; she herself is very bright and has broad cultural interests. Her parents have been always emotionally unreliable: in her everyday interactions with them, they display an unpredictable mix of support, indifference, and offensiveness. She attended university in another town, where she felt unable to live up to her parents' expectation that she should be independent. During this troubled university period, she began taking drugs and abusing alcohol. A few years later, after hitting a particularly low point, she decided to give up drugs, and did so successfully and on her own. After completing her studies, she planned to pursue her longstanding dream of working abroad. However, the sudden news that her mother was seriously ill interrupted this project, and she decided not to leave so she could care for her mother. In recent years, she has worked on and off and decided to enroll at university again, although she feels like "a fish out of water." Nevertheless, she has recently experienced a "pleasant sense of continuity" from devoting herself to work and recreational activities that "at last have meaning."

The COVID-19 home confinement hit F. hard. On the one hand, she became increasingly concerned about the social and personal effects of the pandemic, worries that were exacerbated by news stories in the media, which she followed incessantly during the lockdown period. On the other hand, her sense of disconnect – which habitually took the form of feeling "unusual" or "odd" (on account of still attending university in her late thirties, being able to afford not to have a proper job, having unusual and varied cultural interests, etc.) – was progressively exacerbated by a lack of interaction with others due to the home confinement measures. Her sense of personal identity gradually became more fragile, in the absence of habitual reference points such as interpersonal interactions, daily routines, work, and recreational activities. She felt that the continuity in her life – which she had finally achieved after "meaningless years without building anything significant" – was in danger: the temporary disruption of her routines had triggered a sense of meaninglessness, associated with low mood, hypersomnia/insomnia, hypervigilance, and occasional convulsive crying.

F. found unexpected relief when – by chance – she tuned into an independent radio station, whose contents she perceived as surprisingly in harmony with her own worldview and interests. Day after day, F. felt increasingly more connected, reporting the clear perception that "there are people out there that I feel connected with: I'm not alone anymore!" She perceived this connection to be profound, rooted in the arts, human values, and cultural interests. Her contact and interactions with the radio presenters and their guests – although mediated by technology – had the effect of "turning something around." First, the distress F. reported having experienced gradually remitted; second, she became determined to stop delaying completion of her university course and decided to seriously devote herself to her studies. In view of the above, F. requested a psychological consultation.

During the first session with the clinician, F. displayed a generally disparaging attitude toward herself, behaving as though she expected the clinician to judge her for being "odd" and "unusual." The clinician challenged this "given" definition of herself, asking the client to explain what she meant by "odd" or "unusual." Their ongoing exchanges on this topic progressively led the client to acknowledge that her "isolation made her feel like she was 'unique,' in the negative sense of the word". She also recognized that she might have been feeling like this because she had hardly ever had the opportunity to meet people with similar interests and cultural awareness before tuning into the radio station (see the *criterion of normalization*). This discussion with the practitioner encouraged the client to do a "reality check" (as she evocatively said) and to "come out of my own narrow subjective perspective" (cit.) to consider the possibility that her personal experience – although private – could, nonetheless, be shared with many other individuals, at least on the basis of "our common human nature" (see the *criterion of widening the observational field*). This gradually led F. to develop a more appreciative attitude toward herself, as well as toward her own areas of knowledge, interests, and personal resources, in general. The practitioner pointed out to her that these resources can be useful for coping with reality, even in the face of an unprecedented event such as the pandemic: he connected the challenges of the present time with her skills and capacities. These comments were received with a mixture of suspicion and curiosity, and progressively fostered the construction of new meanings related to the events surrounding the pandemic. F. began to perceive herself differently, as "more resilient," and found the courage to leave her home to safely meet other people. Borrowed from a popular saying, a metaphor emerged in the course of therapy, thus formulated by F.: "we are all experiencing the same storm. We are not in the same boat though: some people are sailing in fancy yachts with all the comforts, others in flimsy cheap rowing boats. Everyone is reacting in their own way to this pandemic, and there's nothing wrong with that. I know I have to take care of my boat, the same as everyone else. Still, F., don't forget there's a storm out there!" (see the *criterion of fostering meaning-making processes through the use of narratives and metaphors*). This metaphor expressed F.'s gradually developing awareness of being personally responsible for her life decisions.

CONCLUDING REMARKS

Undoubtedly, the dramatic impact of the COVID-19 pandemic on the mental health of the general population gives much cause for concern. Individuals, families, and communities have been cast back on their own resources on an unprecedented scale. In light of this scenario, we have attempted to sketch out a perspective on psychological intervention that we believe to be appropriate for addressing the crisis and its aftermath.

In summary, clinical interventions aimed at relieving the distressful consequences of the pandemic should fulfill a set of general, but crucial, criteria:

1. *Flexibility*. There should be scope for interventions to address forms of distress whose manifestations are blurred and/or milder than expected, and do not necessarily fully conform to any specific diagnosis.
2. *Personalization*. Interventions should be informed by an assessment of symptoms that takes the client's underlying meaning systems into account, given that similar adverse stimuli may hold very different meanings for different individuals and in different contexts. Attending to the dimension of meaning should not exclude the use of symptom-centered techniques where required.
3. *Extended focus*. Interventions should conceptually link the development of mental problems to external triggers and stressors ascribable to the interpersonal domain (vs. solely internal triggers ascribable to the internal and/or biological domain). This is what we have defined as widening the field of observation to situate events (such as the client's complaints or symptoms) within their interpersonal contexts and promote an understanding of distressful experiences as strategies for coping with objective external challenges.
4. *Emphasis on positive resources*. Intervention should foster awareness of personal, familial, and social resources and their deployment to develop personalized coping strategies, in a shift away from exclusively deficit- and disorder-centered outlooks.

We believe that all practitioners, independently of their clinical orientations, may benefit from adopting these overarching criteria. Our recommendations are not in conflict with the theoretical and methodological specifics of the various clinical approaches. Rather, we advocate for a broader psychological perspective on forms of distress associated with the negative cascade of events that has ensued upon the COVID-19 outbreak, suggesting that they call for a departure from more classically disorder-oriented and deficit-centered outlooks. In short, our ultimate purpose is to contribute to the debate on how traditional forms of clinical intervention may best be adapted to the novel contextual factors being shaped by the pandemic.

The Public Health Impact of Coronavirus Disease on Human Trafficking

Jordan Greenbaum[1,2*], *Hanni Stoklosa*[2,3] *and Laura Murphy*[2,4]

[1] *Institute on Healthcare and Human Trafficking at the Stephanie V. Blank Center for Safe and Healthy Children at Children's Healthcare of Atlanta, Atlanta, GA, United States,* [2] *HEAL Trafficking (Health, Education, Advocacy, Linkage), Los Angeles, CA, United States,* [3] *Department of Emergency Medicine, Brigham and Women's Hospital, Harvard University, Boston, MA, United States,* [4] *Helena Kennedy Center for International Justice, Sheffield Hallam University, Sheffield, United Kingdom*

The global pandemic of severe acute respiratory syndrome coronavirus 2 exacerbates major risk factors for global human trafficking. Social isolation of families and severe economic distress amplify the risk of interpersonal violence, unemployment and homelessness, as well as increased internet use by under-supervised children. Aggravating the situation are overwhelmed health systems, severe limitations in activities of social service organizations, and decreased contact of healthcare professionals with children. Healthcare professionals have a duty to be alert to possible indicators of trafficking, and aware of available victim resources which can be offered to at-risk patients. Healthcare facilities should take steps to increase public awareness of trafficking and community resources.

INTRODUCTION

Human trafficking is a major global public health problem (1, 2). In all likelihood, the prevalence of exploitation will increase as a result of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic (3–6). Trafficking involves the exploitation of others using force, fraud, coercion, or abuse of power, principally in the contexts of commercial sex and forced labor (7). The impact of human trafficking ranges from individual health consequences (e.g., traumatic injury, infections, unwanted pregnancy, malnutrition, exposure to toxins, post-traumatic stress disorder, and depression) to family strife and division, community discrimination, business expectations for docile and unpaid labor, and societal norms of cheap consumer goods.

The recent global outbreak of SARS-CoV-2 has led to major social changes severely limiting social interaction and restricting movement of individuals and populations. While research on the specific impacts of COVID-19 has yet to emerge, the current state of knowledge provides some insight into the ways such a global crisis will likely exacerbate vulnerabilities to trafficking (5, 6). Social distancing and closures of schools and businesses have decreased in-person contact and expanded online communication. Dramatic changes in the economy have also significantly increased unemployment, poverty, and homelessness (8). The changes have the potential to markedly increase the risk of human trafficking both during and after the pandemic. Notably, baseline risk for trafficking is not equally distributed in society. People of color, gender minorities, migrants, those with a history of abuse, and the working poor are more likely to experience trafficking (9–14). The pandemic's impacts will likely magnify these risks among

already marginalized populations. COVID-related trafficking risks may be grouped into three interrelated categories: family life, economic distress, and limits in external professional assistance. Intensification of family strains due to quarantine may be exacerbated by both economic strain and limited access to services, all combining to produced new and heightened vulnerabilities, especially for those marginalized populations who are unequally affected by both COVID-19 and human trafficking. It is incumbent upon HCPs to be aware of these heightened risk factors during pandemics.

FAMILY LIFE

1. **Rise in intimate partner violence (IPV) and child maltreatment**. Family violence, including IPV and child abuse are risk factors for human trafficking (15, 16). Given the mandated restrictions in movement seen in many countries as part of the coronavirus disease (COVID-19) mitigation effort, as well as closures of alternative safe housing, and increased financial pressures, families struggling with violence and interpersonal dysfunction are forced to spend increasing amounts of time together, which may exacerbate tensions, Reports related to IPV and child sexual exploitation increased in multiple countries during the early period of the Covid pandemic (17, 18). Increased financial strains may result in family members exploiting each other into forced labor. Overcrowding within a residence, and/or the presence of a sexual offender may render children in the home vulnerable to sexual abuse or exploitation. Maltreated children are less likely to come to the attention of mandated reporters now that schools are closed (19). This allows abuse to go unchecked and potentially drives a child to run away from home, rendering them at an even higher risk of exploitation.
2. **Increased use of internet by children.** With school closures many children turn to social media and other online activities to fill their time. For those who engage in risky online behaviors such as acting aggressively toward others, or sharing personal information with people met online (20), and who have risk factors associated with offline sexual abuse may experience increased risk of online sexual exploitation, especially if the added time on the internet occurs in the context of limited supervision (21). The allure of fraudulent online job ads can also increase risk of labor trafficking for children, youth, and adults who lack safe job searching skills.

ECONOMIC DISTRESS

1. **Labor exploitation/trafficking**. Globally, economic stress could increase cross-border migration in search of work, which can put people at risk of exploitation (9, 22). Simultaneously, border closure to prevent the spread of infection could limit workers' options to migrate for safer work conditions outside their home countries or increase the cost associated with migration (23). In these situations as well as others involving increased economic crisis due to COVID-19, desperate adults and youth may be forced to accept exploitative, coercive, unpaid, or inescapable work conditions (5, 6). Caregivers may allow children to engage in hazardous child labor such as work with dangerous machinery, or work in an unhealthy environment. Children and youth may be induced to engage in illicit activities to earn money, such as selling or transporting drugs.
2. **Sexual exploitation/trafficking**. Caregivers in financially fragile positions at baseline may resort to sexual exploitation of children to pay for food or other necessities (24). Adolescents may decide to assist the family in obtaining money by selling sex. Adults involved in consensual commercial sex may find it more difficult with COVID-19 restrictions to solicit clients, forcing them to engage in riskier behaviors and to accept clients who might present greater danger of abuse, rape, or trafficking (25).
3. **Traffickers.** In addition to the increased vulnerability described above, economic strain could encourage people to engage in illicit activity, including compelling or coercing others into unpaid labor or forced sex work (6, 24, 26). Addressing economic strain is as relevant to preventing victimization as it is to preventing perpetration.

