Front. Psychol. 12:555613.  
doi: 10.3389/fpsyg.2021.555613

The coronavirus disease 2019 (COVID-19) pandemic caused by severe acute respiratory syndrome coronavirus 2 is challenging the dental community to an unprecedented degree. Knowledge of the increased risk of infection in dental settings has been disseminated to the public and guidelines have been formulated to assist dental attendance decision-making. However, dental attendance behaviors incompatible with treatment need is not uncommon in clinical settings. Important gaps remain in the knowledge about how psychological factors are affecting dental attendance behaviors during the COVID-19 epidemic. In this cross-sectional study, a questionnaire survey was performed during February and March 2020. A total of 342 and 294 dental patients who attended and avoided dental visits, respectively, were included. The participants were classified into four groups based on dental attendance behavior and emergent/urgent dental treatment need. Bivariate analysis was performed to investigate factors associated with dental attendance. Multivariable logistic regression based on principal component scores was performed to identify major psychological constructs associated with unnecessary dental avoidance and attendance. Among all the factors explored, inability to wear masks during dental treatment ( $P < 0.001$ ; effect size: 0.32) was most closely associated with the overall pattern of dental attendance among participants. Multivariable regression suggested that unnecessary dental avoidance was associated with perceived risk of infection in general and in dental settings (odds ratio [95% CI]: 0.62 [0.53, 0.72];  $p < 0.001$ ), perceived impact of COVID-19 and dental problems on general health (0.79 [0.65, 0.97]; 0.021), and personal traits such as trust and anxiety (0.77 [0.61, 0.98]; 0.038). Unnecessary dental attendance was associated with optimism toward the epidemic (1.68 [1.42, 2.01];  $< 0.001$ ) and trust (1.39 [1.13, 1.74]; 0.002). Multidisciplinary efforts involving dental and medical professionals as well as psychologists are warranted to promote more widespread adoption, among the general public, of dental attendance behaviors compatible with dental treatment need during the COVID-19 epidemic.

**Keywords:** dental attendance, dental avoidance, COVID-19 epidemic, psychological characteristics, dental emergency

## INTRODUCTION

The spread of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a novel strain of coronavirus of zoonotic origin, since its emergence in early December 2019 has resulted in a global pandemic of coronavirus disease 2019 (COVID-19) (World Health Organization, 2020). This has put the dental community against an unprecedented challenge. Dentists and dental patients in clinical settings are at an increased risk of exposure and infection due to the physical proximity between dentists and patients, generation of large volumes of droplets and aerosol during treatment (Cristina et al., 2008), and the inability of the patients to wear masks during treatment. Moreover, patients can be exposed to cross-contamination in the dental office in the absence of adequate precautions (Izzetti et al., 2020). On the other hand, dental problems such as acute pulpitis, acute apical abscess, and traumatic dental injury can lead to extremely painful symptoms and, if left untreated, may develop into life-threatening conditions. Therefore, patients suffering from dental problems are faced with the dilemma of two choices: either visiting dental care providers to alleviate symptoms at the cost of an increased risk of infection or living with symptoms of dental problems at home.

Government and dental professional associations in China and other countries have issued instructions and guidelines regarding the operation of dental services during the COVID-19 epidemic (Ather et al., 2020). In China, all private dental clinics are required to shut down while only selected public dental hospitals to remain open to sustain dental care services for patients in distinct need of emergency treatment. The Chinese government (Li and Meng, 2020; National Health Committee, 2020) and ADA (American Dental Association) formulated guidelines for patient triage and screening and specified the spectrum of emergent/urgent dental diseases that require immediate treatment [American Dental Association (ADA) (2020)]. Both guidelines were developed with the fundamental principle that only patients with emergent/urgent dental problems should be treated and efforts should be made to minimize the risk of contraction of SARS-CoV-2 in the dental office by dental professionals.

In spite of public advocacy of these government policies and professional guidelines, clinical observation suggested that it was not uncommon for patients without emergent/urgent need of dental care to visit dental hospitals. On the other hand, a large number of patients with distinct needs of immediate care refused to visit dental hospitals. These inadequate dental attendance behaviors impede proper prioritization of dental care resources and unnecessarily increase the risk of SARS-CoV-2 exposure and infection by dental professionals and patients. Dental attendance behaviors are evidently influenced by psychological factors. Dental phobia results in irregular dental care-seeking behavior (Bernson et al., 2013). Likewise, pregnant women tend to be hesitant in terms of dental visits although dental care can lead to improved pregnancy outcomes (Al Habashneh et al., 2005; Wrzosek and Einarson, 2009). Consequently, we hypothesize that inadequate dental attendance behavior during the COVID-19 epidemic is influenced by psychological factors.

At the time of writing, limited studies have discussed the impact of the COVID-19 epidemic on dentistry, and even fewer have examined the impact of the epidemic on the psychological status of dental patients. Zhai and Zhou (2020) reviewed dental diseases associated with psychological status and emphasized the need for dentists to pay attention to the psychological status of dental patients. During the SARS outbreak, over 30% of the dental patients in Hong Kong were worried about being infected from dental treatment (Yip et al., 2007). However, only dental attendees were surveyed in this study. Psychological factors associated with dental avoidance and attendance during major disease epidemics cannot be identified from this study. Therefore, the usefulness of this study was limited in terms of informing individualized, targeted psychological interventions that promote the adoption of adequate dental attendance behavior.

In addition to perception toward COVID-19 and perception toward dental visits during this period, coping strategy, anxiety, and trust were also potentially associated with dental attendance behavior. The coping strategy changes the assessment of stress events and regulates physical and emotional responses related to the event (Li et al., 2014). The relationship between individual coping style and mental and physical health has become an important research area in clinical psychology. Previous studies have shown that coping style was related to mental health (Yu et al., 2007). Social anxiety may lead to hesitant behavior, avoidance, and performance difficulties and is therefore potentially associated with reluctant dental-seeking behavior (Maner et al., 2007). In addition, we investigated the trust of the respondents toward others and toward health care workers separately since they may differentially impact dental attendance behavior (Trachtenberg et al., 2005).

The present study aimed at comprehensively assessing psychological factors belonging to multiple domains that influence the attendance behavior of dental patients during the COVID-19 epidemic. Emphasis was placed on psychological factors that are, respectively, associated with unnecessary dental avoidance and attendance. Identification of such psychological determinants would help address inadequate dental attendance behavior and promote widespread adoption of dental attendance behavior compatible with real dental treatment needs of the patients during the COVID-19 epidemic.

## METHODS

### Research Approach

A cross-sectional questionnaire survey was performed to investigate psychological factors associated with dental attendance behavior during the early stage of the COVID-19 epidemic. Analyses were performed separately for each type of dental attendance behavior to investigate how dental attendance behavior is associated with varying psychological factors.

### Procedure and Participants

Participants consisted of 636 adults age 18–80 years who had varying severity of dental diseases during February and March 2020, when the COVID-19 epidemic was at its peak in China. A

**TABLE 1** | Criteria for classification of participants.

	T-V	T-nV	nT-V	nT-nV
Level of pain ≥7/trauma/localized swelling	+	+	-	-
Dental visit	+	-	+	-
Hypothetical question	+	NA	NA	+

For the hypothetical question, participants in group T-V were asked if they would still visit dentists if their symptoms do not constitute dental emergency/urgency. Participants in group nT-nV were asked if they would still avoid visiting dentists if their symptoms constitute dental emergency/urgency.

total of 355 participants who visited the Hospital of Stomatology of Xi'an Jiaotong University, a teaching hospital that remained functional throughout the epidemic period, were recruited. To recruit potential dental patients who did not visit the dental hospital, questionnaires were distributed through WeChat, the largest social media platform in China, covering populations of varying ages, and a total of 946 individuals responded. Among the respondents, 281 were identified as having dental problems and were therefore included in the analysis conducted. Patients were excluded if they themselves or their dependents were unable to cooperate to complete the questionnaire online. Ethics approval was obtained from the Clinical Research Ethics Committee of the Hospital of Stomatology of Xi'an Jiaotong University. Participants gave informed consent prior to their participation.

On the basis of Chinese government policies and guidance from ADA, which are essentially in mutual agreement, we classified participants into four groups according to their emergent/urgent treatment needs and dental attendance behavior (**Table 1**): patients with emergent/urgent dental treatment needs who visited dentists (T-V); patients with emergent/urgent dental treatment needs who did not visit dentists (T-nV); patients without emergent/urgent dental treatment needs who visited dentists (nT-V); and patients without emergent/urgent dental treatment needs who did not visit dentists (nT-nV). Participants in groups T-V and nT-nV demonstrated dental attendance behaviors compatible with their treatment needs and were combined into a single group, termed group C (C for compatible), during further analysis.

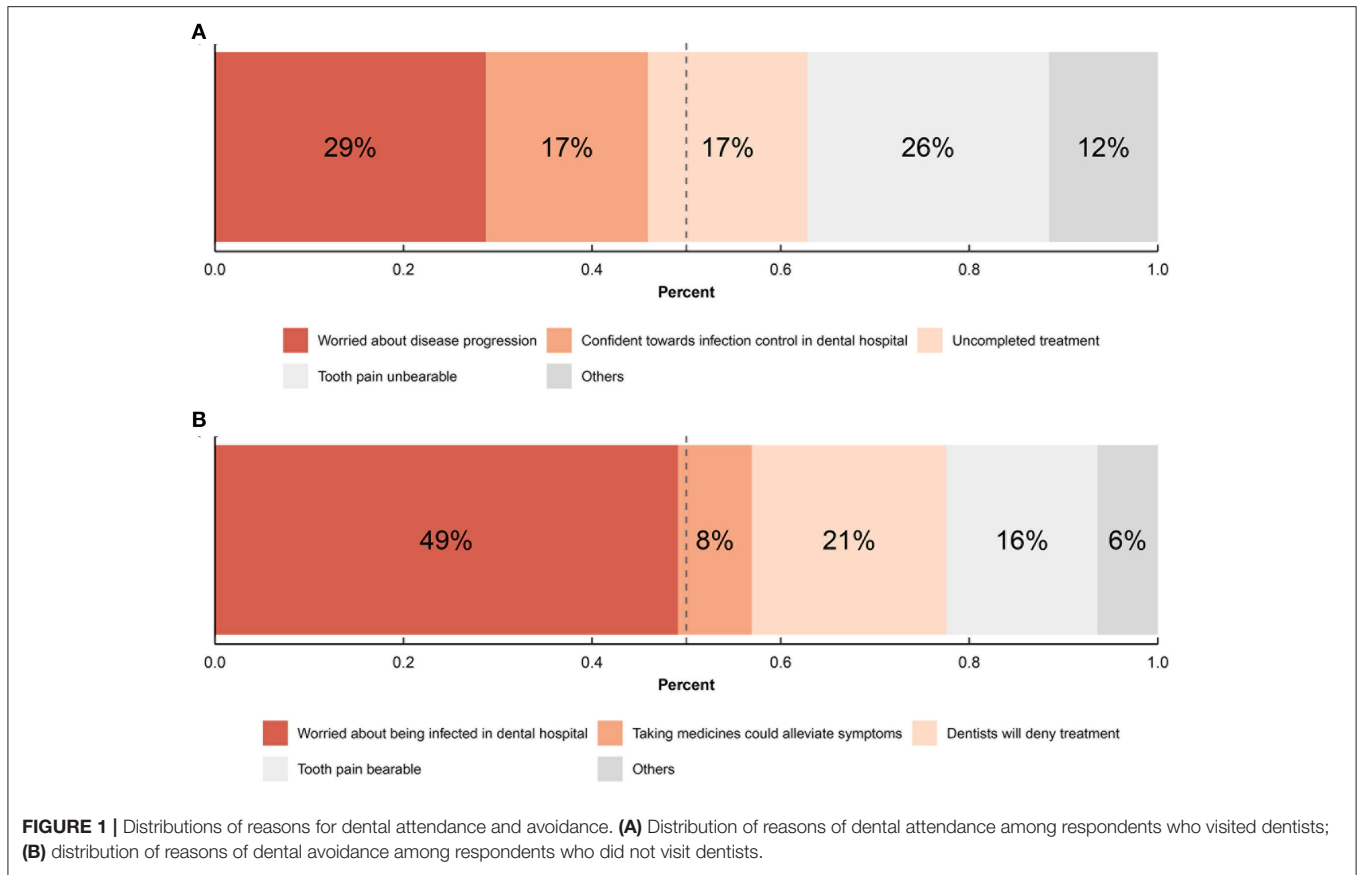

## Measures

All participants responded to the questionnaire (**Supplementary Table 1**) online. The demographic and socioeconomic characteristics of the participants were recorded at the beginning of the questionnaire (Q1–4). The occupation of the participants was classified into occupational groups, namely I (professional), II (managerial and technical), III (skilled), IV (partly skilled), and V (unskilled), according to the Registrar-General's Social Classes (Bland, 1979). Reasons for dental attendance and avoidance were also included (Q6–10). Distribution of participants by reasons of attendance/avoidance

provides an understanding of the impact of psychology-related factors on the dental attendance behavior (**Figure 1**).