LIMITS IN ASSISTANCE FROM PROFESSIONALS

1. **Overwhelmed health systems**. The surge in hospital and emergency department admissions related to COVID-19 has overwhelmed health systems in many countries. Major concerns about infection exposure, PPE and ventilator shortages, and treatment of severely ill patients take priority in the attention of healthcare professionals (HCP) and administrators. Understandably, other urgent situations including human trafficking may be overlooked and the opportunity for offering resources to exploited persons missed. HCPs may assume there is no time to screen for trafficking and exploitation or to spend time counseling about worker rights, community referrals, and resources.
2. **Overwhelmed social service agencies**. As social service agencies struggle with cuts to funding and keeping clients and staff safe, typical face-to-face contact and service provision for high risk families may be limited (4). Organizations providing services to trafficked persons, immigrants/refugees, and homeless/runaway youth and adults will need to shift outreach techniques to identify and serve those in need.
3. **Under-staffed law enforcement agencies**. Economic desperation, homelessness hunger, and anti-immigrant bigotry may lead to marked increases in crime and general social unrest. Over-stretched law enforcement staff may shift their focus away from trafficking investigations.

DISCUSSION: WHAT CAN HCPs DO?

Trafficking is a public health issue that affects people of all ages, races, genders, nationalities, and sexualities. While trafficking and other forms of violence occur regardless of pandemics or natural disasters, it is critical in moments of heightened risk that

HCPs equip themselves to be particularly vigilant and prepared to assist survivors. The following are recommendations that HCPs can implement to address the overlapping heightened trafficking risk factors related to familial life, economic distress, and HCP capacity. These actions are designed to increase the likelihood of identifying individuals at risk of trafficking and providing them appropriate care, regardless of the underlying exacerbating circumstances, which will often be obscured to the practitioner.

1. While HCPs may have very little time to spend with patients in person, especially those without concerns of SARS-CoV-2 infection, even emergency department staff can offer at-risk patients written resources related to worker rights, IPV, national human trafficking hotlines, and/or immigrant/refugee services (27). If delivering healthcare via telemedicine the provider can type in the links in the "chat" box. Such resources can be downloaded from HEAL Trafficking (https://healtrafficking.org/patient-resources/, and https://healtrafficking.org/covid-19-resources-2/).
2. When conducting telemedicine evaluations, HCPs should be observant of conditions in the patient's environment. If such a visit occurs in the home of a trafficked/exploited person, possible indicators of exploitation may be evident, such as apparent bullying or violence occurring in the home environment, other suspicious activity in the background, or the presence of a domineering companion who wants to speak for the patient.
3. Healthcare facilities should display posters on human trafficking, IPV and other forms of violence, including contact information for resources and other assistance for both patients and providers. These posters should avoid using sensational images that reinforce stereotypical images of white cis-gendered female sex trafficking victims, and rather capture a diversity of lived experience, in order to improve outreach to the most affected communities.
4. HCPs may collaborate with community providers serving vulnerable populations and, with the patient's permission, refer patients for virtual or in-person services. Lists of national online resources are also a potential source of assistance to vulnerable patient populations.
5. Encourage HCPs to identify community and government agencies providing emergency support (e.g., food and basic supplies) and make a list of such service providers easily accessible to patients who travel to health facilities or engage in telehealth sessions.
6. Encourage health professional organizations to advocate for labor rights and enforcement of labor laws, especially those related to minimum wage, work hour limits, safety requirements, and healthcare benefits for workers.
7. Since there is significant overlap in risk factors for online and offline sexual abuse/exploitation, as well as for online and offline labor exploitation, research suggests that HCPs use established strategies for offline abuse prevention to help reduce the risk of online exploitation. For example, they may counsel pediatric patients and caregivers about healthy and unhealthy relationships, the importance of consent, respect for others, safety planning, and safe job search strategies (28).
8. Talk to caregivers about joining online support groups or having their children join safe, supportive, well-monitored peer groups.
9. If an HCP suspects exploitation/trafficking, they should report concerns to authorities ***IF*** (1) the patient appears to be in imminent danger (call emergency services), (2) the HCP has a mandatory reporting obligation, or (3) the report is not mandatory but the patient requests law enforcement involvement. All HCPs should be aware that reporting can lead to negative consequences including (but not limited to) criminalization of victims, immigration proceedings, and violent repercussions, so it is imperative that patient requests regarding law enforcement engagement be respected when possible, given mandatory reporting laws. In addition, if the decision is made to involve law enforcement, every effort should be made to engage the members of law enforcement most informed about the complexities of trafficking.

For information on how HCPs can assess for trafficking and connect trafficked patients to resources, see **HEAL Trafficking (resources for health professionals): www.HEALtrafficking.org.** Health professionals may connect trafficked persons with the **National Human Trafficking Resource Center hotline: 1-888-373-7888 (SMS "BEFREE") 24/7.**

Introduction: The COVID-19 outbreak is having an impact on the well-being of healthcare workers. Mindfulness-based interventions have shown effectiveness in reducing stress and fostering resilience and recovery in healthcare workers. There are no studies examining the feasibility of brief mindfulness-based interventions during the COVID-19 outbreak.

Materials and Methods: This is an exploratory study with a post intervention assessment. We describe an on-site brief mindfulness intervention and evaluate its helpfulness, safety, and feasibility.

Results: One thousand out of 7,000 (14%) healthcare workers from La Paz University Hospital in Madrid (Spain) participated in at least one session. One hundred and fifty out of 1,000 (15%) participants filled out a self-report questionnaire evaluating the helpfulness of the intervention for on-site stress reduction. Ninety two subjects (61%) participated in more than one session. Most of the participants were women (80%) with a mean age of 38.6 years. Almost half of the sample were nurses (46%). Sessions were perceived as being helpful with a mean rating of 8.4 on a scale from 0 to 10. Only 3 people (2%) reported a minor adverse effect (increased anxiety or dizziness).

Discussion: Our data supports the utility, safety and feasibility of an on-site, brief mindfulness-based intervention designed to reduce stress for frontline health workers during a crisis. There is a need to continue testing this type of interventions, and to integrate emotion regulation strategies as an essential part of health workers' general training.

Clinical Trial Registration number: NCT04555005.

INTRODUCTION

The pandemic caused by the SARS-CoV-2 poses a major challenge for national health systems around the globe. Along with Italy, Spain was one of the European epicenters of the pandemic, with more than 220,000 people infected and over 25,000 dead by May 15th 2020, the core period of the pandemic in Madrid (Spain) until date (1). Currently (by August 10th) 322,980 people have been infected and 28,576 have died (2). Almost one third of the people infected were diagnosed in the region of Madrid, where more than 8,000 people died from February 25th to May 15th (8,464 to August 10th). Hospitals had to change their structure almost entirely in order to effectively respond to the emergency.

La Paz University Hospital is a public, general hospital in Madrid that provides healthcare to a catchment area of over 500,000 people. Around 3,000 patients infected with SARS-CoV-2 have been treated in this Hospital by May 15th (3). Since the beginning of March 2020, most of its units were converted to COVID-19 wards, non-emergency surgeries were canceled, and beds in intensive care units (ICUs) were quadrupled. Additionally, many professionals from different specialties were deployed to the frontline. This entailed working with unknown colleagues in novel settings where safety and trust are critical.

Healthcare workers have been a vulnerable population exposed to close contact with infected patients, to an excessive workload and to experiences of physical exhaustion, fear, emotional disturbance, and dysregulation of sleep patterns during the COVID-19 pandemic (4–8). Many studies have been conducted in China during the outbreak, and the results reveal high rates of anxiety and depressive symptoms, sleep problems and psychological distress in more than 70% of the surveyed samples (4, 9). In addition, follow-up studies show that psychological effects may persist long after the outbreak. Wong et al. found that 3 years after the 2003 SARS outbreak, 23% of healthcare workers reported moderate to greater depressive symptoms (10). This outbreak is also putting healthcare workers into ethical and moral dilemmas. They have to make decisions that may include how to allocate scant resources to equally needful patients, how to balance their own physical and mental health needs with those of the patients and how to align their commitment to help patients with their willingness to be with family and friends (11). In light of this situation, the Word Health Organization has made recommendations for identification and management of physical, mental health and psychosocial well-being in healthcare workers (12, 13).

Previous studies outline the importance of safeguarding the morale and mental health of healthcare professionals as this can influence the success of healthcare delivery (14, 15). Stigma and abandonment have been reported across various outbreaks despite differences in culture, education levels and available healthcare services (16, 17). Besides physical recommendations that may help reduce psychiatric symptoms, studies emphasize as coping strategies the support from colleagues and sustained engagement with updated, reliable information about the outbreak (18).

Our Mental Health Team participated in the Ebola Health Emergency in Madrid (Spain) in 2014. A total of 100 people, most of them healthcare workers, were attended (19). One emphasized conclusion was that the mental health team should be involved during the emergency from initial stages providing training in emotion regulation techniques for the rest of professionals.

Mindfulness is the ability to pay attention to the present moment in an intentional, non-judgmental way (20). Mindfulness-based programs have shown efficacy in reducing stress (21) and increasing quality of life and self-compassion in healthcare professionals (22). Gilmartin et al. conclude in a systematic literature review that brief mindfulness interventions (lasting 5–20 min once a day) may be effective in improving healthcare provider's well-being and decreasing levels of anxiety and stress (23). Furthermore, mindfulness training is associated with emotion regulation, fostering well-being and resilience and promoting switching from a state of automatic pilot to one of cognitive awareness, enabling a more thoughtful approach to clinical decision-making (24–26). Other studies outline the importance of self-compassion because of its positive association with happiness and recommend to include specific self-compassion components in future programs aimed at enhancing well-being in healthcare workers (27, 28).

Mindfulness can certainly be a "pathway to resilience and recovery" during the COVID-19 pandemic (29). One of the actions taken by La Paz University Hospital's Mental Health Team was developing a brief Mindfulness-based intervention for frontline healthcare workers to train emotion regulation. Following the recommendations given by some authors with experience in mindfulness training (24, 30), the intervention was

conceived as a brief experience (between 5 and 10 min), delivered on-site (at COVID-19 wards) and repeatedly (twice a day, 7 days a week), during 7 weeks.

The aim of the present study is to describe an on-site, brief mindfulness-based crisis intervention and explore its feasibility, helpfulness and safety for frontline healthcare workers in the midst of the COVID-19 storm.

MATERIALS AND METHODS

This study was developed as an exploratory research design with a post-intervention assessment.

From the beginning of the emergency, at least two members of the Mental Health Team went to the places where frontline health professionals were working (emergency department, ICUs, COVID-19 wards) and offered the intervention on-site.

The Ethics Review Board approved the study and concluded that due to the emergency situation and the fact that such type of intervention was delivered as routine care at our hospital, participants' consent was not required. Trial registration number: NCT04555005.

Measures

An anonymous, short self-report questionnaire was designed *ad hoc* to collect the following variables: age, gender, profession, workplace, session attendance, and perceived helpfulness in reducing current stress (ranked on a 0–10 point visual analog scale). Subjects filled out the questionnaire right after the session.

We collected the following data as indicators of the utility, safety and feasibility of the implementation of this intervention:
Utility:

- Mean "perceived helpfulness in reducing current stress."

Safety:

- Number and % of participants who reported any kind of adverse event.

Feasibility:

- Number and % of professionals who attended at least one session, out of the total number of health care workers of the hospital.
- Number of sessions that were held in COVID-19 wards between March 10th and April 26th.
- Number and % of participants who filled out the survey out of the total number of professionals who attended at least one session.
- Number and % of professionals who attended more than one session.