The remainder of the questionnaire involved five major domains. The first domain was designed to evaluate the cognition, emotion, and behavior of the participants (Q14–22) to the epidemic. Cognition and emotion significantly affect human behavior (Dolan, 2002). Cognition and emotion-related questions were incorporated into the questionnaire based on questions from a large-scale study on the perception of the general public toward COVID-19 among Chinese citizens (Fang et al., 2020). Cognitive questions involved views on the current status and future trends of the epidemic and knowledge about dental diseases. Emotional questions mainly captured emotional reactions. Behavior-related questions evaluated the perceived impact of the epidemic on daily lives. The second domain investigated knowledge and attitude toward dental attendance during the COVID-19 epidemic based on questions developed by dental experts from different fields (Q23–28). Trust in People Questionnaire (TPQ), which assessed how individuals trust others (Robinson et al., 1973), was included as the third domain of the questionnaire (Q29–35). We additionally included a question (Q32) on the trust of the respondents toward health care providers (Trachtenberg et al., 2005). The Simplified Coping Style Questionnaire (SCSQ) in the fourth domain (Q36–55) of the questionnaire, which assessed individuals' consciousness, purposefulness, and flexibility in regulating behaviors in the real environment, was developed by Xie (1998) on the basis of the Ways of Coping questionnaire by Folkman and Lazarus (1988). SCSQ is a 20-item self-administered questionnaire, including 12 positive response items and 8 negative response items. A higher score represents a more positive/negative coping style. Subjects were asked to indicate their level of agreement on the four-point Likert scale based on the frequency of their adoption of items ranging from 0 ("Never") to 3 ("Very frequent"). The questionnaire has been proven to be reliable and effective and widely used in China (Li et al., 2014). The fifth domain (Q56–62), the Interaction Anxiousness Scale (IAS), assessed the tendency of the subjective social anxiety experience independent of behavior. IAS is a self-reported measure of dispositional social anxiety with proven reliability and validity (Leary and Kowalski, 1993). The IAS contains 15 items, which are answered on a 5-level scale (1 = Does not match me at all; 2 = Matches me a little bit; 3 = Agrees with me to a moderate degree; 4 = Consistent with me; 5 = Very consistent with me). Its total score ranges from 15 (the lowest level of social anxiety) to 75 (the highest level of social anxiety). Cronbach's alpha was calculated for each of the five domains using the "alpha" function from the R package "psych." The values of Cronbach's alpha were 0.61, 0.51, 0.62, 0.85, and 0.79 from the first to the fifth domain, respectively.

A question on the degree of anxiety toward dental visits before the epidemic was used to identify and exclude participants with dental phobia (Q13). A question was designed to exclude all respondents without any dental problems (Q5). It is noteworthy that participants in the T-V group may still visit dentists if their dental conditions were not as emergent/urgent, and *vice versa* for participants in the nT-nV

group. To ensure that the T-V and nT-nV groups included only participants whose perceived need toward dental visit is compatible with the emergency/urgency of the dental condition, two hypothetical questions were asked. In these two questions, participants belonging to the T-V group were asked to indicate if they would still visit dentists if their dental conditions were not emergent/urgent (Q11). A similar question was asked to participants belonging to the nT-nV group (Q12).

## Statistical Analysis

The distribution of participants by demographic and socioeconomic characteristics was described for each behavioral group. The distribution of reasons for dental attendance and avoidance were evaluated. ANOVA was performed to investigate mean differences in response to each question among the four dental attendance behavior groups. The effect size of ANOVA was determined by  $\eta = \sqrt{\frac{SS_M}{SS_T}}$ , where  $SS_M$  is the model sum of square and  $SS_T$  is the total sum of square. Furthermore, response to each question was compared between the T-nV and C groups, as well as between the nT-V and C groups, through planned contrasts. In the first contrast, group T-nV is assigned a weight of 2, nT-V is assigned a weight of 0, T-V and nT-nV are each assigned a weight of -1. This allows for the comparison of groups T-nV and C.

In the second contrast, group T-nV is assigned a weight of 0, nT-V is assigned a weight of 2, and T-V and nT-nV are each assigned a weight of -1. This allows for the comparison of groups nT-V and C. Effect size of planned contrast was determined by  $r = \sqrt{\frac{t^2}{t^2 + df}}$  (Rosenthal, 1994). Following Cohen's guidelines, 0.3 and 0.5 were used as the threshold for small, medium, and large effect for both  $\eta$  and  $r$ , respectively. Categorical variables were compared among and between groups through a chi-square test with effect size estimated through Cramér's  $V$ .

Factors significantly associated with dental attendance behaviors in bivariate analysis (ANOVA and planned contrast) were then jointly examined through multivariable logistic regression. Logistic regression models were established separately for T-nV vs. C and nT-V vs. C. Since items in the questionnaires are not mutually independent, principal component analysis (PCA) was performed to extract principal components (PCs) from those significant items. The "prcomp" function in R was used for the PCA and the calculation of PC scores. Multivariable logistic regression was then performed based on individual PC scores. All tests were two-sided and the level of statistical significance was set at 0.05. ANOVA and logistic regressions were performed using R software (version 4.0.2). The "contrasts" function in R was used for the construction of contrasts and the "aov" function was used for ANOVA. Logistic regressions

were performed using the “glm” function with the logit link. All functions used in this study are available in base R.

## RESULTS

### Demographic and Socioeconomic Characteristics

Completed questionnaires were received from 636 surveyed participants. Among the participants, 44% were males. Young people (age 18–30) accounted for 35%, middle-aged people (age 30–59) accounted for 24%, and the elderly (age 60–80) accounted for 10%. There were 63% of respondents who had an undergraduate degree or above. Skilled workers (Occupation group III) had the largest proportion of participants (35.7%) among all occupational categories. The distributions of each characteristic among the four behavioral groups are described in **Table 2**. It was found that 63 and 78% of dental avoidance and attendance behaviors of the participants, respectively, were psychologically related.

Mean differences were presented for all questions except for questions with categorical responses. SE, standard error; ES, effect size. When groups T-nV and nT-V are compared against group C, mean values for group C were subtracted from those for groups T-nV and nT-V, respectively. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

### Factors Associated With the Pattern of Dental Attendance During the COVID-19 Epidemic

The ANOVA and planned contrast identified factors associated with dental attendance behavior from each of the five domains in the questionnaire (Table 3, Figure 2). The behavior of being worrisome about getting infected was most closely associated with the overall pattern of dental attendance ( $P < 0.001$ ; ES = 0.28) and was significantly associated with both unnecessary dental avoidance ( $<0.001$ ; 0.16) and attendance ( $<0.001$ ; 0.19). Perceived likelihood of being infected was likewise associated with both unnecessary dental avoidance ( $<0.001$ ; 0.20) and attendance ( $<0.001$ ; 0.12) behaviors. The expected epidemic duration was uniquely associated with unnecessary dental attendance behavior (0.01; 0.10). Considering dental hospital to be the most dangerous place was uniquely associated with dental avoidance behavior ( $<0.001$ ; 0.12). Perceived impact of the epidemic on dental visits ( $<0.001$ ; 0.31) and degree of fearfulness toward dental visits ( $<0.001$ ; 0.16) were associated with the general pattern of dental attendance. Unmasking during dental visits was most closely associated with the pattern of dental attendance ( $<0.001$ ; 0.32) but further analysis revealed that it was only associated with unnecessary dental avoidance ( $<0.001$ ; 0.18). The perceived impact of oral health on general health was significantly associated with only unnecessary dental avoidance (0.01; 0.10). Trust toward health care providers was associated with both unnecessary dental avoidance ( $<0.001$ ; 0.11) and attendance ( $<0.001$ ; 0.18). Positive coping, on the other hand, was uniquely associated with unnecessary dental avoidance ( $<0.001$ ; 0.16). In terms of anxiety, trait anxiety (0.002; 0.13) and social anxiety (0.01; 0.10) were uniquely associated with unnecessary dental avoidance. Table 3 suggests that participants who avoided necessary dental visits differed from group C in the reverse direction in which participants who unnecessarily visited dental hospitals differed from group C.

Multivariable logistic regression based on group T-nV and group C (Table 4, Supplementary Table 2) suggested that higher PC1 scores, which represented a lower perceived risk of SARS-CoV-2 infection in dental hospitals, was associated with reduced likelihood of unnecessary dental avoidance (odds ratio [95% CI]: 0.62 [0.53, 0.72];  $p < 0.001$ ). Participants with higher scores along PC3, which was indicative of the less perceived impact of COVID-19 and greater impact of dental problems toward general health, were less likely to avoid necessary dental visits (0.79 [0.65, 0.97]; 0.021). PC6, which was associated with positive personal traits such as the adoption of positive coping and less social anxiety, was associated with reduced likelihood of unnecessary dental avoidance (0.77 [0.61, 0.98]; 0.038). Multivariable logistic regression based on group nT-V and group

**TABLE 4 |** Multivariable associations between principal components of psychological factors and dental avoidance.

	OR (95% CI)	P-value
PC1 (Perceived increased risk of SARS-CoV-2 infection in dental hospital)	0.62 (0.53, 0.72)	<0.001***
PC2	1.13 (0.95, 1.34)	0.175
PC3 (Perceived relative importance of COVID-19 vs. dental problems on general health)	0.79 (0.65, 0.97)	0.021*
PC4	0.87 (0.71, 1.07)	0.188
PC5	0.90 (0.73, 1.12)	0.366
PC6 (Personal trait)	0.77 (0.61, 0.98)	0.038*
PC7	1.06 (0.84, 1.35)	0.626
PC8	0.91 (0.70, 1.19)	0.491
PC9	1.05 (0.79, 1.40)	0.718

OR, odds ratio; 95% CI, 95% confidence interval. Participants in group C were coded as 0 and in group T-nV were coded as 1. \* $p < 0.05$ ; \*\*\* $p < 0.001$ .

**TABLE 5 |** Multivariable associations between principal components of psychological factors and unnecessary dental attendance.

	OR (95% CI)	P-value
PC1 (Judgement of COVID-19 epidemic)	1.68 (1.42, 2.01)	<0.001***
PC2 (Trust toward others)	1.39 (1.13, 1.74)	0.002**
PC3	0.89 (0.71, 1.11)	0.310
PC4	0.98 (0.79, 1.21)	0.840
PC5	0.99 (0.78, 1.26)	0.914
PC6	1.03 (0.80, 1.34)	0.813

OR, odds ratio; 95% CI, 95% confidence interval. Participants in group C were coded as 0 and in group nT-V were coded as 1. \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

C (Table 5, Supplementary Table 3) suggested that higher PC1 scores, indicative of a positive perception toward the COVID-19 epidemic, increased the likelihood of unnecessary dental attendance (1.68 [1.42, 2.01]; <0.001). PC2, which accounted for increased trust toward health care providers and less fearfulness toward dental visits, increased the likelihood of unnecessary dental visits by 39% (1.39 [1.13, 1.74]; 0.002).

## DISCUSSION

To the knowledge of the authors, this is the first study that has comprehensively investigated the impact of psychological factors on the patterns of dental attendance behavior during the COVID-19 epidemic. By separately analyzing psychological factors influencing unnecessary dental avoidance and attendance, we were able to provide evidence on psychological factors that differentially influence these two dental attendance behaviors.

This study was performed in the city of Xi'an, a prominent city in northwest China whose epidemiological profile of COVID-19 ranked middle among all major cities in China. The study was performed during February and March when the COVID-19 epidemic was at its height in China. Distributions of demographic

and socioeconomic characteristics were comparable across the four groups of participants. The findings presented herein are therefore generalizable to the local population. However, care should be taken when extrapolating the present findings to the wider population because differences in the degree of severity of COVID-19 may interact with psychological determinants to affect dental attendance behavior. Whether and how cultural and socioeconomic differences across regions and nations impact dental attendance behavior in addition to psychological factors is worthy of further investigation.

Dental care-seeking behavior is most commonly influenced by dental symptoms. However, the impact of psychological factors on dental attendance should not be neglected. The presented findings suggest that the dental avoidance and attendance behavior of more than half of the participants during the COVID-19 epidemic was psychologically related. This highlighted the importance of psychological factors on dental visits during the COVID-19 epidemic.

Further analyses revealed that participants who unnecessarily avoided dental visits responded to these questions in the reverse direction in which those who unnecessarily attended dental visits responded. This lends further support to the regulatory role of psychological factors in driving dental attendance behaviors. Such findings also justified the need to analyze the groups T-nV and nT-V separately. However, a close examination revealed that factors leading to unnecessary dental avoidance and attendance were not exactly the same. This points toward the complex pathways in which multiple psychological factors interact and ultimately affect dental attendance behaviors.

Multivariable logistic regression identified three components that were associated with unnecessary dental avoidance behavior. The first component characterized individual perception toward the risk of infection both in general and inside dental hospitals. Knowledge about the routes and dynamics of SARS-CoV-2 transmission was limited during the early stage of the COVID-19 epidemic, which resulted in prevalent anxiety and a feeling of uncertainty among the general public. It was estimated that around 70% of the public were worried or terrified of the epidemic. This creates the possibility for cognitive bias to prevail among the general public (Fang et al., 2020). Chinese health authorities have advised the public to use masks since the early stage of the epidemic. Compared to individuals in other countries, especially westerners, masks are given greater importance in their role in individual protection during the COVID-19 epidemic by Chinese individuals. This likely explains the contribution of worry toward unmasking during dental treatment to the first component. As a result, perception toward the epidemic and toward dental visits jointly influenced unnecessary dental avoidance behavior. Dissemination of the knowledge of COVID-19 and timely updates of epidemic status could help relieve the feeling of uncertainty and terror by the general public. Dental patients should be educated that necessary dental treatment should nevertheless be delivered as long as necessary precautions are taken. The strict measures of infection control taken by the dental hospitals should be made aware to the public. Education of this kind could serve as a strategy during cognitive behavioral therapy to help those who would

have avoided dental visits to assume a more evidence-based stance toward COVID-19 that is less affected by cognitive bias.

The perceived risk of COVID-19 and dental problems toward general health also impacted dental avoidance. Individuals avoiding necessary dental visits tended to overestimate the impact of COVID-19 and underestimate the impact of dental problems on general health. Expert opinions converge to indicate an uncertain to low risk of SARS-CoV-2 infection in dental hospitals under the condition of adequate precautionary measures taken by both dental hospitals and dental patients. In contrast, there exists a real and distinct risk for dental emergencies to progress into a general health threat. Therefore, to correct for the misjudgment of patients, coordinated efforts from medical and dental health care workers are required to disseminate evidence-based knowledge of the impact of both COVID-19 and dental problems on general health; the emphasis should be placed on the impact of both COVID-19 and dental problems on general health during the consultation and psychological intervention. Greater awareness of general health impact from both aspects would enable the general public to make better-informed dental visit decisions and reduce unnecessary dental avoidance.

Another component associated with dental avoidance involved coping and anxiety. Coping styles directly impact the emotional and physical outcomes of stressful events (Beutler et al., 2011). Positive coping styles affect emotional regulation and facilitate behavioral regulation (Iwata, 2002; MacNeil et al., 2012). A meta-analysis suggests that coping style plays an important role in deciding whether to accept medical and psychological therapeutic interventions (Glanz et al., 2008; Beutler et al., 2011). During the SARS epidemic, positive coping was found to be associated with increased willingness to accept medical treatment and decreased incidence of mental illness (Sim et al., 2010). The findings by the authors likewise identified an association between dental attendance behavior and positive coping, which expands the current knowledge on the impact of coping styles on treatment-related decision-making. Furthermore, the observed findings suggest that strategies that boost positive coping, such as meditation and exercise, may play an essential role in alleviating stress and reducing trepidation. Social anxiety, on the other hand, may lead to hesitant behavior, avoidance, and performance difficulties (Oakman et al., 2003). Increased social anxiety is therefore associated with more frequent unnecessary dental avoidance.

Multivariable logistic regression identified two components associated with unnecessary dental attendance. The first component reflected optimism/pessimism toward the COVID-19 epidemic. Participants unnecessarily attending dental visits were more likely to be optimistic toward the epidemic. Although such optimism is not to be discouraged, proper education is necessary for this population so that limited dental care resources are more effectively delivered to those truly in need. In addition, the presence of this group of population in dental hospitals highlights the importance of the unrelenting effort in infection control in dental hospitals to prevent nosocomial spread of infection because these overly optimistic patients are more likely to be ignorant regarding personal protection. Another

component associated with unnecessary dental attendance was trust toward health care providers and the resultant decrease in fear of dental attendance. Like optimism, trust toward health care provides is in no way to be discouraged; better education of the risks of unnecessary dental attendance during the COVID-19 epidemic is critical to this population.

The observed findings suggest that cognitive regulation and knowledge dissemination would help the general public adopt dental attendance behaviors compatible with their real treatment needs. In addition, the promotion of the infection control measures taken by dental hospitals could help offset the perceived risk of unmasking during dental treatment to reduce unnecessary dental avoidance. Methods to boost coping behaviors are also likely to reduce unnecessary dental avoidance. Education about the risk of dental attendance is important in restraining those who planned unnecessary dental visits at home. All of the above strategies require efforts by dental professionals, as well as medical and psychological experts, to actively engage in the decisions of patients toward dental visits. Websites and hotlines maintained by professionals may provide a means to identify the need of each individual so as to develop individualized opinions and, when necessary, psychological interventional strategies, to better serve the general public.

Several limitations of the study bear noting. First, trait anxiety and the perception of the dental hospital being the most dangerous place in terms of being infected were not included in multivariable logistic regression although they were found to be significantly associated with patterns of dental attendance. This is because the answers to these two questions are categorical instead of ordinal or continuous. There is no way in which these questions could be included in PCA. However, we have included other questions of the same domain as these two questions, and hence, the results are not likely to be significantly biased. Second, the findings may be subject to the reporting bias of participants. Classification of dental patients who avoided dental visits with regard to emergent/urgent treatment need was performed purely based on self-reported signs and symptoms. This constitutes a potential source of bias since the rating of the severity of pain may be subject to subjectivity and recall bias. Besides, since the participants of this study were suffering from varying severities of dental symptoms, their response to the questionnaire may be biased by an emotional response to dental symptoms. We included two hypothetical questions at the outset that required participants to indicate their likely dental attendance decision if the severity of their symptoms is different. These hypothetical questions required the devotion and thinking of the participants, which could help the participants calm down and respond to the rest of the questionnaire more sensibly. Third, factors that may influence the strength of the impact of psychological factors on dental attendance behaviors, such as regional level of risk, medical history, and the number of visits, were not taken into consideration. Inclusion of these factors in future studies is likely to produce more robust findings unaffected by variations in these variables. Fourth, the domain of "Perception toward dental attendance during COVID-19 epidemic" is composed of questions that have not been previously validated. These questions were prepared by the joint effort of a team of dental

specialists and psychologists with experience in questionnaire development. However, Cronbach's alpha suggested a lower level of internal consistency for this domain relative to other domains. The level of internal consistency is not unacceptable (Cronbach's alpha of  $<0.5$  is considered unacceptable) but we do acknowledge that better-structured questionnaires would provide more valid and robust findings. Given the timeliness of this study, the presented findings are still useful in identifying psychological factors associated with dental attendance during the COVID-19 epidemic.

## CONCLUSION

Psychological factors play an important role in influencing dental attendance behavior during the COVID-19 epidemic. The perceived risk of SARS-CoV-2 infection in general and in dental hospitals, the perceived impact of COVID-19 and dental problems on general health, and personal traits such as coping style and anxiety influence unnecessary dental avoidance. Unnecessary dental attendance, on the other hand, is driven by optimism/pessimism toward the COVID-19 epidemic and trust toward health care providers. Multidisciplinary efforts are required to better educate and serve the general public and to promote more widespread adoption of dental attendance behavior compatible with dental treatment needs during the current COVID-19 epidemic.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Clinical Research

Ethics Committee of Hospital of Stomatology of Xi'an Jiaotong University. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

YW collected data, performed the statistical analysis, and drafted the manuscript. PF collected data, performed the statistical analysis, and revised the manuscript. J-xP, SW, and XL designed the questionnaire, participated in statistical analysis, and critically reviewed the manuscript. QD conceived the study, designed the study, supervised the data collection process, advised on statistical analysis, and critically revised the manuscript. All authors agree to be accountable for the content of the work.

## FUNDING

This study was funded by China Postdoctoral Science Foundation (2019M653963) and Army Logistics Research Project during the 13th Five-Year Plan Period (CWS20J007).

## ACKNOWLEDGMENTS

The authors would like to thank all dentists and dental assistants in the Department of Operative Dentistry and Endodontics, Hospital of Stomatology of Xi'an Jiaotong University, for their assistance with data collection.

Preparedness, and Perceived Impact  
of Covid-19 Pandemic on Nurses'  
Mental Health.  
Front. Public Health 9:566700.  
doi: 10.3389/fpubh.2021.566700

**Background:** In times of global public health emergency, such as the COVID-19 pandemic, nurses stand at the front line, working in close contact with infected individuals. Being actively engaged in fighting against COVID-19 exposes nurses to a high risk of being infected but can also have a serious impact on their mental health, as they are faced with excessive workload and emotional burden in many front-line operating contexts.

**Purpose:** The aim of the study is to analyze how risk factors such as perceived impact, preparedness to the pandemic, and worries were associated with mental health outcomes (crying, rumination and stress) in nurses.

**Methods:** A cross-sectional study design was performed via an online questionnaire survey. Participants included 894 registered nurses from Italy. Participation was voluntary and anonymous. Multiple binary logistic regression was carried out to analyze the relationship between risk factors and health outcomes.

**Results:** Increased job stress was related to higher levels of rumination about the pandemic (OR = 4.04,  $p < 0.001$ ), job demand (OR = 2.00,  $p < 0.001$ ), impact on job role (OR = 2.56,  $p < 0.001$ ), watching coworkers crying at work (OR = 1.50,  $p < 0.05$ ), non-work-related concerns (OR = 2.28,  $p < 0.001$ ), and fear of getting infected (OR = 2.05,  $p < 0.001$ ). Job stress (OR = 2.52,  $p < 0.01$ ), rumination (OR = 2.28,  $p < 0.001$ ), and watching colleagues crying (OR = 7.92,  $p < 0.001$ ) were associated with crying at work. Rumination was associated with caring for patients who died of COVID-19 (OR = 1.54,  $p < 0.05$ ), job demand (OR = 1.70,  $p < 0.01$ ), watching colleagues crying (OR = 1.81,  $p < 0.001$ ), non-work-related worries (OR = 1.57,  $p < 0.05$ ), and fear of getting infected (OR = 2.02,  $p < 0.001$ ).

**Conclusions:** The psychological impact that this pandemic may cause in the medium/long term could be greater than the economical one. This is the main challenge that health organizations will have to face in the future. This study highlights that the perceived impact and worries about the pandemic affect nurses' mental health and can

impact on their overall effectiveness during the pandemic. Measures to enhance nurses' protection and to lessen the risk of depressive symptoms and post-traumatic stress should be planned promptly.

**Keywords:** COVID-19 pandemic, nurses, stress, health outcomes, risk factors, perceived impact

## INTRODUCTION

The Coronavirus Disease (COVID-19) pandemic represents a serious concern for public and occupational health (1). This pandemic is having an unprecedented impact on the nursing profession. According to the World Health Organization, nurses represent the largest group of Health Care Workers (HCWs) involved on the front line of health care systems. In this sense, nurses deliver care to patients in close physical proximity and thus they are directly exposed to the virus and are at high risk of developing the disease (2–4). To protect HCWs, physical distancing in taking care of COVID-19 patients can limit the spread of the infection, although it reduces nurses' ability to meet the patients' needs. However, during the first months of the pandemic, the European Center for Disease Control and Prevention (ECDC) (5) announced that up to 10% of the reported cases in China and up to 9% of all cases in Italy were among HCWs. According to the CDC (6) in the US the percentage of positive cases among HCWs ranged from 3 to 11%. However, due to the preventive measures, the infection risk among HCWs gradually decreased (7). What rapidly became important was to preserve the mental health of HCWs (8), challenged by the tremendous psychosocial crisis they were experiencing (9–11).

In pandemic scenarios, all HCWs are at risk of long working hours, higher job demands, psychological distress, fatigue, stigmatization, and physical and psychological violence (2). Studies showed the impact of this critical situation on HCWs' mental health in terms of worries, fatigue, insomnia, anxiety, depression, and stress (8, 11–13). Moreover, the increased percentage of patient deaths results in an augmented exposure to emotional and psychological suffering: a recent systematic review on HCWs' mental health during the COVID-19 pandemic found an anxiety incidence of 24.6%, a depression incidence of 22.8%, and an insomnia incidence of 34.3% (14). Regarding the psychological impact of the outbreak, the literature points out a prevalence of post-traumatic stress disorder (PTSD) among HCWs between 11 and 73.4% (15). The continuous exposure to stressful events may result in post-traumatic stress symptoms, which, in turn, may mine professionals' ability to cope with the situation. As to the nursing profession, previous studies investigating the impact of outbreaks/pandemic showed that the more nurses perceived risks for their health, the more they left their job (16–18). Furthermore, those who did not leave were exposed by the pandemic scenario to higher levels of distress, increased workload, emotional burden, workplace conflicts, increased depression risk, and suicide (19, 20). In a recent literature review investigating the impact of respiratory pandemic on nurses, Fernandez et al. (21) reported that nurses experienced fear, worries for personal and family safety, a sense of powerlessness, increased job demands, anxiety, and stress.

Furthermore, perceived organizational preparedness and safety played a crucial role.

In this sense, preserving nurses' mental health during the COVID-19 pandemic is a very important global challenge as it may increase health systems' ability to deliver timely care. Worries and emotional impact of the COVID-19 pandemic among nurses are still barely analyzed. Most of the available studies on the topic usually include physicians or other health care professionals (22). In relation to the peculiarities of its professional mandate and the current organization of the Italian health care service, the nursing profession is facing this critical situation in a transversal way, in different care contexts. Moreover, nurses are faced with an excessive workload and emotional burden in many front-line operating realities, even compared to the actual available resources (23). In Italy, in the first months of the pandemic, 25,629 health workers were infected with Covid-19 (24), including 12,000 nurses (25). In addition, of the 80 health workers who died (16), 39 were nurses, four of whom committed suicide (25). To our knowledge, there is no Italian study analyzing nurses' mental health perception during this pandemic, because most of the COVID-19-related research includes Asian samples (26). Therefore, this study would contribute to expand the knowledge on the topic and provide additional value to the existing studies.