Intervention

The intervention consisted of 5–10 min of mindfulness practices delivered twice daily by experienced psychiatrists, psychologists, and mental health nurses. They were supervised by certified mindfulness trainers. The intervention was presented to each new team with an introduction as a justification of the action based on: (1) The importance of self-care, as professionals are the most valuable means the system has to deal with the crisis. There is no care for others if there is no care for oneself; (2) Placing mind training and emotion regulation at the same level of importance as the dressing and undressing of the personal protective equipment; and (3) The need to build an inner space of calm in the midst of the storm, from which successful actions can be taken. This explanatory introduction seems a key element to improve the acceptability and the adherence to the intervention. Three elements were trained in each session: (1) Focused attention through the invitation to kindly rest attention on a specific anchor, such as breathing, parts of the body like hands or feet, or the surrounding sounds; (2) Conscious movements through soft hatta yoga stretching exercises which were done standing or sitting, adapted to any physical condition; and (3) Compassion, through kind and inviting language and attitude, *via* specific sentences and gestures which invite to care for oneself (i.e., placing one or both hands on the chest). Participants were invited to recognize and accept without judgment any emotion, thought and body sensation that arose during the practice.

Sessions were characterized by being proactive, on-site, flexible, repetitive, generating an internal pause and place of empowerment. Flexibility was manifested in the order in which each element was presented and the duration, which could be changed depending on the context and the level of energy or concern of each team at each moment. For example, if we felt that the team was highly aroused, we started with a set of conscious movements. The aim was to recognize the tension and restlessness present at that particular moment and to invite, through the practice, to focus the attention to the present moment in a kind and compassionate way.

RESULTS

More than 3,000 sessions were held in COVID-19 wards between March 10th and April 26th, the core period of the pandemic in Madrid (Spain) until date. Any worker of La Paz University Hospital could participate. One thousand out of 7,000 healthcare professionals (e.g., physicians, nurses, social workers, physical therapists, technicians, cleaning staff) attended at least one of the sessions. Therefore, the initial enrollment rate was of 14%. **Table 1** shows, utility, safety and feasibility outcomes.

The rate of survey completion collected for 3 days (from April 13th to April 15th) was 15% (150/1,000). Demographic characteristics of the participants are shown in **Table 2**, while **Table 3** shows data of the intervention. Most interventions were carried out in Intensive Care Units (23%), COVID-19 Medical Units (38%), and the Emergency Department (22%). Ninety two participants out of 150 (61%) attended more than one session.

Participants perceived the intervention as being helpful for reducing stress with a mean rating of 8.4 on a scale from 0 to 10. There was no significant statistical difference ($t = -0.599$, $\alpha > 0.05$) on the perceived helpfulness between those participants who attended just one session (mean = 8.4; SD = 1.7) and those who attended more than one session (mean = 8.6; SD = 1.3).

Mild adverse effects were found in 3 participants (2%) who reported dizziness and increased anxiety after the session.

DISCUSSION

This study explores whether an on-site mindfulness-based crisis intervention designed for stress reduction for frontline healthcare professionals could be implemented on acute health wards of a public, general hospital during the outbreak of the COVID-19 pandemic in Madrid and shows data of feasibility, utility and safety of the intervention.

One core issue in this research is that the team developed and implemented the intervention in a short period of time and under extremely adverse circumstances (scarcity of protection materials and equipment, professional fatigue due to long shifts, hospital wards closed due to the infection, etc.). In this context, the initial enrollment was of one in every seven workers (14% participation rate). La Paz University Hospital has more than 7,000 workers but we could not access all of them probably due to factors such as fatigue, shifts, sick leaves, lack of time (the intervention was offered during working hours), among others. Moreover, not all of the 7,000 professionals were frontline health workers.

We collected questionnaires for 3 days only. Results of the 150 people (15% of the global participation) show that participants perceived the intervention as being helpful for reducing stress with a mean rating of 8.4 on a scale from 0 to 10, with a continuous participation rate over 61%, and few mild adverse effects (2%). We are aware of the fact that there may be some bias among people who completed the survey -e.g., those who found it particularly helpful may have been more likely to respond-. In addition, the rate of participation (14%) might reflect the bandwidth of the research team to only be able to reach a portion of providers. Although certainly the benchmark for determining feasibility may be lower during a pandemic, there is no established cut-off for what that benchmark would be. Taking these limitations into account our data suggest feasibility and good utility and safety outcomes during a pandemic.

Randomized controlled trials are the best study design to test the comparative effect of an intervention. This was far from the objective of the current research. We cannot answer the questions "was this intervention effective?" or "was there any change after the intervention?" The intervention was rated by health workers as very helpful with no differences in the ratings between those who attended one session and those who attended more sessions. This finding is similar to Gilmartin's conclusion (24). To our knowledge, there are no studies that evaluate the implementation of a brief mindfulness-based intervention during a crisis.

The acceptability of the intervention may be related to the fact that it was facilitated on-site, and it was an invitation to stop on a voluntary stance. The aim was to practice and train self-care strategies without adding excessive time-consuming practices and strain. In addition, the sessions were open to all members of the team working at that moment, so people were not marked or stigmatized as someone who specifically needed mental health support.

We asked for adverse effects and three participants reported increased anxiety and dizziness. A recent review about the

possibility of harm in mindfulness-based programs concluded that adverse events are no more common in these programs than comparison conditions (exercise or psychotherapy) and may not be attributable to the intervention or are not clinically significant (31).

We provide some hypotheses that we are currently exploring with a qualitative research method in a representative sample. The intervention may be considered as a peer support strategy. Members of the Mental Health Team were in the acute wards with healthcare employees sharing the same reality and all emotions that could arise. This may have helped participants generate a sense of closeness and connectedness which is associated with calmness and helps counteract experiences of stigma and shame (32). In a context where collaborative networks are as critical as they are fragile (because of professionals' deployment or fatigue), this is of great importance. Moreover, the invitation to participate in the sessions could reduce stigma and empower the person who actually connected with their own resources. Delivering the intervention in a group format might also alleviate the sense of loneliness and foster a feeling of "being part of" which has been found to be beneficial (33). Finally, having these mindfulness slots was useful for detecting professionals in situations of special vulnerability. In these cases, we invited them to take care of themselves and contact other members of the Mental Health Team for individual support.

Interventions like the one we describe in this article might constitute a beneficial response to some of the challenges faced when supporting frontline healthcare providers (34, 35). Some of these challenges are: the consideration on the part of managers and the own health professionals that self-care is a luxury and not a need; struggles of healthcare professionals with being in touch with their own feelings, and the recognition of emotions such as fear or anxiety that may produce shame or guilt; asking for help and support can be associated with stigmatization (36); frontline health workers tend to be in "doing mode" during the emergency, having difficulty to take or make little breaks during work time (24).

We cannot generalize the acceptability to all professions. The intervention was well-accepted specifically by nurses and nursing assistants. Doctors had more difficulty to make a pause and some of them reported "not having time," or "not being interested in this approach." The question why doctors are not interested or not convinced to participate needs further investigation. In addition, the majority of the participants were women, who have shown to be more empathetic and compassionate than men (37) and maybe more willing to participate in the sessions and contribute filling out the questionnaire. However, up to 70% of people who work in health professions are women according to global data of the 2019 Labor Force Survey in Spain (38), which might explain the high percentage of female participants in our sample. Moreover, we cannot state that this type of intervention could be implemented in settings with no mindfulness experienced professionals. In this study, psychiatrists and clinical psychologists specifically trained in standardized mindfulness programs delivered sessions and supervised the intervention done by professionals with less experience in mindfulness.

The findings of this study are promising and show the feasibility and safety of a brief mindfulness-based intervention to promote healthcare workers' well-being in highly demanding places like ICUs and emergency units. More studies are needed in cross-cultural contexts. The World Health Organization popularized the slogan "no health without mental health" to underscore how important mental health is. We agree with this claim. Furthermore, we assert "no healthcare without self-care."

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by La Paz University Hospital Research Ethics Committee. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

AUTHOR CONTRIBUTIONS

BR-V, ÁP, AM-S, and CB wrote the first draft of the manuscript and reviewed the successive versions of the manuscript. RM, MT, and M-PV-V made relevant contributions to the manuscript. All authors contributed to the implementation of the intervention in an acute setting and approved the final version of the manuscript.

ACKNOWLEDGMENTS

A special thanks to all the colleagues whom we have worked with during the COVID-19 outbreak in La Paz University Hospital in Madrid, Spain.

Li X, Wu H, Meng F, Li L, Wang Y and Zhou M (2020) Relations of COVID-19-Related Stressors and Social Support With Chinese College Students' Psychological Response During the COVID-19 Pandemic. Front. Psychiatry 11:551315. doi: 10.3389/fpsyt.2020.551315

This study examines the main and interactive relations of stressors and social support with Chinese college students' psychological symptoms (e.g., anxiety, depression) during the COVID-19 pandemic. All the constructs are assessed by self-report in an anonymous survey during the pandemic outbreak. The results show that the number of stressors has a positive relation with psychological symptoms, and social support has a negative relation with psychological symptoms. In addition, social support serves as a buffer against the negative impact of stressors. These findings hold implications for university counseling services during times of acute, large-scale stressors. Specifically, effective screening procedures should be developed to identify students who experience large number of stressors and provide suitable psychological intervention for them.

Keywords: PTSD, depression, anxiety, social support, COVID-19-related stressors

INTRODUCTION

It is well-established that stressful events (e.g., earthquakes and fatal diseases) have a significant impact on individual physical and mental health (1). However, the impact of large-scale stressors (e.g., infectious disease) on psychological adjustment in the general population is understudied, and we know little about how to improve psychological adjustment in the general Chinese population during the COVID-19 pandemic outbreak. The present study aims to examine the main and interactive relations of stressors and social support to individual psychological responses during the COVID-19 pandemic outbreak and holds the promise of information for counselors to prevent the negative psychological effects of the pandemic on the general college student population.

Relation of Stress to Psychological Response

Lazarus and Folkman (2) define stress as "a particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (p.19). To maintain biological homoeostasis during environmental or physiological challenges, our physiological coping mechanisms involving the hypothalamic-pituitary-adrenal axis, the autonomic nervous system, and the cardiovascular, metabolic, and immune systems protect the body from internal or external stress (3).

A mild, brief, and controllable state of challenged homeostasis could actually be perceived as pleasant or exciting and could be a positive stimulus for emotional and intellectual growth and development (4). However, if the normal stress response occurs frequently, it is not self-limited, and if the individual does not adapt to a repeated stressor of the same type, adverse metabolic consequences occur. A large body of research literature has shown links between chronic and acute stress and short- or long-term psychological and physical disorders, such as anxiety, depression, and PTSD (5–7). Specifically, people who experience a large number of stressors related to infectious diseases tend to show more psychological symptoms (e.g., PTSD, depression) than those who experience fewer stressors (6, 8). The COVID-19-related stressors are those stressful events related with COVID-19 disease that might endanger their well-being, such as an important person being infected with COVID-19 or having to cancel a vacation due to the pandemic. Facing the COVID-19 pandemic, an individual might experience different COVID-19-related stressors for many other reasons. Thus, the first hypothesis is proposed as follows:

Hypothesis 1: Individuals who experience more COVID-19-related stressors might have more psychological symptoms than those who experience less.

Relation of Social Support to Psychological Adjustment

The conservation theory of resources posits that both resource loss and resource gain are key predictors of psychological response, such as depression (9). Infectious diseases, such as with the COVID-19 pandemic, are often large scale and beyond individual control, and they lead to major resource loss. Social support is often regarded as an important compensation mechanism in buffering individual psychological responses when facing challenging environments (10). On the one hand, social support could be beneficial to individual mental health by providing the needed material and mental resources for dealing with life challenges. On the other hand, social support could improve individual psychological adjustment by enhancing the individual sense of control in dealing with stressful events. A vast body of research has demonstrated that the adequacy of social support is negatively related to the severity of psychological symptoms, such as depression (5, 11–13), and is positively related with well-being (14). A meta-analysis shows that social support is the strongest predictor of PTSD severity (15).

Social support is also regarded as a moderator in the relation between stressors and psychological outcomes (10). The moderating role of social support can be explained in the following ways. First, previous work suggests that perceived social support fosters feelings of belonging and security and a sense of control over the environment, which may enhance self-esteem, thus reducing the negative effects of stress on psychological adjustment (16–18). Second, research shows that social support could decrease the likelihood of maladaptive inferences about actual stressful life events by forming new schemas or revised schemas, which may attenuate the negative psychological outcomes of stressful events (19–21). Many studies show that people who perceive adequate social support find negative events to have fewer adverse consequences (e.g., anxiety, depression) than those who perceive little or no support (22–24). Thus, social support might moderate the stress-psychological symptom relation during the COVID-19 pandemic. The second hypothesis is proposed as follows:

Hypothesis 2: Social support (a) is a protective factor in predicting individual psychological symptoms and (b) could be regarded as a buffer in the relation between COVID-19-related stressors and psychological symptoms.

The COVID-19 Outbreak as a Unique Context for Studying Stressors, Social Support, and Psychological Symptoms

As an unusual and contagious pneumonia, the COVID-19 pandemic is caused by a novel and highly transmissible coronavirus. It caused international concern for its speed of transmission and varying degrees of illness and is designated by WHO as a public health emergency of international concern (25). As of March 15, 2020, a total of 150,000 laboratory-confirmed cases and 5,720 deaths have been documented in 141 countries or areas (26), and mainland China is one of the most highly infected areas. Under this circumstance, the Chinese government officially stepped up pandemic prevention and control with stricter measures to prevent the virus from spreading (25). These measures include tracing contacts, strengthening traffic control in each city, forbidding mass gatherings, closing nonessential public places, deferring the opening time of schools, and replacing in-person teaching with online teaching. Despite the benefits, these strict measures may also create heavy psychological and emotional burdens on the general population. For example, an individual may be quarantined because of a suspected or confirmed infection or an individual might cancel a vacation trip because of the COVID-19 pandemic. In particular, the student population (e.g., college students) became susceptible to the pandemic due to its large population density and their immaturity. Research shows that individuals across samples (from the general public to healthcare workers) report significant psychological responses during the outbreak (27–29). Psychological responses include perceiving COVID-19-related fear, threat, and worry and experiencing symptoms of psychological disorder. Moreover, these studies report significant individual differences in psychological response to COVID-19-related stressors and in susceptibility to mental health problems during the pandemic. However, these studies mainly focus on general local residents who live in infected areas and front-line health care workers rather than the general population. Although these studies investigate the impact of COVID-19 disease on individual psychological responses (e.g., perceived stress to COVID-19 disease) and psychological disorders (e.g., depression) during pandemic outbreaks, the relationship between COVID-19-related stressors and psychological adjustment during pandemics and their underlying mechanisms have not been thoroughly investigated. Therefore, studying the impact of the COVID-19 pandemic holds the promise of information for counselors to prevent the

negative psychological effects of pandemics on the general college student population.

METHOD

Participants

Data were collected between March 2 and March 15, 2020, using an anonymous, self-reported questionnaire. A total of 450 college students with different majors who participated in the curriculum of "Happy psychology" and "Mental health and education for primary and secondary school students" were invited to take part in our survey. The research material was sent to each student by email. The students were asked to return the completed survey as well as signed informed consent by the deadline. This study was conducted under the approval of the Moral and Ethics Committee of the School of Psychology, Jiangxi Normal University (Nanchang, China). Questionnaires with more than 15% of the items unanswered were excluded from the late analysis. A total of 431 survey responses were used in the following analysis. Of the respondents, 267 (61.9%) are female, and participant ages range from 18 to 22 ($M = 19.1$, SD $= 0.92$). Regarding their grade, 140 (32.5%) are freshmen; 197 (45.7%) sophomore; 54 (12.5%) junior, and 40 (9.3%) senior students. There are 33 (7.7%) students who lived in Hubei Province (the hardest hit areas) during the pandemic outbreak.

Measurement

COVID-19-Related Stress

According to the stress definition of Lazarus and Folkman (2), stressors are events that might endanger one's well-being. Main et al. (6) found that the stressors related to infectious disease could be grouped into six categories during the SARS epidemic, including self-, family-, friend-, acquaintance-, information-, and other infectious disease–related events. Main's view on stressor categorization of infectious disease is supported in our interview survey during the COVID-19 pandemic. Therefore, we developed a checklist measure to assess participants' experience of COVID-19-related stressful events (stressors) based on Main's SARS-related stressor scale. These events are grouped into six categories: (a) self-related events (three items, e.g., "You have experience contacting someone with a confirmed COVID-19 case"), (b) family-related events (three items, e.g., "A member of your family is suspected of having COVID-19"), (c) friend-related events (three items, e.g., "A close friend of yours is diagnosed with COVID-19 and receives treatment"), (d) acquaintance-related events (three items, e.g., "Someone you know [not including your family or a close friend] has COVID-19-like symptoms [fever, coughing]"), (e) information-related events (two items, e.g., "You heard others talking about the severity and contagiousness of COVID-19"), and (f) other COVID-19-related events (two items, e.g., "You had to cancel your vacation because of the COVID-19 pandemic"). Participants indicated whether each event occurred since the COVID-19 pandemic outbreak. The total number of events endorsed across all categories was computed with a high score indicating that students experience more COVID-19-related stressors.

Anxiety

The Chinese version of the GAD-7 is a one-dimensional, self-reported scale that is used to assess the symptoms of anxiety in adults (30). The participants were asked to rate perceived symptom burden during the past 2 weeks between 0 (not at all) and 3 (nearly every day), resulting in a total score ranging from 0 to 21. Higher scores indicate that the students might have higher symptoms of anxiety during the pandemic. The Chinese version of the GAD-7 demonstrates good psychometric properties (31) with a Cronbach's α of 0.86 in the present study.

Depression

The PHQ-9 is widely used to measure depression severity in adults with one item for each of the nine depressive symptoms (32). The participants were asked to rate perceived symptom burden during the past 2 weeks between 0 (not at all) and 3 (nearly every day), resulting in a total score ranging from 0 to 27. Higher scores indicate that the students might have higher symptoms of depression during the pandemic. The PHQ-9 is translated into various languages (including Chinese) and yields robust reliability in adults (including Chinese samples) (31, 32). The Cronbach's α of the PHQ-9 is .85 in the present study.

PTSD

The Impact of Events Scale – Revised [IES-R; (33)] is used to measure PTSD symptoms. The IES-R consists of 22 items: eight for re-experiencing/intrusion symptoms, eight for avoidance symptoms, and six for hyper-arousal symptoms. Each item is rated on a 5-point Likert-type scale between 0 (not at all) and 4 (extremely), reflecting the extent to which the particular symptom is a problem for the respondent during the past 1 week. The IES-R is demonstrated to be a valid tool in diagnosing PTSD in a Chinese sample (33) with Cronbach's α of the three dimensions of the IES-R ranging from 0.85 to 0.91 in the present study.

Perceived Social Support

The perceived social support scale (34) is used to measure the individual's degree of satisfaction of the support received from family, close friends, and other-related persons (such as teachers and common students but excluding close friends and family members). The scale includes three items, and the participants were asked to rate each item scored on a four-point Likert scale ranging from "very satisfied" to "very dissatisfied." Higher scores indicate greater satisfaction with the support from family members and others. The Cronbach's α of the perceived social support scale is 0.85 in the present study.

Control Variables

Previous research shows that sex, family residence (or the degree of exposure to disease), and age (or grade) are important influencing factors in predicting individual psychological adjustment during infectious disease (6, 29). Therefore, the variables of sex, grade, and family residence (Hubei vs. non-Hubei) are used as control variables in the present study.

TABLE 1 | Zero-order correlation of study variables for the full sample ($N = 431$).

Variable	$M \pm SD$	1	2	3	4	5	6	7
1 Anxiety	3.85 ± 3.62	1						
2 Depression	5.73 ± 4.36	0.51**	1					
3 Avoidance	6.61 ± 5.77	0.48**	0.32**	1				
4 Intrusion	6.21 ± 5.12	0.60**	0.40**	0.75**	1

*Stressors, COVID-19-related stressors. **$p < 0.01$ (two-tailed test).*

Data Analysis

Considering that the indicators of psychological symptoms might be correlated with each other, it is appropriate to test the relations between those outcome variables and their predictors simultaneously in one model (35). The multivariate general linear model is used to investigate the effect of predictors (e.g., COVID-19-related stressors, social support) on the following psychological symptoms (e.g., anxiety, depression, avoidance, intrusion, and hyper-arousal) while simultaneously controlling for the effect of sex, grade, and family residence. Before running the model, the parametric assumptions on data (linearity, multicollinearity, multivariate normality, and homogeneity of variances) and the potential presence of multivariate outliers were assessed by inspecting diagnostic plots and performing ad hoc statistical tests, such as the Shapiro–Wilk test for multivariate normality, the Box's M test for homogeneity of covariances, and the Mahalanobis distance test for multivariate outlier detection. With the exception of linearity and collinearity (pair-wise correlations among dependent variables ranged from 0.32 to 0.83, all $p < 0.01$), the results of which were acceptable, all other assumptions were more or less violated. However, the multivariate general linear analysis is robust enough to such violation when the sample size is large (36). After deleting the 22 multivariate outliers that were identified by the Mahalanobis distance method, all skewness values became low and acceptable (between 0 and 1). A separation score was finally calculated for each dependent variable (e.g., anxiety) as the ratio of its between-group variance and its within-group variance. The higher the score, the greater the separation between groups that a variable gives. Data exploration and statistical analyses were performed with SPSS 16.0.

RESULT

The means, standard deviations, and zero-order correlation for the full sample are presented in **Table 1**. The results show that the number of COVID-19-related stressors is positively related to psychological symptoms (e.g., anxiety, depression, intrusion, avoidance, and hyper-arousal) (all $P < 0.01$), and social support is negatively related to the psychological symptoms above (all $P < 0.01$).

One-way Multivariate Analysis

The effect of predictors and demographic variables on psychological symptoms was tested one by one. A multivariate general linear model was used for factors (e.g., sex, grade, family residence) and continuous variables (e.g., COVID-19-related stressors and social support scores). All indicators of psychological symptoms (including anxiety, depression, avoidance, intrusion, and hyper-arousal) were regarded as outcome variables and were entered into the multivariate general linear model simultaneously. Results show that all demographic variables and predictors are significantly related with psychological symptoms (all $P < 0.05$). Furthermore, the examination of η^2 (eta squared) reveals small to medium effect sizes (from 0.03 to 0.11) with COVID-19-related stressors ($\eta^2 = 0.06$) and social support ($\eta^2 = 0.11$) showing a one-way moderate effect according to Cohen's criteria (37). In contrast analysis, significant linear (all $P < 0.001$), and quadratic (all $P < 0.05$) trends across the variables of COVID-19-related stressors and social support were found. Specifically, students who perceived high levels of COVID-19-related stressors (or social support) reported more (or less) psychological symptoms than did peers who perceived less, and hypothesis one is supported. The significant linear trends across the demographic variables (all $P < 0.001$) are also found in contrast analysis. That is, female students report more psychological symptoms than male students. Junior or senior students report more psychological symptoms than freshmen or sophomores. Students whose family residence is in Hubei province report more psychological symptoms than peers whose family residence is not in Hubei Province.