## STUDY AIM

The aim of the study was to analyze how the perceived impact, preparedness to the pandemic, and worries are associated with mental health indicators (crying, rumination, and stress) in nurses.

## MATERIALS AND METHODS

### Study Design, Participants, and Data Collection

A cross-sectional study design was performed via an online questionnaire survey. Participants included registered nurses from Italy. The only inclusion criterion was to be working during the COVID-19 pandemic. To collect data, the LimeSurvey application was implemented and the link to the questionnaire was shared through social networking platforms. Participants were briefed about the study purpose through written information reported on the questionnaire's homepage. Informed consent was obtained from all nurses before filling out the online questionnaire. Privacy was assured because no IP address was registered and no sensitive data were requested. The data were collected from April 15th to April 24th 2020.

## Ethical Statement

The study complies with the Declaration of Helsinki and with the General Data Protection Regulation (EU) 2016/679 (GDPR). Participation was voluntary and anonymous, according to Italian Data protection law (e.g., Decree n. 196/2003). Participants could interrupt their participation in the survey at any time without any adverse consequence. We consulted the Institutional Review Boards of the University of Cagliari, which informally said that Ethical review and approval was not required for the study on human participants, in accordance with the local legislation and institutional requirements.

## Measures

The online self-report questionnaire consisted of two sections. The first one regarded demographic information including gender, age, working geographical area, civil status, children, current clinical-healthcare area, job description, and professional tenure. The second one was developed by combining items from different questionnaires. Specifically, we used measures from previous international studies on other epidemics (SARS and Avian Influenza) (27, 28) to assess worries, preparedness and impact of the COVID-19 pandemic among nurses. The aim was to use a short survey to avoid cognitive overloading for workers. In this sense, items unsuitable for the target work population were not selected. Also, we used Ruminations on Sadness Scale (29, 30) to measure nurses' ruminations about the pandemic. Finally, we measured the frequency of crying at work and watching one's own colleagues crying at work. For the scales that did not have an Italian version, cultural adaptability of the items was assured via translation and back-translation procedures (31). Two bilingual experts independently translated the questionnaire from English into Italian. The two translations were then compared to identify and discuss the main inconsistencies. After this revision, a final Italian version of the questionnaire was created. Then, the translated questionnaire was back-translated into English by another bilingual linguistic expert to evaluate equivalence. Finally, the back-translated version of the questionnaire was compared with the original version. Meanings and concepts were considered as equivalent. A pre-test was carried out on 10 nurses to assess the appropriateness of the translation, comprehensibility and clarity of the items, and time of completing questionnaire.

Regarding the specific measures considered into the whole questionnaire, we investigated the following variables: (1) organizational preparedness (1 item) and Regional Health System (RHS) preparedness (3 items). A sample item was "My hospital RHS has a preparedness plan for the COVID-19 pandemic"; (2) personal preparedness (1 item: "I am personally prepared for the COVID-19 pandemic"); (3) fear of getting sick with COVID-19 (2 items: "I am afraid of falling ill with COVID-19"); (4) non-work-related concerns (3 items: "People close to me are at high risk of getting COVID-19 because of my job"); (5) increased job demands (3 items: "I had an increase in workload in my job") and job role (1 item: "I would had to do work not normally done by me"); (6) impact on personal life (3 items: "People avoid me because of my job"); (7) perceived job stress (1 item: "I feel more stressed at work"). Ruminations about the

pandemic was measured by adapting 2 items from the Italian version of Ruminations on Sadness Scale changing "sadness" with "pandemic" (e.g., "I have difficulty getting myself to stop thinking about this pandemic") (29, 30). Finally, 2 items were *ad hoc* developed to measure the frequency of crying at work and watching one's own colleagues crying at work (e.g., "I have been crying at work because I felt like I could not take it anymore"). Cronbach's Alpha was calculated for the scales with at least three items. For the measures with two items, inter-item correlation was performed. All the items were based on a five-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree).

## Statistical Analysis

To performing data analysis, the SPSS (IBM, Chicago, IL, USA) version 23.0 was used. Descriptive analyses such as frequencies, percentages, mean and standard deviation, and median and interquartile range (IQR) were carried out to analyze the descriptive characteristics of the sample for the study variables. Multi-item scores were computed by calculating the mean of the items in each scale. All the study variables were divided in low/high rate for the variable. The central point (=3) of the rating scale was considered as the cut-off criteria: the values  $\leq 3$  were rated as 0 (low) and those  $\geq 3$  were rated as 1 (high). Mann-Whitney *U* and Pearson chi-square ( $\chi^2$ ) tests were performed to compare sub-groups of the sample by discriminating for work context (frontline/non-frontline) and for presence/absence of patients who died of COVID-19. Frequencies and percentages for the variables regarding the work history (working geographical area, working area, and professional tenure) and demographic characteristics (gender, age, civil status, and children) of the participants, were compared to detect possible differences between groups. Also, we explored differences between groups of age ( $\leq 45$  and  $> 45$  years old), family status (single, conjugate, divorced, widower, and other), work geographical area (North-Center and South-Islands), and work context (frontline/non frontline) with regard to social ostracism (low/high), non-working concerns (low/high), concern for friends (non-worried/worried), concern for colleagues (non-worried/worried), concern for patients (non-worried/worried). Cut-off for age was defined based on sample distribution in percentiles, namely considering all the individuals who were below and above the 50<sup>th</sup> percentile. Crying at work, ruminations, and perceived stress were identified as potential risk outcomes for health among nurses. Perceived impact, preparedness for the pandemic, and worries were considered as main risk factors. To analyze the risk factors on health outcomes, multiple binary logistic regression was carried out by reporting odds ratios (ORs) and 95% Confidence Intervals (CI). The model was adjusted for gender, age, frontline/non-frontline nurse, and caring/non-caring for patients who died of COVID-19. These variables were considered as potential confounders. The significance level was set at  $p = 0.05$ .

About the instrument reliability, Cronbach's alpha coefficients for RHS preparedness was 0.80, for non-work-related concerns was 0.66, for increased job demands was 0.74, and for perceived impact on personal life was 0.74. Inter-item correlations were all significant at  $p < 0.001$ . Specifically, inter-item correlation

for fear of getting sick with COVID-19 was 0.37, for rumination about the pandemic was 0.76, and for crying at work was 0.52.

## RESULTS

A total of 894 nurses completed the questionnaire. However, 34 nurses who were not actively at work at the time of the study had to be excluded from it. Thus, the final sample for this study consisted of 860 nurses, most of whom were women (77.7%, *n* = 668). Regarding age, the larger proportion ranged from 50 to 59 years (32%, *n* = 275). The majority of respondents worked in southern Italy or on one of the Islands (60.3%, *n* = 519), had an average professional tenure of 18.5 years (SD = 11.6), worked in hospital context (79.5%, *n* = 684), had children (51.6%, *n* = 444), and was married (43.7%, *n* = 376). Furthermore, 44.3% (*n* = 381) were frontline nurses working in a COVID-19 emergency unit. Finally, 32.7% of nurses (*n* = 281) attended training courses and 17.2% (*n* = 148) attended audits on infection control in the 6 months before the pandemic; 26.7% (*n* = 230)

purchased personal protective equipment; 34.7% (*n* = 298) cared for patients who died of COVID-19.

## Nurses' Descriptive and Job Characteristics

Tables 1, 2 show both the demographic and the job characteristics of the sample. We split the sample into frontline/non-frontline nurses and caring/non-caring for patients who died of COVID-2019. Specifically, Table 1 shows significant differences between frontline and non-frontline nurses for all the variables in the analysis (Gender:  $\chi^2 = 6.06$ ,  $p = 0.014$ ; Median age: Mann–Whitney  $U = 74.26$ ,  $p < 0.001$ ; Age range:  $\chi^2 = 29.03$ ,  $p < 0.001$ ; Working geographical area:  $\chi^2 = 66.09$ ,  $p < 0.001$ ; Civil status:  $\chi^2 = 13.45$ ,  $p = 0.009$ ; Children:  $\chi^2 = 5.25$ ,  $p < 0.022$ ; Working area:  $\chi^2 = 70.06$ ,  $p < 0.001$ ; Professional tenure: Mann–Whitney  $U = 78.68$ ,  $p = 0.001$ ). Table 2 shows significant differences between nurses who cared and those who did not care for

patients who died of COVID-2019 for age (Median age: Mann–Whitney  $U = 68.04$ ,  $p < 0.001$ ; Age range:  $\chi^2 = 22.42$ ,  $p < 0.001$ ), working geographical area ( $\chi^2 = 173.20$ ,  $p < 0.001$ ), working area ( $\chi^2 = 46.40$ ,  $p < 0.001$ ), and professional tenure (Mann–Whitney  $U = 70.65$ ,  $p < 0.001$ ).

## Worries, Preparedness, and Perceived Impact of the COVID-19 Pandemic

Regarding worries about the pandemic, 73.3% ( $n = 630$ ) of nurses was afraid of getting sick with COVID-19, and 73.7% ( $n = 634$ ) was concerned about putting their family at risk of getting infected. Regarding nurses' preparedness, 79.9% ( $n = 687$ ) of respondents did not feel prepared for the pandemic. In fact, a small percentage (18.3%,  $n = 157$ ) of the sample declared to have received adequate training regarding COVID-19, and 34.3% ( $n = 295$ ) referred to have received adequate training and support on personal protective equipment (PPE). Ninety-three percent ( $n = 799$ ) of nurses referred that their organization was not prepared for COVID-19 pandemic, and 91.0% ( $n = 783$ ) felt that the RHS was not prepared for the pandemic. Seven hundred seventy-nine (90.6%) participants declared that RHS did not inform them about the pandemic management plan.

With regard to the perceived impact of the pandemic on job duties, 46.2% ( $n = 397$ ) of nurses referred increased job demands, and 39.2% ( $n = 337$ ) declared to have carried out tasks outside of their daily duties. Regarding the perceived impact on personal life, 25.0% ( $n = 215$ ) of the participants referred to have been avoided by other people because of their job; 12.2% ( $n = 105$ ) declared that their families were avoided as well because of their job; 8.8% ( $n = 76$ ) referred to avoid telling people about the nature of their job. With regard to non-work-related worries, 63.5% ( $n = 546$ ) of nurses felt that their job would cause their loved ones to run a high risk of COVID-19 infection; 72% ( $n = 619$ ) of nurses reported that their own health was a cause of worry for their loved ones, and 56.0% ( $n = 482$ ) reported that their loved ones were worried to be infected by them. Moreover, results highlight that nurses were fairly concerned for their close friends (29.3%,  $n = 252$ ), for their colleagues (38.1%,  $n = 328$ ), and for their patients (28.5%,  $n = 245$ ). They were very concerned for their partner (25.6%,  $n = 220$ ) and extremely concerned for their children (21.4%,  $n = 184$ ), parents (35.3%,  $n = 304$ ), and old relatives (31.2%,  $n = 268$ ). Regarding health results, 66.0% ( $n = 568$ ) of the participants felt more stressed because of the pandemic, 44.0% ( $n = 378$ ) declared to have a high level of rumination about the pandemic, 19.9% ( $n = 171$ ) referred to have cried at work, and 34.5% ( $n = 296$ ) reported to have watched colleagues crying at work. Furthermore, we compared the study variables discriminating by age, family status, region, and working context. Regarding differences between age ranges, the results showed that young nurses perceived higher non-work-related concerns about infecting family members (79.5%) than elderly nurses (67.8%) ( $\chi^2 = 15.07$ ,  $p < 0.001$ ). Moreover, younger nurses were more worried for both their colleagues' health (79.1%) and their patients' health (84.0%) ( $\chi^2 = 9.70$ ,  $p < 0.01$ ) than older nurses (69.7 and 77.3%, respectively) ( $\chi^2 = 5.76$ ,  $p < 0.05$ ). Regarding differences in terms of family status, single

and divorced nurses are more worried for their friends (73.4 and 61.8%, respectively) ( $\chi^2 = 22.86$ ,  $p < 0.001$ ) and colleagues (80.5 and 75.8%, respectively) ( $\chi^2 = 14.99$ ,  $p < 0.01$ ) than nurses with a different family status (conjugate, widower, and other). Regarding work context, frontline nurses registered higher levels of perceived ostracism (16%) than non-frontline nurses (10.6%) ( $\chi^2 = 5.39$ ,  $p < 0.05$ ), and higher non-work-related worries (78.0 and 70.4%, respectively) ( $\chi^2 = 6.32$ ,  $p < 0.05$ ). No significant differences were found between nurses working in different geographical areas (North-Center and South-Islands) for the study variables.

## Relationships Between Worries, Preparedness, and Perceived Impact of the Pandemic on Health Results

Table 3 presents the results of multivariate analyses. Three binary logistic regression models were performed: the demographic variables included gender, age, frontline/non-frontline nurse, and caring/non-caring for patients who died of COVID-19. The first model included perceived job stress as a dependent variable. The results showed that increased job stress was significantly related to a higher level of rumination (OR = 4.04, 95% CI = 2.77–5.89, and  $p < 0.001$ ), increased job demand (OR = 2.00, 95% CI = 1.38–2.90, and  $p < 0.001$ ), impact on one's job role (OR = 2.56, 95% CI = 1.74–3.77, and  $p < 0.001$ ), watching coworkers crying at work (OR = 1.50, 95% CI = 1.01–2.22, and  $p < 0.05$ ), non-work-related concerns (OR = 2.28, 95% CI = 1.54–3.38,  $p < 0.001$ ), and worry about getting infected (OR = 2.05, 95% CI = 1.39–3.01, and  $p < 0.001$ ). Among control variables, gender was significantly associated with job stress (OR = 1.71, 95% CI = 1.14–2.56, and  $p < 0.05$ ). Specifically, women are more vulnerable to higher levels of stress. Age, caring for patients who died of COVID-19, and being a frontline nurse did not affect perceived job stress. The second regression model included crying at work as a health outcome for nurses. The results showed that increased job stress (OR = 2.52, 95% CI = 1.39–4.56, and  $p < 0.01$ ), rumination on pandemic (OR = 2.28, 95% CI = 1.48–3.51, and  $p < 0.001$ ), and watching colleagues crying at work (OR = 7.92, 95% CI = 5.16–12.16, and  $p < 0.001$ ) were the predictors significantly associated with crying at work. Among the demographic variables, gender was significantly associated with crying at work (OR = 4.61, 95% CI = 2.40–8.86, and  $p < 0.001$ ): females were used as a referral for the regression analysis as well, and the results show that women cry more than men. The third model included rumination on the pandemic as a dependent variable. The results showed that higher levels of rumination were associated with caring for patients who died of COVID-19 (OR = 1.54, 95% CI = 1.07–2.21, and  $p < 0.05$ ), increased job demand (OR = 1.70, 95% CI = 1.25–2.33, and  $p < 0.01$ ), watching colleagues crying at work (OR = 1.81, 95% CI = 1.32–2.48, and  $p < 0.001$ ), non-work-related worries (OR = 1.57, 95% CI = 1.08–2.30, and  $p < 0.05$ ), and worries about getting infected (OR = 2.02, 95% CI = 1.39–2.93, and  $p < 0.001$ ). Gender and age were both significant (OR = 1.45, 95% CI = 1.01–2.07, and  $p < 0.05$ ; OR = 1.32, 95% CI = 1.16–1.50, and  $p < 0.001$ , respectively). Regarding gender, women are more inclined

to rumination than men. Regarding age, older nurses are more ruminative than younger ones.

## DISCUSSION

Investigating HCWs' perceived impact and worries on the COVID-19 pandemic is crucial to safeguard professionals' mental health.

The results showed that younger nurses reported higher worries about infecting their family members than older nurses, as well as higher worries about their colleagues and patients' health. Therefore, as a result of this emotional state, younger nurses might be at greater risk for developing stress (13), thus suggesting healthcare organization should pay attention to safeguarding young nurses during this pandemic. Moreover, frontline nurses perceived higher levels of perceived ostracism than non-frontline nurses due to their close contact with patients affected by the virus and high worries about infecting their families and loved ones. Stigmatization and ostracism are aspects that also emerged in recent studies (11, 32) and previous outbreaks (27). These factors emerged to be negatively related to nurses' mental health and stress (33).

With regard to the perceived impact of the COVID-19 pandemic on job duties, 46% of nurses reported increased job demands during the emergency. This aligns with literature that emphasized augmented workload during pandemics (34). Regarding the perceived impact on personal life, about 46% of nurses reported that people avoided them or their families because of their job. This is quite consistent with a previous study developed during the SARS virus in which health care providers experienced discrimination during the epidemic (28). As to non-work-related worries, 64% of nurses were concerned

about putting their loved ones' life at risk. Analogously with previous studies (35), they were mostly worried about their partner, children, parents, and old relatives. Thus, ensuring quarantine to professionals who work with COVID-19 patients would be important to strengthen safety-feeling among nurses. Previous studies showed that the main emotional response to the epidemic/pandemic is increased job stress (36, 37). Our findings support those results by revealing that 66% of nurses perceived high level of stress. In addition, 44.0% of the Italian nurse sample declared to have had higher levels of ruminative thinking about the pandemic. Although there is no study on rumination in HCWs during outbreaks/pandemics, literature shows that rumination is associated with greater burnout, depression, and risk of psychiatric morbidity (38). Rumination is a frequent automatic and passive cognitive activity: people with ruminative thinking tend to remain fixated on the problems without taking action (39). As a result, this dysfunctional response style may compromise emotional processes and negatively influence nurses' mental health (40), as well as hindering an individual's goal achievement (41). About 20% of nurses stated to have cried at work, and 34% declared to have watched their colleagues crying. Crying is a signal that typically communicates emotional distress and is an important symptom that indicates the difficulty to manage work-related emotional pressures (42). For this reason, crying should be considered as a sign of nurses' mental health.

The analysis of the relationship between variables on the three health outcomes (job stress, crying at work, and rumination) showed that worries about getting infected, increased job demand, impact on job role, non-work-related worries, watching colleagues crying, and ruminative thinking were significantly associated with perceived job stress. Moreover, rumination,

job stress, and watching colleagues crying were the risk factors associated with crying at work among nurses. Finally, job demands, non-work-related worries, worries about getting infected, and watching colleagues crying were the main factors associated with rumination about the pandemic. Overall, these results are in line with previous research showing that HCWs experienced increased stress through infectious epidemics (34, 43). According to these studies, we found that worries about falling ill with COVID-19 and putting nurses' loved ones at risk were the main sources of stress. Although, in line with previous research (34, 43), this study showed that the impact of the pandemic on personal life (social ostracism), personal preparedness, RHS and workplace preparedness, and adequate support and information about PPE are important safety aspects for nurses which are not significantly associated with health outcomes. They could likely have an indirect effect on health outcomes, but worries are the main factor that may affect nurses' perceived effectiveness in the pandemic. As a result, pandemics increases nurses' workload due to the increased number of patients to care for, prolonged working hours, and working on tasks that they normally do not perform (27, 44), thus increasing perceived job stress. In addition, the important demands that nurses have to face during the pandemic usually add further emotional requests. Continuous exposure to patients' death and suffering can lead to vicarious trauma and secondary traumatic stress (12, 45). Furthermore, our study shows that crying at work is associated with higher levels of job stress and rumination about the pandemic. This can be due to excessive demands and emotional pressures (42, 46) perceived by nurses during the pandemic. Very interesting is also the role of emotional contagion in watching colleagues crying at work, which would result in a worsening of the symptoms probably due to the shared psychological environment. Finally, increased job stress is associated with rumination about the COVID-19 pandemic, whose main factors are job demands, working and non-work-related concerns, and watching colleagues crying at work. Previous research suggests that person-directed interventions such as cognitive behavioral therapy and relaxation exercises would effectively decrease ruminative thinking (38, 47) and protect nurses' wellbeing. Among covariates, our findings show no difference between frontline or non-frontline nurses in terms of health results. Therefore, although previous studies on epidemics (SARS) paid attention especially to frontline HCWs as professionals at risk of developing traumatic stress (36, 48), in this study we found that being a frontline nurse is not a significant health risk factor. This suggests that the mental health of all professionals from any clinical-care context is at risk during the pandemic. In fact, a recent study on COVID-19 pandemic emphasized that non-frontline workers were more exposed to the risk of vicarious traumatization (12), probably because of inadequately trained to manage emergencies like epidemics/pandemics. On the contrary, gender was the only demographic variable we found to be significantly associated with all three health outcomes. This is likely due to the fact that the nursing profession is mainly female and 78% of our sample included women. Moreover, gender was highly associated with crying at work due probably to the fact that women usually cry more than men (49).

Lastly, age and caring/non-caring for patients who died of COVID-19 were both significantly associated only with rumination. Regarding age range, our results showed no significant difference in rumination, although it would seem that ruminative thinking increases as age progresses. However, given the contrasting results on the matter presented in literature, it remains unclear how age affects rumination (50). Regarding caring/non-caring for patients who died of COVID-19, the results show that nurses with experience of dead patients had higher levels of rumination. Therefore, nurses may perceive the death of patients whom they cared for during the pandemic as a strong emotional experience that adds excessive pressure, thus leading to rumination.

## Limitation and Future Research

This study presents a few limitations that may be addressed in further research. Firstly, the online system used to collect data may have determined a sampling bias due to the random selection of participants. In this sense, our sample might not be representative of the nursing population and generalizability should be done with caution. A stratified survey would reduce sampling errors and enhance the external validity of studies (51). Secondly, this study lacks longitudinal study design. We carried out a cross-sectional study that does not allow for causal connections between variables (52). While our results are overall consistent with previous studies on epidemics/pandemics, future studies should test long-term effects of the COVID-19 pandemic on nurses' health outcomes. Thirdly, we used a self-administrated questionnaire that has limitations in terms of rating bias. Nevertheless, the health outcomes analyzed in this study (job stress, crying, and rumination) are based on the perception of a discomfort at work during a pandemic. In this sense, self-report questionnaires are adequate instruments to collect perception data. Finally, we chose measure some variables with one item. We are aware that multi-item psychometric scales are more reliable in assuring content validity. Nevertheless, single-item scales can be a good compromise between practical needs and psychometric concerns (53), especially when emergency situations like the pandemics demand to reduce the time needed to complete the survey. Fourthly, we measured some variables by using single items in order to complete the survey in <10 min. This choice was due to the period of high emergency in which the study was conducted (in the middle of the first COVID-19 wave in Italy), such that it was necessary to collect data promptly without cognitively overloading the workers. Although the choice to use single items is questioned as multiple-item scales tend to be more reliable and ensure content validity, it is generally agreed that single-item measures provide an acceptable balance between practical needs and psychometric concerns. They are usually used in occupational health studies and are considered to be reliable (54). Finally, the main measures used in our study were adapted from a previous instrument developed during SARS outbreak. Our study was carried out during the early phase of the pandemic and there was not sufficient time to develop and validate new scales. In this sense, we decided to use a reliable measure from previous studies. However, new scales were developed in the last months and future research could examine the validity of these measures.

## Practical Implications for Nurses' Health

Despite the limitations, this study can have important implications for nurses. Nurses' work-related and non-work-related worries about the pandemic could affect their overall effectiveness at work. Therefore, these concerns should be addressed by devising effective preventive strategies to avoid prolonged consequences in terms of mental health. Among the interventions to reduce nurses' worries, providing a place where they can temporarily isolate themselves from their family (55) may be an effective strategy. In addition, as stress theory revealed (56, 57), workload represents a crucial stressor for professionals. It should thus be reduced by increasing human resources and providing organizational support to limit the negative impact in terms of stress and rumination. Moreover, as crying at work is associated with both higher levels of job stress and rumination, due probably to excessive demands and emotional pressures during the pandemic, health organizations should implement actions to reduce stress and foster psychological support especially for nurses with inadequate training in emotion regulation labor. Finally, as rumination is associated with a number of stress-related disorders, it would be important to reduce ruminative thinking about the pandemic through coping strategies which help nurses to recover during leisure time and reduce job stress (58).

## CONCLUSIONS

The psychological impact that the COVID-19 pandemic may cause in the medium/long term could be greater than the economic one. This is the main challenge that health organizations will have to face in the future: in fact, we are currently experiencing the third wave of this outbreak. In this phase, it is crucial that decision-makers develop awareness of the impact of this pandemic on nurses' mental health and promptly implement regional and national interventions to lessen the risk of developing depressive symptoms and post-traumatic stress disorders.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors upon reasonable request.

## ETHICS STATEMENT

The study complies with the Declaration of Helsinki and with the General Data Protection Regulation (EU) 2016/679 (GDPR). Participation was voluntary and anonymous, according to Italian Data protection law (e.g., Decree n. 196/2003). Participants could interrupt their participation in the survey at any time without any adverse consequence. We consulted the Institutional Review Boards of the University of Cagliari, which informally said that Ethical review and approval was not required for the study on human participants, in accordance with the local legislation and institutional requirements.

## AUTHOR CONTRIBUTIONS

MG, IPi, and IPo conceived and designed the study, collected, analyzed and interpreted the data, and drafted the manuscript. FM analyzed the data, edited, and revised the manuscript. GE, ED'A, PC, and MC edited and revised the manuscript critically. All authors approved the final version of the manuscript.

## ACKNOWLEDGMENTS

We would like to thank all the Italian nurses who participated in this study. A special thanks goes to the Vice President of the Nursing Profession Order of La Spezia (Italy) Francesco Falli and the Vice President of the National Association of Critical Area Nurses (ANIARTI) Gaetano Romigi for their precious collaboration on data collection.

Major global public health emergencies challenge public mental health. Negative emotions, and especially fear, may endanger social stability. To better cope with epidemics and pandemics, early emotional guidance should be provided based on an understanding of the status of public emotions in the given circumstances. From January 27 to February 11, 2020 (during which the cases of COVID-19 were increasing), a national online survey of the Chinese public was conducted. A total of 132,482 respondents completed a bespoke questionnaire, the Emotion Regulation Questionnaire, and the Berkeley Expressivity Questionnaire (BEQ). Results showed that at the early stage of the COVID-19 epidemic, 53.0% of the Chinese population reported varying degrees of fear, mostly mild. As seen from regression analysis, for individuals who were unmarried and with a relatively higher educational level, living in city or area with fewer confirmed cases, cognitive reappraisal, positive expressivity and negative inhibition were the protective factors of fear. For participants being of older age, female, a patient or medical staff member, risk perception, negative expressivity, positive impulse strength and negative impulse strength were the risk factors for fear. The levels of fear and avoidant behavior tendencies were risk factors for disturbed physical function. Structural equation modeling suggested that fear emotion had a mediation between risk perception and escape behavior and physical function disturbance. The findings help to reveal the public emotional status at the early stage of the pandemic based on a large Chinese sample, allowing targeting of the groups that most need emotional guidance under crisis. Findings also provide evidence of the need for psychological assistance in future major public health emergencies.