Multiple Multivariate Analysis

To test the independent impact of COVID-19-related stressors and social support on psychological symptoms, all independent variables (COVID-19-related stressors, social support, sex, grade, and family residence) were entered into a multivariate general linear model together. As presented in **Table 2**, all variables are significantly associated with psychological symptoms (all $P \leq 0.05$) and $\eta^2 s$ were not much dissimilar from one-way multivariate analysis results. The effect size of COVID-19-related stressors and social support became a little bit smaller. Although the quadratic trend is not statistically significant, the linear trend continues to be statistical significant (for COVID-19-related stressor: Wilk's $\lambda = 0.87$, $F_{(25,1,491)} = 2.54$, $P < 0.001$, $\eta^2 = 0.05$; social support: Wilk's $\lambda = 0.76$, $F_{(85,1,943)} = 2.84$, $P < 0.001$, $\eta^2 = 0.1$).

In order to examine the interaction effect, a new multivariate general linear model was built, including COVID-19-related stressors, social support, sex, grade, and family residence as factors. In the new model, both COVID-19-related stressors and social support are classified as three groups: low (the scores below−1 SD from the mean), medium (the scores between −1 SD from the mean and +1 SD from the mean), and high (the scores above +1 SD from the mean). Two two-way interaction effects (e.g., family residence × COVID-19-related stress and social support × COVID-19-related stress) are significant. Hypothesis 2 is supported. Specifically, for social support, with the COVID-19-related stressors increased, the psychological

TABLE 2 | Multivariate general linear results with effect sizes ($N = 409$).

	Wilks	*F*	Hypothesis df	Error df	*P*	η^2
COVID-19-related stressors	0.92	3.59	10	782	<0.001	0.05
Social support	0.84	7.74	10	782	<0.001	0.08
Sex	0.97	2.72	5	391	<0.05	0.03
Grade	0.96	3.24	5	391	<0.01	0.04
Family residence	0.98	2.23	5	391	<0.05	0.03

Multivariate general linear was used to investigate our hypotheses, in which the indicators of anxiety, depression, avoidance, intrusion, and hyper-arousal are outcomes variables; both COVID-19-related stressors and social support are predictors; and sex, grade, and family residence are covariates.

symptoms (e.g., anxiety, depression, and avoidance) of students increased sharply at the lower level of the social support group; in contrast, the psychological symptoms of students increased relatively slowly at the high level of social support group (see **Figure 1**). For family residence, with the COVID-19-related stressors increased, the psychological symptoms of students increased sharply at non-Hubei province; in contrast, the psychological symptoms of students increase relatively slowly at Hubei province (see **Figure 2**).

Finally, separation scores show that COVID-19-related stressors are mostly associated with the symptoms of depression scale, followed by intrusion and anxiety symptoms; social support is mostly related with the symptoms of depression scale, followed by anxiety symptoms (see **Table 3**). In other words, the significant trend that is found in the multivariate general linear model, i.e., the differences of psychological symptoms in different levels of COVID-19-related stressors (or social support) groups, is mainly due to the large between-group differences in depression and anxiety mean scores. In addition, similar results are found for demographic variables. That is, the demographic variable (e.g., sex, grade, family residence) differences on individual psychological symptoms are mainly due to the large between-group differences in depression and anxiety mean scores, too (See **Table 3**).

DISCUSSION

As a global public emergency issue, the COVID-19 pandemic has caused great suffering for those people who live in infected areas. Although there has been some research focusing on the influence of the pandemic on the psychological adjustment of patients and front-line healthcare workers, we know little about the influence of the COVID-19 pandemic on general population (e.g., college students). Therefore, studying the relationship between COVID-19-related stressors and Chinese college students' psychological adjustment during pandemics and their underlying mechanism could enrich our understanding about the impact of the pandemic on the general population. Our findings also could hold the promise of information for counselors to prevent the negative psychological effects of pandemics on the general college student population.

Main Effects of COVID-19-related Stressors and Social Support on Psychological Symptoms

Correlation analysis shows that the number of COVID-19-related stressors has a positive relation with psychological symptoms (including anxiety, depression, and PTSD symptoms), which is consistent with previous findings on individual adjustment during other infectious disease pandemics (e.g., SARS) in the general public sample (6). That is, during an acute, large-scale pandemic, such as the COVID-19 pandemic, even among individuals who are not directly contaminated with the disease, the psychological impact of the pandemic on the general population is significant. In addition, the negative relation found between social support and psychological symptoms is consistent with previous studies in which social support could be a protective predictor in stressful events, such as SARS, swine flu, or Middle East respiratory syndrome (MERS) (7, 38, 39).

Interactions Between Stress and Social Support or Family Residence in Predicting Symptoms

COVID-19-related stressors and social support interact with one another in predicting anxiety, depression, and the avoidance of PTSD. That is, the negative effect of COVID-19-related stressors on individual psychological symptoms is larger at a low level of social support than those at a high level. The symptoms of depression, anxiety, and avoidance could explain most of the interaction effect. This suggests that social support serves as a buffer against the impact of COVID-19-related stressors on psychological symptoms during the COVID-19 pandemic. For PTSD, comparing with the subscales of intrusion and hyper-arousal, the symptom of avoidance is more likely explained by the interaction of COVID-19-related stressors and social support. A possible reason might be that social support could provide enough resources in dealing with stressors and decrease the usage of avoidance coping strategies during acute, uncontrollable circumstances. However, the symptoms of intrusion and hyper-arousal might be common psychological responses related to biological mechanisms during the pandemic, which could be less affected by environmental factors (e.g., social support). For family residence, comparing with the students whose family residences are in Hubei province (the most affected area), the psychological symptoms of those students whose family residences are not in Hubei province are more likely affected by COVID-19-related stressors. This could be explained by the "psychological typhoon eye" effect, in which the impact of stress on psychological symptoms could be reduced because of the low level of posttraumatic event concern in extremely devastated areas (40).

Sex and Demographic Differences

Consistent with previous research (38), women tend to report higher psychological symptoms (e.g., anxiety, depression, and hyper-arousal symptoms) than men during a large-scale and uncontrollable pandemic. The possible reason might be that women tend to be more sensitive to external threat due to

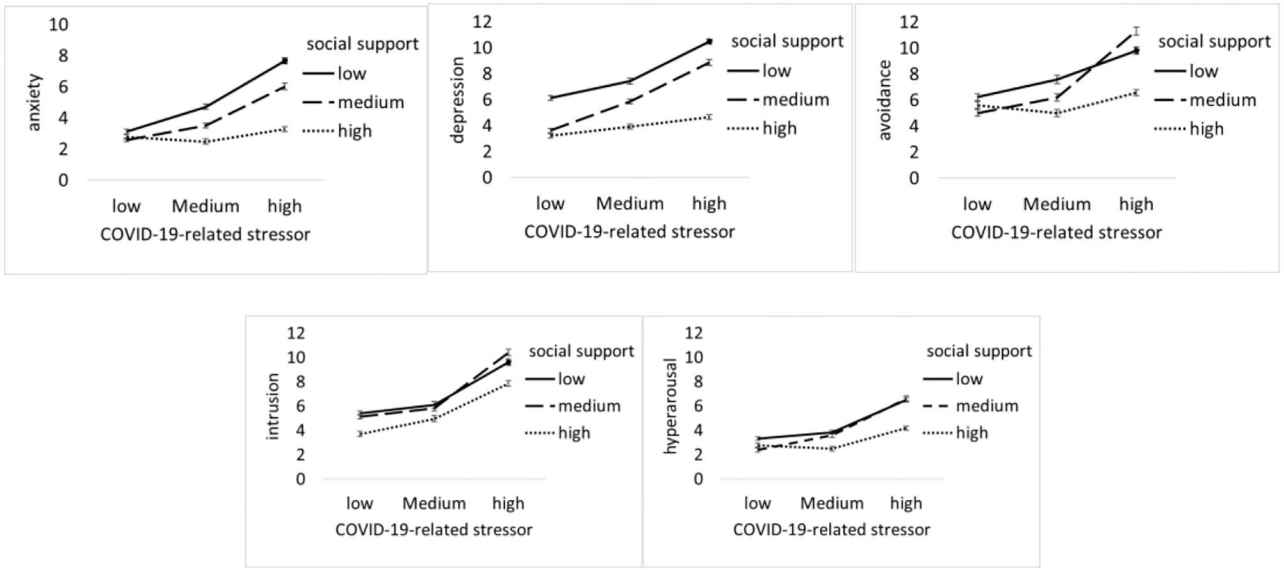

FIGURE 1 | COVID-19-related stressor by social support. Unadjusted psychological symptoms (including anxiety, depression, avoidance, intrusion, and hyper-arousal) data are plotted; means and standards errors are displayed.

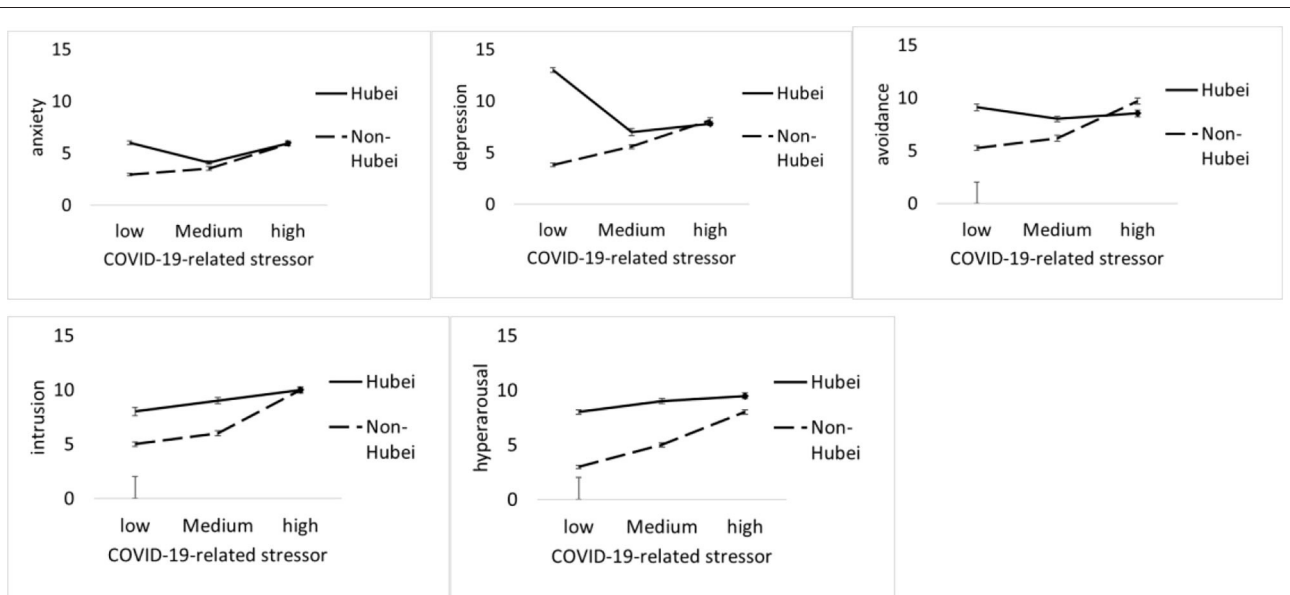

FIGURE 2 | COVID-19-related stressor by family residence. Unadjusted psychological symptoms (including anxiety, depression, avoidance, intrusion, and hyper-arousal) data are plotted; means and standards errors are displayed.

their biological factors (41, 42). For grade, students in a higher grade (e.g., junior or senior) reported increased symptoms of anxiety, depression, and PTSD than those students with lower grade (e.g., freshmen or sophomores). A possible reason might be that, compared with freshmen and sophomores, senior or junior students may experience more stress from graduation and looking for a job. With regard to other demographic variables, students whose family residence was in Hubei Province (the most infected area) reported higher anxiety and depression symptoms than did peers whose family residence was not in Hubei Province. The possible reason might be that, in an infected area, such as Hubei Province, students themselves and their family members or friends experience a greater threat from COVID-19. Therefore, in such cultures emphasizing family and relationships, students from the most infected areas tend to experience more psychological symptoms during a pandemic.