**Keywords:** COVID-19, Chinese population, fear, pandemic, mental health

## INTRODUCTION

Major public health emergencies have a profoundly negative influence on public health, which not only seriously threatens the life safety of the public, but also brings huge psychological impact to the population. The COVID-19 pandemic occurred at the beginning of 2020. The World Health Organization announced that COVID-19 is a “worldwide public health emergency” on the 30th of

Chen B, Sun X, Xie F, Zhang M, Shen S, Chen Z, Yuan Y, Shi P, Qin X, Liu Y, Wang Y and Dai Q (2021) Fear in the Chinese Population: Influential Patterns in the Early Stage of the COVID-19 Pandemic. *Front. Psychol.* 12:567364. doi: 10.3389/fpsyg.2021.567364

January 2020. By the end of May 2020, there were more than 5 million confirmed cases worldwide, with about 347 thousand losing their lives because of infection. As a result, the global social stability has been significantly endangered.

Fear is an instinctive emotional response in human beings when facing life-threatening events. During an epidemic, fear is potentially adaptive or protective for the individual (McEwen, 2007). However, over-generated fear might endanger physical function and produce negative behavioral reactions, which will have adverse effects on people's mental health, quality of life and social stability (Su and Wei, 2005). During the Ebola outbreak in West Africa from 2013 to 2016, behaviors caused by fear were significant throughout the outbreak, leading to an increase in virus transmission, interference with effective treatment, and indirect mortality from non-Ebola diseases (Shultz et al., 2016). During the Ebola epidemic in 2016, a survey in Guangzhou of China, a city with a large number of African immigrants, showed that 31% of students reported negative emotions, such as panic, fear, and worry (Lau et al., 2016). During the SARS epidemic in 2003, as people became more aware of the seriousness of SARS, there was widespread panic and fear of going out (Wang and Luo, 2003). In the Taiwan region, fear seriously affected people's daily lives, and there was evidence that the underground passenger flow reduced by 1,200 people for each new case (Wang, 2014). The spread of fear may lead to disturbances in physical health, e.g., during the SARS period, a student showed fever symptoms, and then 15 classmates in the same class consequently developed into fever symptoms, which was diagnosed as a mass hysteria caused by the "SARS" panic after investigation (Pu et al., 2003). These results highlighted the importance of fear during epidemics. However, there is a lack of investigations using large samples into the early public fear response during health outbreaks. Such research would be of great value in informing the development of targeted psychological interventions and providing effective psychological guidance.

Under crisis, many factors might influence the emotion of personal fear. Risk perception refers to people's feelings and understanding about the potential risks affecting daily life, and is also an index of public panic (Sitkin and Pablo, 1992; Sitkin and Weingart, 1995). Individuals with higher risk perceptions are more likely to develop irrational tension or panic (Shi et al., 2003). For example, during the H1N1 pandemic outbreak in 2009, people who considered the severity and susceptibility of the pandemic to be higher and who concerned whether the government was well prepared were more likely to be depressed than others (Lau et al., 2010). Relatively, reasonable perception of the risks guaranteed adequate health-seeking behavior (Lau et al., 2005). However, excessive risk perception may lead to escape behaviors (Jiang et al., 2009). These results confirmed the effect of risk perception on personal emotion. However, during the current COVID-19 outbreak, it is not clear whether risk perception is a risk predictor of fear, which is important for the provision of early emotional guidance.

Emotional regulation strategies refer to the processes through which individuals exert influence on the occurrence, expression, and perception of emotions. This important coping style affects the outcome of negative events. Cognitive reappraisal and

expressive suppression are two emotional regulation mechanisms that directly influence individual emotions (Ciuluvica et al., 2019). Cognitive reappraisal occurs early in the emotion-generative process and expressive suppression occurs late in the emotion-generative process (John and Gross, 2007; Cheng et al., 2009). Researchers (Gross and John, 2003) pointed out that cognitive reappraisal allows an individual to re-explain an event and change its effect on emotions. It had been reported that cognitive reappraisal could reduce negative emotions effectively (Kobayashi et al., 2020), while the effect of expressive suppression was weaker. Gross also pointed out that emotional expressivity is a kind of regulation strategy opposite to expressivity suppression, which has a unique influence on emotions, related to negative emotion and mental health problems (Gross and John, 1995). But, it had also been pointed out that the effect of expression suppression on individual emotion regulation was different in different cultural backgrounds (Liu et al., 2016). For example, in the western culture, expressivity suppression usually played a negative role (Boekaerts and Monique, 2013); while in the eastern culture, expressivity suppression may played a positive role (Dou et al., 2013). A study of Chinese college students confirmed that, expressive suppression was as effective as cognitive reappraisal in down-regulating the intensity of experienced negative emotion, and expressive suppression dampens negative emotion more quickly than cognitive reappraisal in Chinese individuals (Yuan et al., 2015). However, previous researchers have usually observed the effect of emotion regulation strategies on emotion broadly, while the protective or risk effects of different types of emotional regulation strategies on different types of emotion, and especially fear during a crisis, have not been systematically revealed.

When fear emotions persist, behavior patterns change. Studies have shown that fear emotion was related to increased avoidant behaviors (Barr et al., 2008; Smith et al., 2009). For example, during the SARS epidemic, some Taiwan nurses (especially married nurses), applied for resignation, and exhibited higher risk perceptions and stronger fear (Chong et al., 2004). Furthermore, people who were depressed during the H1N1 pandemic were more likely to take avoidant action (Lau et al., 2010). These results suggest that negative emotions might increase the avoidant behaviors.

The experience of intense or long-term stress can disrupt personal physical functions, such as loss of appetite, indigestion difficulties, and sleep problems (Chen, 2004). It has been reported that psychological responses, in particular, negative emotions including fear and depression are correlated with sleep disturbance (Zhang et al., 2003). Moreover, people's diet behavior is influenced by emotional arousal, including fear and anger (Canetti et al., 2002). Among which, fear may lead to diet disturbance in young adult and adolescents (Anderson et al., 2018), as well as resulting in greater sleep disturbance (Fidel et al., 2018). These results suggest that negative psychological responses, especially fear, closely correlate with physical disturbance.

Previously, Myer raised a triage assessment system (TAS) for crisis circumstances. The TAS assesses personal affective, behavioral, and cognitive reactions toward crisis events (Myer and Conte, 2006). However, the TAS does not include the

evaluation of physical function, which is also an important index of the acute stress response (Milligen et al., 2020). In Tong's stress response model, panic is the most important factor in the acute stress response, followed by a defense response, and cognition of the outbreak (Tong, 2004). However, what is the relationship between fear and risk factors, avoidant behaviors, and physical disturbance? Does fear bridge a role between them? What kind of risk factors predict fear? Does fear predict avoidant behaviors and physical disturbance? The answers to these questions remain largely unknown but are crucial for the development of psychological support programs for future crises.

In the face of negative events, personal psychological responses interact with each other, and this might also be influenced by demographic variables such as gender. Many studies have shown a significant correlation between gender and fear (Egbor and Akpata, 2014; Kazancioglu et al., 2015), for example, a study showed that women are more dental surgical fear than men (Mohammed et al., 2014). It has also been reported that fear is more common in young patients (Appukkuttan et al., 2015), and has a significant inverse relationship with the age of individuals (Egbor and Akpata, 2014). However, these results have been inconsistent, with evidence of higher levels of fear in older patients (Beatriz et al., 2015). In terms of marital status, there are significant differences in the scores for fear among married, unmarried, divorced, and widowed patients (Egbor and Akpata, 2014). In China, the study of fear in the recurrence of gynecologic tumors has shown that many factors, such as age, marital status, and educational level, have direct and indirect effects on fear (Qi et al., 2016; Meng et al., 2019). These results confirm the potential prediction of demographic factors relating to fear during epidemics. However, which factors are protective and which are risky remains unclear.

In sum, this study aimed to observe the status of fear in the Chinese population during the increasing stages of the COVID-19 pandemic. The trend over time, predictors from demographic variables (gender, age, degree of education, marital status, person type, and confirmed cases in city or area) and psychological variables (risk perception and emotional regulation), and the relationship with avoidant behavior tendencies and disturbed physical function, were explored through a national online investigation. Our hypotheses were: (1) Chinese people may experience fear at an early stage in the COVID-19 pandemic, and the level of fear might gradually decrease along with time; (2) demographic factors, such as gender, age, degree of education, marital status, person type, confirmed cases in city or area, might be related to the level of fear, among them, being female, older age and higher education level may increase the fear emotion, and being unmarried and having fewer confirmed cases may decrease the fear emotion; (3) risk perception and negative expressivity might increase fear emotion, while cognitive reappraisal, expressive suppression, positive expressivity, and negative inhibition might decrease fear emotion; (4) fear might increase avoidant behaviors and disturbed physical function; and (5) fear might have a bridging role between risk perception, avoidant behavior tendencies, and physical disturbance.

## MATERIALS AND METHODS

### Participants

Individuals in the Chinese population aged between 18 and 75 years old, who could read and write Chinese, and were able to access a computer or smartphone with internet, were eligible for this online national investigation conducted between January 27 and February 11, 2020. Questionnaire with incomplete and invalid answers were excluded from the formal analysis. From the 135,458 collected questionnaires, 132,482 questionnaires were effective. This included 129,190 participants (97.52%) from the general population, 3,025 participants (2.28%) classified as medical staff member, 95 (0.07%) confirmed patients, 93 (0.07%) suspected patients, 36 (0.03%) recovered patients, and 43 (0.03%) family members of patients. There were more women (55.1%) than men (44.9%) and 74.8% were aged 20-49 years old. The lower education level (middle school or lower) was 56.5, and 52.8% of the population were married, and 54.5% had experienced outbreaks such as SARS. According to the confirmed cases in the city or area, respondents from cities with >10,000 cases accounted for 3.1% of the overall sample.

### Instruments

Based on previous literature and mature questionnaire at home and abroad (Chen et al., 2003; Shi et al., 2003; Wang and Luo, 2003), a self-designed questionnaire was developed by the authors, which comprised of demographic variables, fear emotion, cognitive sources of fear, risk perception section, avoidant behavior tendency section, and disturbed physical function section.

### Demographic Variables

General information: Basic demographic characteristics, including gender, age, degree of education (middle school or lower, high school, college, and postgraduate degree or higher), marital status (married, unmarried, divorced, and widowed), person type (general population, confirmed patients, suspected patients, recovered patients, family members of patients, and medical staff member), confirmed cases in city or area (>10,000 cases, 1,000–10,000 cases, 500–1,000 cases, 100–500 cases, and <100 cases) and whether the respondent had previously experienced an outbreak such as SARS, were collected.

### Psychological Factors

Fear emotion: one question with five options (none, mild, moderate, severe, extremely and severe/unbearable) was presented: "How much fear do you feel today?"

Cognitive sources of public fear: to explore possible cognitive sources of public fear, 14 questions were presented (with yes or no response options) relating to fear: being infected by the virus, the possibility of people being infected without isolation, new confirmed cases, death after infection, shortage of protective supplies, the possibility of people being infected without protection, death number, disrupted work or study after the pandemic, new foci, new suspected cases, insufficient cooperation of patients, being isolated due to the pandemic,

insufficient duty by medical staff members, and others. The C. Hoyt's reliability  $r$  was 0.251 in this study.

**Risk perception:** to measure people's risk perception during the pandemic, three questions were presented (with yes or no response options): "This is a severe outbreak," "The pandemic is close to me," "I am in danger." Exploratory factor analysis [EFA, principal axis factoring (PAF)] and reliability analysis showed that the KMO of the scale was 0.622, accounting for 57.94% of the total variance and Cronbach's alpha was 0.635.

**Avoidant behavior tendencies:** To measure potential avoidant behavior tendencies during the pandemic, three questions were presented (with yes or no response options): "I am intending to run away if possible," "To escape isolation, I might not go to hospital if I am a suspected case," "To protect myself and families, I might quit the job if I am medical staff member." The KMO of this scale was 0.687, accounting for 77.88% of the total variance, and Cronbach's alpha was 0.857.

**Disturbed physical function:** to observe potential disturbed physical health under pandemic, three questions were presented (with yes or no response options): "Within the past week, I cannot keep regular schedule as usual," "Within the past week, I cannot eat well as usual," "Within the past week, I cannot sleep well as usual." The KMO of this scale was 0.602, accounting for 56.20% of the total variance, and Cronbach's alpha was 0.607.

**Emotional regulation strategies:** the Emotion Regulation Questionnaire consisting of (ERQ) 10 items was used (Gross and John, 2003) as translated into Chinese (Wang et al., 2007). High scores indicate higher cognitive reappraisal and expressive suppression, respectively. Cronbach's alpha coefficient was 0.827 for cognitive reappraisal and 0.714 for expressive suppression in this study.

The Berkeley Expressivity Questionnaire (BEQ; Gross and John, 1995) was used to assess personal emotional expression. The Chinese version of BEQ comprises 16 items and five subscales (Zhao et al., 2015): positive expressivity, negative expressivity, negative inhibition, positive impulse strength, and negative impulse strength. The Cronbach's alpha coefficient was 0.834 in this study.

## Procedures

Questions were listed in an online questionnaire, which was screened and approved by the Human Research Ethics Committee of the Army Medical University of China and Wenjuanxing online platform<sup>1</sup> which providing functions equivalent to Amazon Mechanical Turk. After click-signing on an online informed consent form, individuals completed the questionnaire through an online link. The target population was the individuals under the pandemic (except special careers, such as medical workers, police, military, etc.). The questionnaire included variables about demographic information and psychological factors (fear emotion, sources of fear, risk perception, avoidant behavior tendency, disturbed physical function, emotional regulation, and emotional expressivity).

## Statistical Analysis

$T$ -test and one-way ANOVA were conducted to explore the demographic characteristics of fear.  $t$ -test analyze was carried out to analyze the relationship between risk perception, emotional regulation strategies, and fear.  $\chi^2$  test was carried out to observe the effects of fear emotion on avoidant behavior tendencies

<sup>1</sup>www.wjx.top

and disturbed physical function. Stratified linear hierarchical regression analysis was carried out to observe the predictors of fear emotion, in which demographic variables were put as first layer, and psychological factors were second layer. Linear regression analysis was also carried out to observe the prediction of fear emotion on disturbed physical function. Structural equation model was carried out with AMOS 24.0 to test the direct and mediating effect of fear emotion on avoidant behavior

tendencies and disturbed physical function. Evidence of model fit was determined according to standard interpretations of the fit indices, including CFI values of at least .950, and an RMSEA no greater than .080 (Hu and Bentler, 1999). Bootstrap tests (2,000 repeated samples and 95% confidence interval) were used to test the significance of the mediating effect (Baron and Kenny, 1986), with 95% CI did not contain 0 indicating a significant mediating effect.

**TABLE 1** | Comparison of fear in different variables ( $N = 1,32,482$ ).

Variables		$\bar{x} \pm SD$	$t/F$	$P$
Gender	Male	1.68 ± 0.80	-14.590	$P < 0.001$

Experienced an outbreak such as SARS	Yes	1.73 ± 0.81	9.84	$P < 0.001$
	No	1.69 ± 0.81		

## RESULTS

### Levels of Fear in the Chinese Population

In total, 70,207 (53.0%) of the Chinese population in this study reported different degrees of fear, with a score of  $1.71 \pm 0.81$ . Through frequency analysis, it was found that 62,275 participants (47.0%) reported not experiencing fear, 50,764 participants (38.3%) reported mild fear, 15,255 participants (11.5%) reported moderate fear, 3,404 participants (2.6%) reported severe fear, and 784 participants (0.6%) reported extremely severe fear.

### Cognitive Sources of Fear

Frequency analysis showed that the top three causes of fear were: being infected by the virus, the possibility of people being infected without isolation, and new confirmed cases (see **Figure 1**). In addition, insufficient duty by medical staff member and being isolated due to the pandemic were the bottom two reasons for fear.

### Impact of Demographic Characteristics on Fear

To observe the potential relationship between demographic characteristics and people's fear, independent  $t$ -tests and one-way ANOVAs were carried out. These found that the scores for fear differed by gender, age, degree of education, marital status, person type, city type (categorized by confirmed cases in city or area), and whether having experienced epidemic such as SARS. Higher levels of fear were found in females, people of elder age, individuals with postgraduate or higher degrees, patients and medical staff member, individuals coming from a city or area with most serious levels of pandemic and those who had experienced SARS, while unmarried people reported lowest levels of fear (see **Table 1**).

### Relationship Between Fear With Risk Perception, Avoidant Behavior Tendency, Physical Function, and Emotion Regulation Strategy

#### Impact of Risk Perception and Emotion Regulation Strategy on Fear

As can be seen from **Figure 2**, those who indicated “This is a severe outbreak,” “The pandemic is close to me” and “I am in danger” reported highest levels of fear ( $P < 0.001$ ) (for detailed values see **Supplementary Table 1**).

Through correlation analysis, we found that cognitive reappraisal ( $r = -0.010$ ,  $P < 0.001$ ) and expressive suppression

( $r = -0.018$ ,  $P < 0.001$ ) were negatively correlated with the level of fear. Positive expressivity ( $r = 0.043$ ,  $P < 0.001$ ), negative expressivity ( $r = 0.155$ ,  $P < 0.001$ ), positive impulse strength ( $r = 0.123$ ,  $P < 0.001$ ), and negative impulse strength ( $r = 0.180$ ,  $P < 0.001$ ) were positively correlated with the level of fear; and negative inhibition ( $r = -0.039$ ,  $P < 0.001$ ) were negatively correlated with the level of fear.

### Impact of Fear Emotion on Avoidant Behavior Tendency and Disturbed Physical Function

As the level of fear emotion increases, the proportion of the population “intending to run away if possible” ( $\chi^2 = 6762.34$ ,  $P < 0.001$ ,  $df = 4$ ), planning “not go to hospital if I’m suspected” ( $\chi^2 = 94.23$ ,  $P < 0.001$ ,  $df = 4$ ) and to “quit the job if I’m medical staff member” ( $\chi^2 = 118.54$ ,  $P < 0.001$ ,  $df = 4$ ) increased (see **Figure 3A**).

As expected, as the level fear increased, the disturbed physical function of the population who “cannot keep regular schedule as usual” ( $\chi^2 = 3,112.13$ ,  $P < 0.001$ ,  $df = 4$ ), who “cannot eat well as usual” ( $\chi^2 = 6219.46$ ,  $P < 0.001$ ,  $df = 4$ ) and who “cannot sleep well as usual” ( $\chi^2 = 8725.31$ ,  $P < 0.001$ ,  $df = 4$ ) increased significantly (see **Figure 3B**).

### Regression Analysis of Fear and Disturbed Physical Function

With the level of fear as the dependent variable, a stratified linear regression was conducted with demographic factors (including age, gender, marital status, degree of education, person type, and city type) and psychological factors (including risk perception

and emotional regulation) as independent variables. The results showed that among the demographic factors, being unmarried, having a relatively higher educational level (high school and college), and living in a city or area with fewer confirmed cases were protective factors of the level of fear. Being older, female, having a postgraduate or higher educational level, being a patient or medical staff member, were risk factors for fear. Among the psychosocial factors, risk perception, negative expressivity, positive impulse strength and negative impulse strength were risk factors for the level of fear, while cognitive reappraisal, positive expressivity and negative inhibition were protective factors (Adjusted  $R^2 = 0.105$ ,  $P < 0.001$ ) (see **Table 2**).

With disturbed physical function as the dependent variable, regression analysis showed that the level of fear and avoidant behavior tendencies were risk factors for disturbed physical function (Adjusted  $R^2 = 0.074$ ,  $P < 0.001$ ) (see **Table 3**).

### Mediation Analysis of Fear Emotion

Confirmatory factor analysis of risk perception, escape behavior tendency, and physical function disturbance were carried out (see **Supplementary Figure 1**), which confirmed that path coefficients for each model were significant ( $P < 0.001$ ).

To further explore the interaction between fear emotion and risk perception, avoidant behavior tendency, and physical function, a hypothesis-driven model test was carried out as **Figure 4**. The model fit showed that each index of the model was good ( $\chi^2/df = 7.65$ , GFI = 1.00, AGFI = 1.00, RMSEA = 0.007), which indicated that risk perception had a positive direct effect on fear emotion and avoidant behavior tendency, and indirect

**FIGURE 2** | The effect of risk perception on fear in Chinese population. \*\*\* $P < 0.001$ .

effect on avoidant behavior tendency (0.041, 0.04–0.043) and disturbed physical function (0.073, 0.073–0.075). Fear emotion had positive direct effect on avoidant behavior tendency and disturbed physical function, and indirect effect on disturbed

physical function (0.015, 0.014–0.017). The results indicated a positive effect of risk perception on fear emotion, and a mediation effect of fear emotion between risk perception and avoidant behavior tendency and disturbed physical function.

**FIGURE 3 |** The effect of fear on avoidant behavior tendencies and disturbed physical function in Chinese population. **(A)** The effect of fear on avoidant behavior tendencies in Chinese population. **(B)** The effect of fear on disturbed physical function in Chinese population. \*\*\* $P < 0.001$ .

## DISCUSSION

This study observed fear in the Chinese population at an early stage of the COVID-19 outbreak and its relationship with risk perception, avoidant behavior tendencies, physical function, and emotional regulation through a large sample ( $N = 1,32,482$ ) online national investigation. The findings showed that the Chinese population experienced some fear, but was not panicking during the pandemic. Being unmarried, having a relatively high educational level, living in a city or area with fewer confirmed cases, cognitive reappraisal, positive expressivity and negative inhibition were protective predictors of the level of fear. Being of older age, female, having a postgraduate or higher educational level, being a patient or medical staff member, risk perception, negative expressivity, and positive/negative impulse strength were risk predictors of the level of fear.

### Level of Fear in the Chinese Population

In this study, 53.0% of the Chinese population reported a degree of fear, indicating that fear was prevalent during the outbreak. Further analysis found that this fear was mainly mild, indicating that the Chinese population was not panicking. This finding helps the Chinese government and international organizations better understand the Chinese population's emotional status under the COVID-19 pandemic.

## Cognitive Sources of Fear in the Chinese Population

The top three sources of fear in this study were: being infected by the virus, the possibility of people being infected without isolation, and new confirmed cases. During the SARS epidemic, fear came mainly from the characteristics of SARS (strong infectivity and high risk) and the temporary lack of effective treatment (Chen et al., 2003). It can be seen that the characteristics of the disease itself (infectious and high risk) were the main source of fear in public. Findings confirmed that the main sources of fear came from both the possible influence of the pandemic on the individual, and the macro-development of a national epidemic. These findings provide suggestions to the government about required emotional guidance during the pandemic, i.e., knowledge education and information for the public.

### Influential Factors of Fear

Our study showed that there were stronger levels of fear in females and people of older age. Older participants may have experienced stronger fear due to having poorer health status and being more vulnerable to the virus. This is consistent with the fact that unmarried young people reported the lowest levels of negative emotion due to most likely having better health status in general. Individuals with postgraduate or higher degrees and people who had experienced SARS may have had stronger fear because they knew more about the dangers of viruses. As hypothesized, people from Hubei province (an area with most serious pandemic levels) reported stronger fear. As expected, patients and medical staff members reported the strongest fear, especially patients who were confirmed and suspected cases. However, recovered patients reported relatively lower fear, which was consistent with reporting regarding SARS (Tse et al., 2003). These results allow us to identify the populations that most need emotional guidance, and to focus limited psychological resources during epidemics.

In this investigation, participants who thought “This is a severe outbreak,” “The pandemic is close to me,” and “I am in danger” had higher levels of fear. This “cognitive fear” (Song et al., 2018) increased the fear levels significantly.

Therefore, early and reasonable risk perception interventions are particularly important when adjusting fear in the Chinese population. This study have shown that cognitive reappraisal, expressive suppression and negative inhibition were negatively correlated with fear emotion; while positive expressivity, negative expressivity, positive/negative impulse strength were positively correlated with fear emotion. In Chinese culture, expressive suppression was not entirely an inappropriate regulation strategy. East Asian culture emphasized avoiding hurting others and striving to maintain harmonious relationships, suppression was associated with better social functioning (Butler et al., 2007; Soto et al., 2011; Yuan et al., 2015). For example, a study of insurance workers in Hong Kong showed that the increase of suppression was associated with fewer negative emotions (Yeung and Fung, 2012). Another study showed that Asian-Americans who rated suppression as more valuable had better emotional responses to anger elicited (Mauss and Butler, 2010). Similarly, among Chinese college students, the relationship between suppression and interpersonal harmony was significantly positive (Su et al., 2012; Wei et al., 2013). Thus, when people experience fear emotion during an epidemic, they can modulate it through the selection of an emotional regulation strategy, i.e., greater cognitive reappraisal and expressive suppression and less expression are recommended.

### **Prediction of Demographic Factors and Psychological Factors for Fear**

As seen from the regression analysis, we could see that being unmarried, having a relatively high educational level, and living in a city or area with fewer confirmed cases were protective factors for fear. Being of older age, female, having studied at the postgraduate or higher educational level, being a patient or medical staff members were risk factors. After controlling for demographic factors, cognitive reappraisal, positive expressivity and negative inhibition were protective factors for fear, and risk perception, negative expressivity, and positive/negative impulse strength were risk factors. This study systematically explored the protective and risk predictors of fear taking into account demographic and psychological variables. These findings will help focus on specific populations most in need of future psychological interventions and offer further evidence to support the development of more effective psychological training programs.

### **Prediction of Fear and Avoidant Behavior Tendency on Physical Function**

We found that fear increased avoidant behavior tendencies and significantly disturbed physical function. This is consistent with a large number of studies, confirming that negative emotions are associated with a poor lifestyle, such as sleep and diet (Huang et al., 2013; Zhu et al., 2016; Cai et al., 2019; Li et al., 2019). Regression analysis indicated that the level of fear and avoidant behavior tendencies positively predicted disturbed physical function. The results suggested a bridging role of fear between risk perception, avoidant behaviors, and physical disturbance. Thus, to better maintain normal psychological and physical

function under crisis, intervention, and guidance on fear emotion is critical. Previously, the TAS for crisis intervention provided a framework for understanding clients' reactions during a crisis. This investigation broadened TAS theory through the inclusion of disturbed physical health, and helped to develop more targeted and directed early intervention to prevent these problems.