Implications of the Study for University Counseling Services

As one of the few studies on the relations of the stressors and social support with psychological symptoms among college students during the COVID-19 pandemic, this study has important implications for university counseling services during acute, large-scale stressors, such as an infectious disease outbreak or natural disaster. First, given the study findings, even students who are not directly affected by COVID-19 report significant numbers of COVID-19-related stressors and psychological symptoms during the pandemic. It is crucial that university campuses develop and implement effective screening procedures to closely monitor students' exposure to stressors and mental health adjustment. Second, the present study shows that social support is negatively related to anxiety, depression, and PTSD symptoms and served as a buffer against the negative effect of COVID-19-related stressors. In Asian culture, which is concentrated on family or kinship support (43), social support is a crucial resource for college students to deal with stressors during pandemic outbreaks. Third, the present study suggests that female students, students at higher grade levels, and those students whose family residences are located in pandemic-affected areas show vulnerability in the face of an infectious disease and experience more psychological symptoms. These students should receive more attention from university counseling services during pandemic outbreaks. In addition, the checklist measure for COVID-19-related stressful events developed in the present study can be modified to monitor students' exposure to disaster-related stressors, and students who are exposed to a large number of stressors should be identified to receive some preventive services.

Limitations

The study has several limitations. First, because all the constructs were assessed by self-report, the estimated relations among stressors, social support, and psychological symptoms might be biased by the reporter effect. Future research should consider a longitudinal design or use a multimethod to examine the role of stressors and social support in individuals' psychological symptoms during an acute, large-scale pandemic outbreak. Second, there has been some speculation that Asian cultures tend to emphasize family and relations more than Western cultures (43). It is possible that the interaction of these stressors and social support might not generalize to Western populations. Future research should test culture as a moderator of the relation between social support and adjustment using cross-cultural comparative samples (6). Third, although the sample used in the present study consists of students with different majors and is a representative sample of the college population to some degree, all of the participants were enrolled in two courses offered by the School of Psychology in one tertiary education institute, which might result in a bias in sampling. Future research could investigate the relations among the studied constructs with a large representative college student sample. In addition, research has shown that different types of stressors might have different degrees of influence on individual mental health (44). For example, some COVID-19-related stressors (e.g., "One of your family members has a confirmed COVID-19 case")

might have a larger impact on individual mental health than other stressors (e.g., "You have to cancel a vacation trip due to the pandemic"). The impact of the pandemic on psychological adjustment might be related to individual personality traits (e.g., coping) (20). For example, individuals who tend to use adaptive coping frequently might experience less psychological symptoms than those who use less adaptive coping during a pandemic outbreak. Therefore, future research could investigate the impact of stressors of different types or personality traits on individual psychological symptoms during pandemics.

The COVID-19 pandemic has created an unexpected situation that has forced people to find educational alternatives to support learning and ensure child well-being. The need for practices that "open doors" at home as a way to promote a quality education and to foster an environment of supportive relationships and a sense of community, has led to the in-depth analysis of successful educational actions, particularly the Dialogic Literary Gatherings (DLGs). The aim of this article is to show how the transference of DLGs to the home environment has had an impact on child subjective well-being in times of confinement, promoting a safe and supportive environment for learning, interacting, coexisting and on emotional development at different educational stages, especially for the most vulnerable children. Data collection consisted of a focus group of 10 teachers, 6 semi-structured interviews addressed to families and 6 life stories of students, from 4 primary education centers, 1 high school, and 1 Special Education School. Communicative methodology structured the two-level data analysis, for studying both the elements provided by online DLGs that favor and achieve child well-being, and the elements that may hinder those achievements. The results confirm that DLGs have had a notorious impact on children's and their families' well-being. Considering the findings in the development of educational public policies and the possibility of extending "open doors actions" as an option for future learning environments beyond the confinement situation is contemplated. Future research on how these spaces can have an impact on child well-being in upcoming contexts of the new normal in the education domain will be of interest.

Keywords: coronavirus, successful educational actions, childhood, well-being, quality relationships

INTRODUCTION

The COVID-19 pandemic crisis has created an unexpected situation that has forced people to interrupt everyday activity to avoid the disease transmission, with schools closing as an emergency action (Enserink and Kupferschmidt, 2020; Wang et al., 2020). The way in which the outbreak is tackled may imply critical long-term effects (Gates, 2020), what is required is the implementation

of successful procedures to reduce to the extent of any possible undesirable effects, especially for the most vulnerable children (Brooks et al., 2020). In this context, the need to give continuity to teaching and learning, despite school suspension, through online education (Zhang et al., 2020), and to rapidly find educational alternatives for supporting this learning and ensuring child well-being has become an urgent necessity. Children are more vulnerable than adults in the face of traumatic situations and their impact on their daily routines (Bartlett et al., 2020). The quickly evolving new situation exposes children to conversations, constant media information, anxiety-inducing environments and changes and continuous adjustments to their routines as a result of the outbreak (Dalton et al., 2020). The global situation in general, and the prolonged home confinement, the social distancing and the school closures in particular, are having particular negative consequences on children's mental and physical health, interfering with their sense of security, structure or predictability (Bartlett et al., 2020; Wang et al., 2020), both in the short and long term, which cannot be neglected (Dalton et al., 2020). Regarding the mental effects, a psychological impact on anxiety, fear, boredom or frustration, *inter alia* (Brooks et al., 2020) has been reported, as well as trauma both for children and their families (Sprang and Silman, 2013). This situation can become a vicious circle, as the subsequent social-emotional and behavioral disorders may also contribute to more adverse results on health such as cardiovascular diseases, excessive weight gain, poor quality of life (Perrin et al., 2016), and a risk for future mental illnesses and cognitive development (Decosimo et al., 2019). These health consequences become more significant and persistent when we talk about vulnerable children with previous trauma or preceding physical, mental, or developmental disorders, as well as those with problems within the family (Bartlett et al., 2020). The lack of interactions with friends and outdoor activities (Wang et al., 2020), the absence of personal space at home, or the family's financial problems, are among other factors affecting child well-being in confinement, which have a challenging impact on youth and child well-being (Brooks et al., 2020). But despite the contingencies caused by this outbreak, especially on education around the world, this interruption is also providing new opportunities to find and discover transformative and stimulating practices, where the whole community—families and teachers—with the support of institutions and administrations, meet and reinvent education for the sake of the continuation of learning (Dryden-Peterson, 2020).

Organizations like the World Health Organization–UNICEF–Lancet Commission agree that children must be placed at the center of the Sustainable Development Goals (Clark et al., 2020), an idea that becomes imperative in the new situation. The Children's Bureau of the U.S. Department of Health and Human Services, through the Child Welfare Information Gateway, puts the focus on family support and engagement and community-based practices to ensure children's safety and well-being (Child Welfare Information Gateway, 2020). Those activities and the resources developed for promoting healthy behaviors in children should take under consideration some preconditions, such as protecting children in the face of online exposure, considering minimal equipment and small spaces, and guaranteeing opportunities for family-child interactions (Guan et al., 2020).

Child well-being is imperative in the current situation, in the wider present, and in the future as it will influence and predict forthcoming outcomes as adults (Lansford et al., 2019). The literature on child well-being is large and keeps on expanding, and therefore several and different definitions and indicators can be found, what makes the research review and the choice for a definition more complex (Pollard and Lee, 2003; Statham and Chase, 2010). From science, research projects, governments, institutions, organizations such as OECD or UNICEF and committees of the European Union or the United States, *inter alia*, there have been different attempts to create a system of indicators for measuring child well-being. Nevertheless, more work and attention on this is needed (Moore, 2020). In order to understand the concept, a multidimensional notion of child well-being definition seems the most suitable to approach a holistic reality incorporating physical, mental and social aspects of the person (Statham and Chase, 2010), influenced by the interactions with family, peers, the community, but also by policies and programs (Lansford et al., 2019). Different studies provide their classifications of child well-being domains, but many of them coincide to focus on cognitive, physical, psychological, educational, social or behavioral domains to define and measure the feeling of wellness in children (Pollard and Lee, 2003; Bradshaw and Richardson, 2009; Lansford et al., 2019). The latest tendencies in measuring child well-being have gradually evolved into engaging children in defining their perception and interpretation of well-being, what emphasizes the importance of subjective well-being in studies (Statham and Chase, 2010) and the consideration of a communicative perspective of research through the inclusion of the participants' voices (Flecha, 2000; Puigvert et al., 2012). This study will focus on the latter, paying special attention to the subjective well-being dimension as the sense of happiness or life satisfaction (Dinisman and Ben-Arieh, 2016), where the supportive interpersonal relationships constitute one of the main predictors (Diener et al., 2018). It will also measure it from a communicative perspective, considering the participants' view through the voices of families and teachers, but mainly focusing on students.

The role of schools in child well-being is decisive for its educational and psychological aid (Wang et al., 2020). Broader environments or connection to community settings have a major role in overcoming childhood adversities and in resilience (Bartlett et al., 2020). Health depends on the contexts that nurture both physical and mental wellbeing, and healthy environments go beyond the home, including the community or the school, implying stable relationships and interactions or the development of learnings and skills through education, among others (Center on the Developing Child, and Harvard University, 2014).

Thus, the need for actions that "open schools' doors" at home to promote a quality education and to foster an environment of supportive relationships and a sense of community, reinforcing child development and mental health (Roca, 2020) and improving the social, emotional and academic dimensions has led to the in depth analysis of the implementation of successful educational actions (Flecha, 2015) in confinement through virtual

means. Thus, some schools have started to implement *Open Doors Actions*: actions that emerge from new developments and from the transference of identified evidence-based strategies, aimed at educational communities, families, teachers and mainly students, that traditionally have created a safe and friendly environment for improving learning and coexistence in schools, and which are now brought through a virtual medium to home spaces. These actions for training, sharing and exchanging are forming a response to the challenge of maintaining caring, rich, and supportive interactions among peers and their educational communities. Evidence reported from eight schools has shown a positive impact on the emotional and cognitive development of children in confinement (Roca et al., 2020).

Among these evidence-based actions, one of the most extended practices are the Dialogic Literary Gatherings (DLGs), globally implemented in more than 3000 schools and centers around the world (Lopez de Aguileta, 2019). DLGs are dialogic spaces for educational purposes where participants—children and/or adults—involving egalitarian dialogs around classical readings of the universal literature, and where all of them have the same opportunities to speak without hierarchies, and creating in interaction new meanings about the text discussed (Flecha, 2000; García-Carrión et al., 2020). In them, participants delve into universal values, issues and feelings of concern that humankind has experienced since ancient times through the discussion of complex and rich works, finding meanings and reflecting on them upon the participants' own experiences and building new interpretations all together. The functioning is as follows: all students read alone, at home or at school, a previously decided piece of text from the book being read, which can be a faithful and high-quality adapted version of the original classic work. They choose a paragraph and note down the reasons that led them to select it. Along the DLG session, the students who wish to share their chosen paragraph as well as their reasons, and all the students start a debate or discussion on the raised idea, with the aim being to reflect on and to share and build meanings according to the participants' experiences (Flecha, 2009; Lopez de Aguileta, 2019). The egalitarian dialogue (Serrano et al., 2010); the diversity of voices to enrich interpretations and debate (Flecha, 2009); or the fact of grounding the contributions on arguments instead on of power claims (Oliver and Gatt, 2010) are crucial premises according to the dialogic learning principles (Aubert et al., 2008) executed when implementing DLGs.