### **Limitations**

First, fear in the population was only assessed using one subjective item, and there was a lack of systematic objective evaluation. Second, there was a lack of in-depth exploration of the impact factors of fear, such as psychological resilience, coping style, and so on. Third, this was a cross-sectional study, which precludes causal conclusions. However, with a large sample that covered all provinces and areas of China, this study was sufficiently powerful to accurately reflect public fear in China during the COVID-19 pandemic. Moreover, this online investigation was carried out during the case increasing stage of the pandemic (from January 27 to February 11, 2020), which allowed clear observation regarding the trends of fear during this period.

### **CONCLUSION**

At the early stage of the epidemic, the Chinese public experienced a mild degree of fear which declined over time. Fear functions as a bridge between risk perception, avoidant behaviors, and physical disturbance. The protective factors (being unmarried, having a relatively high educational level, living in city or area with fewer confirmed cases, cognitive reappraisal, positive expressivity, and negative inhibition) and risk factors (being of older age, female, having a postgraduate or higher educational level, being a patient or medical staff member, risk perception, negative expressivity, and positive/negative impulse strength) for fear suggest that the government could establish a long-term psychological stress monitoring mechanism to grasp the psychological dynamics of the public under major emergencies in a timely way and provide effective psychological interventions. The current snapshot of public emotion offers theoretical evidence for psychological assistance and emotional guidance during a crisis, and provides suggestions as to how best to deliver psychological support in future major public health emergencies.

### **DATA AVAILABILITY STATEMENT**

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

### **ETHICS STATEMENT**

The studies involving human participants were reviewed and approved by the Human Research Ethics Committee of the Army Medical University of China and Wenjuanxing online platform (www.wjx.top). The participants provided their written informed consent to participate in the study.

## AUTHOR CONTRIBUTIONS

QD designed the study, collected the data, and reviewed and revised the manuscript. BC collected and analyzed the data and final manuscript. XS and FX assisted the data collection and contributed to the manuscript writing. MZ, SS, ZC, YY, PS, XQ, YL, and YW assisted the data collection. All authors have read and approved the submitted version.

## FUNDING

This study was supported by the Key Project of Nature Science Foundation of Chongqing (cstc2020jcyj-zdxmX0009), the Innovation Projects of People's Liberation Army of China (18CXZ005 and 17QNP008), and the Military Medical Project of Army Medical University (2019ZLX003).

The novel coronavirus disease 2019 (COVID-19) represents a massive global health crisis leading to different reactions in people. Those reactions may be adaptive or not depending on situational or psychological processes. Disordered eating attitudes and behaviors are likely to be exacerbated by the pandemic through multiple pathways as suggested by Rodgers et al. (2020). Among the psychological variables that may have increased dysfunctional eating attitudes and behaviors as a consequence of the social distancing and isolation, we looked at perfectionism. Perfectionism is a well-recognized risk and maintaining factor of eating-related symptoms and interact with stress increasing the probability of dysfunctional reactions (e.g., Wang and Li, 2017). The present study investigated the relationship between multidimensional perfectionism and eating behaviors by considering the mediating role of psychological distress. Data were collected from two countries (Italy and Spain) by means of an online survey. The samples included 465 (63.4% female) participants from Italy and 352 (68.5% female) from Spain. Participants completed the short form of the Hewitt and Flett Multidimensional Perfectionism Scale (Lombardo et al., 2021) to assess self-oriented, other-oriented and socially prescribed perfectionism, as well as the short form of Three Factors Eating Questionnaire (Karlsson et al., 2000) and the Italian version of Depression Anxiety and Stress Scale-21 (Bottesi et al., 2015), respectively used to assess restrictive, emotional and uncontrolled eating on one hand, and depression, anxiety and stress on the other. Multigroup analysis was performed to test the hypothesized model. Results showed that other-oriented and socially prescribed perfectionism were indirectly related to most of the dysfunctional eating aspects through the mediation of psychological distress, and the pattern obtained was consistent in both countries. These findings evidence that the psychological distress potentially related to the COVID-19 disease mediates the negative impact of interpersonal perfectionism and the tendency to eat in response to negative emotions.

**Keywords:** COVID-19, perfectionism, multidimensional, mediation, eating behavior, stress

## INTRODUCTION

The novel coronavirus disease 2019 pandemic (COVID-19; World Health Organization [WHO], 2020) has spread to most countries in the world and represents a massive global health crisis. To date, the number of COVID-19 patients has increased dramatically, with 4,320,946 currently positive cases in the world. Moreover, as suggested by the CDC<sup>1</sup>, governors of most

doi: 10.3389/fpsyg.2021.580943

countries ask to all citizens to adopt social distancing, quarantine and isolation as strategies for containment. According to the Stress Theory (Norris et al., 2002), public emergencies may trigger negative emotions and enhance dysfunctional cognitive beliefs, predisposing people to mental health difficulties. The COVID-19 pandemic is one of the most stressful situations for its own unpredictability and prolonged social isolation, therefore, it is crucial to understand the potential psychological outcomes influenced by this health emergency. Different reactions of people to the COVID-19 pandemic may involve their personality, as dispositional traits may shed light on people's different reactions (Blagov, 2020). Findings from personality research have highlighted that personality-related variables could profoundly change the impact of stress in challenging situations (Greene et al., 2020). Personality traits play an essential role in predicting coping strategies with emotional distress in stressful events and have significant consequences on mental health (Kessler, 1997).

One of the personality dimensions potentially implicated is perfectionism, a multidimensional personality characteristic composed by two major dimensions, namely perfectionistic strivings (i.e., incessantly demanding perfection of oneself) and perfectionistic concerns (i.e., extreme concern over mistakes and others' evaluations; see Stoeber and Otto, 2006). These two dimensions respectively reflect adaptive and maladaptive facets of perfectionism since they showed opposite associations with psychological adjustment and well-being (see Limburg et al., 2017, for a review). Hewitt and Flett (1991) developed a multidimensional model of perfectionism that distinguishes inter and intrapersonal facets reflecting both perfectionistic strivings and perfectionistic concerns. According to this model, self-oriented perfectionism (SOP), a key aspect of perfectionistic strivings, refers to the tendency to set high standards and the belief that striving for perfection is personally crucial. Socially prescribed perfectionism (SPP) refers to the perception that other people place unrealistic expectations for oneself and reflects perfectionistic concerns. Other oriented perfectionism (OOP) involves the tendency to expect that others should achieve unrealistic outcomes (Hewitt and Flett, 1991), and is typically conceptualized as a component of perfectionistic concerns (see Limburg et al., 2017), although some authors suggested it should be considered as a unique distinct form (e.g., Sherry et al., 2016). These aspects of perfectionism show different associations with mental well-being and maladjustment. More specifically, SPP is a maladaptive form of perfectionism as it results significantly related to negative characteristics and psychological distress (e.g., Stoeber and Yang, 2010). OOP is an ambivalent form of perfectionism, sometimes associated with positive, sometimes with dysfunctional outcomes (Stoeber, 2012). On the other hand, SOP has been proposed as the adaptive side of perfectionism (Stoeber and Otto, 2006), more consistently associated with functional outcomes (Lee et al., 2012), although its adaptive nature is still debated (Molnar et al., 2012).

Perfectionism increases concerns about under achievements, especially in stressful situations (Hasel and Besharat, 2011), as it plays an important role in modifying psychophysiological responses to psychosocial or environmental stress. Research has also shown that individuals with perfectionism display higher

levels of distress than non-perfectionists and use ineffective strategies to cope with life challenges (Dunkley et al., 2003; Wagner, 2016). Their greater perception of stress is generated by the pursuit of unrealistic standards which often end in failure (Flett et al., 2020).

Studies available in literature employing the Hewitt and Flett (1991) model showed mixed findings concerning the relationship between perfectionistic facets and perceived stress. Some authors found positive associations between perceived stress and SOP and SPP (Molnar et al., 2012) and non-significant results concerning OOP (Smith et al., 2017). However, in some cases, positive correlations between OOP and perceived stress were observed (Chang and Rand, 2000). Meta-analytic evidence on the associations between perfectionism and general psychological distress indicated larger effects for perfectionistic concerns (e.g., SPP) relative to perfectionistic strivings (e.g., SOP), thus confirming the dual nature of the construct in explaining perceived stress (Limburg et al., 2017).

When people with high perfectionism perceive stress, they are also more prone to report psychopathological difficulties like anxiety (see Burgess and Di Bartolo, 2016), depression (Flett et al., 2016), and eating disorders (e.g., Mello, 2016).

Perfectionistic individuals are more likely to develop maladaptive eating attitudes (Machado et al., 2014) with evidence showing that both the major dimensions discussed above (i.e., perfectionistic strivings, perfectionistic concerns) equally contribute to explaining variance in dysfunctional eating outcomes (Limburg et al., 2017). It was observed that the association between perfectionistic dimensions and eating symptoms increased in magnitude under stress situations (Ruggiero et al., 2003; Sassaroli and Ruggiero, 2005). Moreover, findings showed that stress triggers maladaptive eating behaviors in individuals with high perfectionistic concerns, thus suggesting that the mechanism underlying the association between perfectionism and eating symptoms may be related to stress. This issue was addressed in a cross-sectional study examining the mediating role of stressful life events in the relationship between self-evaluative perfectionism (i.e., maladaptive form of perfectionism) and eating disorder symptoms (Mello, 2016). Results show that stress partially mediates this association. More specifically, high self-evaluative perfectionism was associated with high perceived stress, that, in turn, explained significant variance in eating symptoms. A more recent work proposing a mediation model tested the impacts of adaptive and maladaptive facets of perfectionism on emotional eating through perceived stress (Wang and Li, 2017). Emotional eating consists of the propensity for eating in response to negative emotions (Hawks et al., 2003), and resulted to be high among individuals who experienced stress (Tan and Chow, 2014). Authors found that maladaptive perfectionism was positively associated with stress, which in turn aggravated emotional eating behavior. Differently, the indirect effect of adaptive perfectionism on emotional eating through stress was significantly negative, suggesting that adaptive perfectionists are less vulnerable to emotional eating even when stressed. Taken together, these findings suggest that stress may be crucial to understand the complex relationship between perfectionism and eating-related symptoms.

In this theoretical framework, the present study aimed to investigate whether psychological distress during the COVID-19 pandemic mediates the relationship between perfectionistic aspects and dysfunctional eating behaviors. More specifically, three cognitive and behavioral components of eating were analyzed, namely cognitive restraint (i.e., the tendency to consciously restrict food intake), uncontrolled eating (i.e., overeating after being exposed to food cues) and emotional eating (i.e., the propensity to eat in response to negative emotions). Individuals rigidly engaging in dietary restraint by limiting food/calories often experience higher disinhibition that in turn might lead to losing control resulting in overeating and subjective feelings of food craving (Keränen, 2011). These three eating behaviors resulted to be closely related to psychological distress as normally the perception of stress can facilitate unhealthy eating in people (e.g., Richardson et al., 2015).

The proposed model was tested in Italy and Spain, the two main European countries most affected by the 2019 coronavirus disease, reporting respectively more than 105,000 and 94,000 total confirmed cases as of April 1st, 2020 (World Health Organization [WHO], 2020). Both countries have faced similar outbreaks since the beginning of the infection spread, showing a rapid increase in both positive cases and deaths compared to other European countries (Giangreco, 2020). Indeed, Spain suffered a surge in the pandemic within a few days which forced the country to follow Italy in the exceptional prevention measures, thus implementing quarantine in less than a week away.

Concurrently, previous research on personality has also provided evidence to support the presence of cultural differences in the correlates of perfectionism (e.g., Francisco et al., 2015), as well as in latent mean scores (e.g., Pietrabissa et al., 2020). Among these, the study carried out by Francisco et al. (2015) has demonstrated that the direct and indirect role of perfectionism on body dissatisfaction varies between Portuguese and Spanish adolescents, despite belonging to two neighboring countries of the southern Europe. In addition, a very recent study reported significantly lower latent factor mean of self-oriented and socially prescribed perfectionism in Italians than in Spaniards (Pietrabissa et al., 2020).

Although Italy and Spain share similar lifestyles, cultural heritages and religious and family values that are less marked, or not present, in other European countries (Micheli, 2012), they remain distinct countries. For example, Italy exhibited an individualistic tendency focused more on competition, results and success rather than on quality of life, unlike Spain (Hofstede et al., 2005). This difference has displayed an important effect on the predictive role of the two dimensions of perfectionism on various psychological outcomes (e.g., Stoeber et al., 2013). Therefore, in addition to clarifying the role of psychological distress due to the COVID-19 pandemic, an attempt was made to investigate possible cross-cultural differences in the proposed model considering two distinct, albeit culturally similar, countries.

It was hypothesized that the three perfectionistic components derived from the Hewitt and Flett's (1991) model would be related to psychological distress that, in turn, would impact eating behaviors. The effect of perfectionistic dimensions (i.e., SOP