Benefits of the DLGs have been shown in a wide range of contexts (Soler, 2015), and their impact can be found in different areas. In the academic field, the children involved have shown a boost in the school-relevant language, literacy skills (Lopez de Aguileta, 2019), reading skills, vocabulary acquisition, communicative skills (de Botton et al., 2014) and an increase of students talk ratio and quality participation through reasoning and argumentation (García-Carrión et al., 2020). Additionally, DLGs have nurtured transformations from a personal to a social and contextual level (Serrano et al., 2010), improving students' and their families' confidence and motivation for learning, as well as fostering community-school links, and transforming child-parents' interactions at home, with the discussion on classical works becoming part of their routine (de Botton et al., 2014). Evidence is provided about their effectiveness at all stages of life and in every context where they are implemented in all their diversity: from rural communities, to extremely disadvantaged backgrounds, high-complexity schools, special education centers, children's residential care institutions, adults educational centers or prisons (Pulido-Rodríguez et al., 2015; Alvarez et al., 2016; García-Yeste et al., 2017; Garcia et al., 2018; Rodrigues and Marini, 2018; Duque et al., 2020), to mention a few examples. The implementation of DLGs in said settings has been conducted on-site until confinement, but since the pandemic situation, the schools participating in the study are developing these meetings online, through a video conference platform, providing an opportunity for social contact during lockdown. The moderator continues to play a very important role both for maintaining a warm environment that encourages participation and for promoting dialogic principles. This study explores DLGs as an evidence-based action replicable in any educational on-site environments, which has been incorporated to European recommendations and public policies (Gómez et al., 2010; European Commission, 2011) and is now being transferred to online spaces. In this new situation, and considering all its benefits, this study seeks to explore two core issues: the extent to which the transference of DLGs to homes through online means can have a positive impact on child well-being in these times of confinement on the one hand, and how this learning action can promote a safe and supportive environment for learning, and how it can interact and coexist in different education stages, especially for the most vulnerable children. This is necessary not only to respond to the challenges of the current pandemic, but also for meeting future demands regarding the protection of child well-being and health (Shonkoff and Williams, 2020). In the framework of this study, the analysis has focused on the measurable areas of child well-being, focusing on prosocial behavior; positive relationships with family, peers and other adults as teachers; and academic performance, covering the behavioral, psychological, social and cognitive domains (Lansford et al., 2019).

MATERIALS AND METHODS

Little agreement is found in the literature when the best way to measure child well-being is discussed as diverse approaches are developed: from objective measures with assessments, records, tests, rates or statistics, to subjective measurements through interviews or scales, finding more subjective measures on literature than objective ones (Pollard and Lee, 2003). To this end, a communicative approach is used, through the joint construction of knowledge between researchers and research participants, what enables a better understanding of the improvements generated in the well-being of children due to the implementation of the DLGs in confinement times (Puigvert et al., 2012). The six DLGs, object of analysis, were already implemented in the participating schools before confinement and have been developed online through a video conference platform during confinement. Communicative methodology recovers the voices and views of the different educational

agents- families, teachers and students themselves, for generating profound analysis with the aim of building useful knowledge for affording child well-being at present, as well as in future crises (Gómez et al., 2019).

Research Site

The schools participating in the study are part of a sub-net of SaLeaCom school (Rodrigues and Marini, 2018), in the neighboring territories of the Valencia and Murcia regions in Spain. These schools are part of the *Open Doors Schools* (Roca et al., 2020) project that started on March 18, 2020, to foster learning and supportive relationships, as well as a safe environment for childhood. This research has been conducted with schools that had already implemented traditional DLGs in person, although this is not a requirement for implementing online DLGs, and neither is the prerequisite of having had families participating before in the face-to-face format. Among all the schools, those that had already been implementing the online DLGs for at least 3 weeks were chosen. All the schools participating in this study ensured access to technology for all their students before starting the implementation of DLGs.

All the participating schools are public ones. The participating schools are diverse and heterogeneous: there are 4 primary education schools (PS), a special education center (ES) and a high school (SS). See **Table 1** for more detailed data on the characteristics of the participating schools.

Participants

With the aim of exploring the transference of DLGs to homes, the data reported in this study includes two communicative focus groups with teachers of the six schools, six semi-structured interviews with relatives and six communicative life stories with students, from the six schools, counting on: (a) one or two teachers per school in the focus group, a total of ten teachers; (b) one relative (mother or father) per school, a total of six, and (c) one child per school, a total of six, too. Three of the schools receive more than 30% of students in situation of vulnerability, including students with special needs and others at risk of social exclusion. **Table 2** shows the details regarding the participants' profiles and the data collection technique (fully explained in subsection "Data Collection and Techniques") employed to gather the information (see **Table 2**).

Ethics

All participants (teachers, families, and students) agreed to provide researchers with relevant data for the purpose of the study. Prior to data collection, they were informed of the nature of the investigation and informed written consent was obtained. In the case of minors, the informed consent of their parents or guardians was collected. All participants were informed that their participation was anonymous and voluntary, and that the data would be treated confidentially and used only for research purposes. The study respects the ethical guidelines of the European Commission (European Commission, 2013) and was approved by the Ethics Board of the Community of Researchers in Excellence for All (CREA)[1].

In order to ensure anonymity, a code was assigned to each participant and school. For participants, the first letter corresponds to their educational profile: T (teacher), P (school principal) and C (school counselor), and the second letter corresponds to the stage or kind of school where they are enrolled: P (Primary school), S (Secondary school), or E (Special Education center). Finally, a correlative number is indicated. For schools, the coding is similar: PS (Primary School), SS (Secondary School) and ES (Special Education School), adding a correlative number for schools with the same profile.

Data Collection and Techniques

Due to the confinement situation, the fieldwork was carried out in an online format between May 2 and May 24, 2020, after more than 3 weeks of implementing virtual DLGs usually for 1 h a week. The data collection was carried out through virtual means. A script was planned for the evidence collection, including questions about different blocks of contents: (a) exploration about the concerns and observations about the implementation of DLGs at schools and now at home, (b) the influence of the implementation of DLGs on well-being, and (c) new opportunities emanated from the transference of DLGs to

[1]The Ethics Board was composed by: Dr. Marta Soler (president), who has expertise in the evaluation of projects from the European Framework Programme of Research of the European Union, and of European projects in the area of ethics; Dr. Teresa Sordé, with expertise in the evaluation of projects from the European Framework Programme of Research and researcher in the area of Roma studies; Dr. Patricia Melgar, founding member of the Catalan Platform against gender violence, and researcher in the area of gender and gender violence; Dr. Sandra Racionero, former secretary and member of the Ethics Board at Loyola University Andalusia (2016–2018), and review panel member for COST action proposals in the area of health; Dr. Cristina Pulido, expert in data protection policies and child protection in research and communication and researcher in communication studies; Dr. Oriol Rios, founding member of the "Men in Dialogue" association, researcher in the area of masculinities, as well as editor of "Masculinities and Social Change," a journal indexed in WoS and Scopus; and Dr. Esther Oliver, who has expertise in the evaluation of projects from the European Framework Programme of Research and is researcher in the area of gender violence.

virtual spaces. The focus group, as well as the interviews and the life stories were audio-recorded and transcribed.

Communicative Focus Groups (CFGs)

Two CFG sessions were held. The objective of CFGs was to develop a shared analysis of the situation under study. The first CFG was carried out with one representative per school, in which the objectives of the study were validated, the dimensions of the impact on child well-being were discussed, and consensus was established around the collection of information to analyze the impact. The second CFG was carried out with 10 teachers from the 6 schools participating in the study. It analyzed how DLGs were being recreated in each of the schools and in the diversity of educational stages. Later, an in-depth analysis was done exploring the aspects of child well-being that were being more susceptible to improvement thanks to the DLGs. The CFG is a moment of analysis that enables the dialogic construction of scientific knowledge by creating bridges between scientific evidence, the object of research, and educational practices (Aubert et al., 2011). In these spaces, not only are the results are identified, but the participating people discover improvements to introduce in their DLGs through dialogue with other teachers.

Interviews With a Communicative Approach (Int)

Six semi-structured interviews with a communicative approach were carried out with six mothers, one from each participating school. The objective of the interviews was to analyze how families appreciated the performance of DLGs in confinement, their impact on the well-being of their daughters and sons, and the extent to which they were a space of prevention and care for boys and girls. Families were able to relate details about how their children prepared for the DLGs, how they saw them before and after participating in them and the extent to which DLGs became part of their children's lives, and also of other family members' lives.

Life History (LH)

Six short life stories were carried out with six students, one for each participating school, five for the primary education stage, one for special education and one for the secondary education stage. The objective of carrying out life histories over a short period of time is to dialogically reconstruct the reality lived by the student, giving voice to their thoughts, feelings and analysis. A cooperative process of understanding their experiences in DLGs was aimed at caring for and improving their well-being and that of their peers.

Data Analysis

The six DLGs under study were analyzed together to understand how they contributed to the improvement of children's subjective well-being in the diversity of educational stages, contexts and characteristics of the students. Taking into account the challenges that confinement has posed for children and their families and the possible consequences for their later development (Decosimo et al., 2019; Dryden-Peterson, 2020; Wang et al., 2020), this study addresses the impact of DLGs, taking as a reference, indicators related to child well-being from a subjective perspective, such as (1) the educational dimension (the developments and improvements achieved in instrumental learning and cognitive development), (2) the social dimension (considering the relationships and interactions of quality, and

the improvements achieved in social cohesion), and (3) the emotional dimension (feelings and affective development), as well as the (4) impact related to home and families, and (5) the barriers that have been identified to hinder those achievements and future perspectives.

RESULTS

The analysis shed light on indicators of child well-being where it is shown, from a subjective dimension counting on participants from the communities, how the DLGs online have impacted the children's feelings of wellness and even their feelings toward home and families in confinement times. This study also takes into account the barriers and challenges of the new implementation of this action, so besides proposing all the transformative dimensions, an account on the barriers is also reflected. Thus, the "Results" section is divided on the transformative conditions according to child well-being dimensions, (a) educational; (b) social; (c) emotional factors, or (d) the impact on families as well as (c) the challenges emerged in this novel situation and future prospects, according to participants' experience.

Learning, Cognition and Performance: The Educational Indicator

The schools participating in this study implement DLGs once a week for 1 or 2 h during the pandemic. More and more students have joined the DLGs since the online transference and, despite the short time of application, participants agree on the positive potential that it is having on different dimensions of child-wellbeing, but also in all the educational stages and with the diversity of children, mainly for the most vulnerable ones, those with special educational needs.

Improvements on the educational field are very noticeable according to the participants. For teachers, advances on different dimensions of learning are shown more sharply along confinement activity. Advances on reading skills, as this teacher comments "I have seen very clearly a progress in the children's reading performance. Since the confinement has started, they have improved a lot" (TP3); or in the linguistic production, very noticeable with the most vulnerable children, those from the Special education center, who were not able to build sentences further than a subject plus a verb, and now one of the school teachers praises "[In confinement] they have been incorporating the linguistic model into their language, creating longer structures."

Enhancements at a learning level have also been shown in relation to the instrumental knowledge. The emanated relations that students establish between the read texts and other school subjects suppose a creation of meaning within learning contents. Teachers, families and students agree on the fact that the readings and debates are very helpful for instrumental learning, mainly in the contextualization of learning, vocabulary acquisition, development of thought and oral expression, without being hindered by the online medium.

> Now, there is a creation of meaning, because you can send them [as task] the "length measurements" and they do it, but for example when in Tom Sawyer the yards come out, and they look for it [the meaning] and they know that they are 91 and a bit more centimeters. . . or the word "stunned," or "dread." It happens that the instrumental learning that you are providing them with online now [with the DLGs] acquires a meaning, that instrumental learning, with the DLGs, has more meaning (TP4).
>
> As we are little children, there are difficult words in the books and there we can learn as we comment on them (. . .). We cannot go to school, we cannot see as much things as when we attend school and the DLGs help us to know more things (SP1). Although we do the DLGs at home, we learn the same (SP4).
>
> The main thing is that it [DLGs] helps them with the vocabulary and to express what they think. Nowadays with so much technology this is has been a little forgotten, the oral aspect, the ideas. everything is writing in WhatsApp and I miss this (DLGs) in my older children. who have not had them (FP4).

Dialogic Literary Gatherings have also shown improvements regarding children's habits, both in maintaining daily routines and even in boosting the reading habit itself. One student expresses how helpful they have been for her, not only for learning, but also for continuing the learning and reading routine in confinement time:

> It is like in the school, to keep on the same habit, but through videocall (. . .) They [DLGs] helped me to read more (. . .) It is a funny way to express yourself while you learn new things, you read. . . It would be amazing that children who don't do DLGs started to! (SP3).

The educational performance has seen benefits through a notorious increase in the students' participation. All participating teachers agree on this improvement, reporting that changes in this direction are regarded as beneficial, especially for those who had more difficulties with engaging in debates:

> Changes have been noted especially at the level of participation, children who did not participate in person, are more participatory in the online [format]. . .. What seems nice is that it is counteracted in another way, the children who found more difficult for participate [in the on-site DLGs] are having a very important benefit now (TP2).

Interactions and Relations: The Social Dimension of Well-Being

According to the social dimension benefited by the DLGs, the fact of meeting online with the DLGs has helped students to better understand the new situation. One of the teachers who forms the special education center reports how for their students the new pandemic, and the subsequent confinement situation, was an odd and inexplicable situation, and how positive it has been to meet online to do the DLGs for their feelings of safety:

> Many did not understand what was happening, why they were inside the house. And then, this moment of meeting everyone (because they did not understand why they were at home), seeing themselves on the screens and explaining to them that we are here. . . they have understood the situation, because it was being experienced in this way (TE1).

Reflections and dialogues around other sociological issues that occurred in these spaces are also important and protective in these confinement times, "this is a place for dialogue, for talking about violence, attraction toward no violence and preventive socialization, that is very important now" (PP1).

Teachers underline the importance of counting on spaces for dialogue and interaction, especially for students who cannot rely on peers at home in the form of siblings or other relatives of their age. "Maintaining a space for dialogue is very important for the diversity of students, because there are children who are alone, do not have siblings, and they don't have the power to create dialogues, to interact" (TP4). All children need to share their concerns, their feelings, their routines with their friends and teachers, as is usually done in school, and according to families, the DLGs improve the communication with friends and teachers openly, and their relationships, as the school community is considered as a second family for many of them:

> The fact that he meets with his classmates, since they cannot meet, makes them very happy. It is their second family and they need that (. . .) they benefit from seeing their mates. (. . .) They feel empowered and they are happy because they are being listened to. It is important to continue promoting this bond with their teachers, their classmates. . . I think the DLGs provide these spaces so that they can communicate more with colleagues (. . .) She [daughter] needs that moment of recognition, and not only for her, to see her classmates, to see how they are. and to share those moments (FE1).
>
> For me, the DLGs [in this time of confinement] have provided me with a space of happiness. I have a great time in the DLGs, I think it gives me and my colleagues a lot of joy and happiness. Friendship with friends is very important, and [DLG] helps me in friendship with my friends and the teacher (SP4).
>
> And this [undergo DLGs online] is very important because families alone cannot, cannot be teachers, because we do not know and because we cannot. We try but we cannot, it is impossible to get there (FP4).

Quality social interactions, crucial for well-being, take place in confinement through online DLGs. According to teachers, it is clear that the DLGs make possible the creation of quality relationships which have impacted on their students' well-being now and for the future, and have opened options for new contexts of safe interactions:

> We ensure the super quality [in DLGs sessions and interaction] and I think that in this sense the DLGs are benefitting the students a lot at this moment [confinement] for their development and their well-being (PP1).
>
> The gatherings have been able to open other relationships and other opportunities to relate, that have created quality relationships and a safe context with an impact on their future (CS1).

Feelings and the Emotional Dimension

It has been generally acknowledged by all the participants that DLGs have a remarkable impact on the emotional well-being of students, which has been increased in confinement times. DLGs are considered a space for interconnection, mainly in the emotional dimension, and in that place the deepest feelings are shared. A teacher expresses that he has set other spaces with his students through virtual calls that have not been as successful and meaningful as the DLGs. Moreover, in a moment of outbreak and isolation, the opportunity to share feelings and to be in touch with "the second family" have been valued as a key condition for child well-being:

> The DLGs are an environment of interconnection but, above all, of emotional interconnection. It happens that all the stories in the end it happens that we address feelings, emotions and such. And oddly enough, although I have done other videocalls with the students so that they have other moments to talk as well and no [it doesn't work]! In other moments there is no excuse. If it is not in DLG, after 5 min, no one knows what to talk about anymore, it's like there is no reason to be there, together, there is no connection (.) I don't know what it is, what I know for sure is that, indeed, with DLGs something happens that would not happen in other circumstances. That, in confinement, must be maintained (PP1).
>
> [I want] To highlight all the emotional part of DLGs because children as my daughter, who have functional diversity, find difficulties to communicate, but above all to transmit and recognize feelings. So, what I would highlight the most is that these [online DLGs] are helping to understand and share feelings. It has been a great help for my daughter. (. . .) They have been all week without seeing each other, without seeing her other family (. . .) they are excited that they are going to see their classmates (FE1).

The DLGs nurture a space for sharing, apart from opinions, views, and knowledge, their emotions and feelings. Students have the opportunity to be in a context where to express freely and without judgment their positive, but also the negative emotions and concerns that maybe, in other spaces, they are not able to share. Thus, some teachers report that children often establish relationships between what is happening in the classical book and in their reality, telling their fears and worries through the characters of the book. But also, with teachers, some students have noticed that the line that separates the relationship of student-teacher with friendship is thinner now because during DLGs they have seen their teachers' emotions, feelings and opinions as "peers":

> Now, with Oliver Twist in all the DLGs, the relationship with the current situation emerges. I think it is a space that helps them a lot to talk about those fears, or those concerns that perhaps they do not even dare to speak [out of DLGs] but empathizing with the characters of the book, yes, these issues appear and appear (FP3).
>
> That moment, [the teacher] is like your friend, because you can tell him or her about your life. . . they are reading the same book as you and sharing ideas, their thoughts and so on. . . I like it because it's like we already passed that little line between teacher-student (. . .) I also like to have volunteers, they can become your friends and you can speak as normal as if you had known them your entire live (SP1).

Dialogic Literary Gatherings have traditionally open methods to encourage the emergence of feelings and the expression of them, something which has been particularly relevant in this pandemic situation. A parent thanks online DLGs as they have helped his daughter to bring out and express the feelings she has kept inside "they bring out feelings that otherwise it would be

difficult, and at that moment [during DLGs] they do it and tell you" (FP3). In this respect, a student recognizes how the book they have been reading has helped him to overcome the concern and to feel empathically through the links between the fiction story and the experienced situation:

> I am comparing it [the book] with this situation of confinement, as in the book they [the characters] had to be so controlled, they couldn't be mixed, no different thoughts were allowed. . . and that seemed to us quite similar to now. Now, we are supervised, we cannot go down into the street, we cannot touch each other, no hugs. . . and we started to compare and the truth is that you realize lots of things, and then you say 'it just seems that I am inside the book! How did I get inside the book, in what moment?' (. . .) Our teacher is who guides us and puts us on track and gives us examples for us to know, that it is not just fiction, that it is a reality and that these things can happen (SS1).

An increase of self-confidence has been highlighted by some teachers as one of the most noticeable changes in confinement times. The fact of being online may have provided them the opportunity to open up and to express their opinions without shyness. To provide some examples, a teacher talks about a girl with especial educational needs who did not used to participate in DLGs and who has started to be involved in and give her opinion much more frequently. The same observation is expressed by her mother, who points to the fact of doing online DLGs as the reason why children are gaining confidence to participating:

> A student with special educational needs who hardly ever participated in the DLGs, since we have been in the online DLGs it happens that we are more in touch with the family, we know that she is fine (. . .) and the fact that she does not have a camera [in the electronic device where she does the online connection] and she can feel more confident, also she can have an adult there, [it is shown that] she participates much more in the DLGs (TP3).
>
> I have realized that maybe as everyone is at home in front of their screen, they feel more confident and, children who did not used to participate so much in the face-to-face classes, they participate a lot now! (FP3).

Motivation has been another of the more commented aspects in the dialogues with participants, which has been very important to overcome confinement with a good state of mind in children. Students try to find the way to get connected to the DLG meetings and more and more students get involved in the sessions. A case was reported of a girl with an autistic disorder who found it difficult to be in all of the on-site DLG sessions, and now, in confinement this girl has started to be more motivated, sharing this moment with her classmates, connecting always to the DLG and staying there for the whole session:

> [The case of] a student whose devices didn't run the audios, also super-shy. So, this girl started to write in the chat because she, despite her shyness. she wanted to be there, because she wanted to be in the DLG. (. . .) Online DLGs started with 13 [students], then 16, then 23, that is, the number of people connecting has been increasing (TP4).
>
> An autistic girl that I have in the classroom, in on-site DLGs never made it through the whole DLG, she had difficulties. . ., but now, her mother told me that she is super motivated (. . .) Now she connects to everything. and she is in the DLG all the time, she does her things, but she doesn't leave the screen (TP4).

Friendship as one of the most important feelings is promoted in many ways through the DLG's online meetings. Students' stories, but also teachers' and families' interviews, have highlighted the condition of friendship as directly related to wellness and one of the first conditions they point out when they are asked about child-wellbeing, together with the emotional dimension:

> Friendship [has enhanced] too, because now [with DLGs] we can see each other, and that means a lot to me. At the beginning [of confinement] we could not meet, neither see nor talk to each other, we could only see the photos we have [of friends] or to think about how they would be doing. . . but now we can see them in reality, what they are doing! (. . .) To see your friends in a DLG, and to be able to speak [with them] can make you feel better (SP1).

Self-esteem can be boosted after the participation in DLGs meetings, as students participate, give their point of view, and their statements enrich and can trigger new interventions:

> After doing the DLG, she [daughter] feels very good, because she feels that her contribution has been appreciated by everyone and that sometimes it leads to more interventions. (. . .) She feels better and happier, her self-esteem grows (FP3).

The feeling of happiness has been shown through the stories and interviews. As a teacher states, families tell them that online DLGs is the happiest moment of the week: "And then the calls we have received from families in which they tell us that it [DLGs] are the happiest moment of the whole week for the kids. They are waiting for us to have the DLGs" (TS1). Families themselves express their children's happiness in the interviews: "It [online DLGs] makes her happy, because she loves to interact with her peers!" (FP3).

Impact at Home, and Homes That Make Impact Possible

One important factor has been identified in families that has enabled the improvements on the aforementioned dimensions. A mother expresses that when she herself gets involved in the online DLG, her daughter seems to have a better performance and seems happier: "I think that the days when I can participate in the DLG (. . .) she interacts more, and she feels happier" (FP4). Some teachers indicate some cases of children with educational needs or disorders that have improved a lot since confinement, due to having their relatives closer and helping them to formulate ideas or to feel confidence:

> I have noticed improvements regarding their interventions thanks to the help and support of the families. One case is that of a boy who has a language disorder, who hardly ever participated in class, and only since DLGs started to participate, and now much more, in less time. . . and I think it is because his mother is close to him and helps him, gives him more confidence. And then the case of a child who also started with many reading difficulties that I have also noticed a lot of improvement now. (. . .) I associate it to being directly related to the help they get from their families, (. . .) they

help them to link the ideas, or if they lose the thread, I hear how they get hooked on the idea again (TP2).

The fact of having more time for getting involved in their children's activities may have been the reason why children are enhancing their development, improving learning and behavior, as this teacher explains. Her student, whose parents normally work all day and had no time to share with their son, now state that they, with the confinement situation, spend more quality time with their child and as a result, the behavior disorders and his academic performance have improved significatively during this time:
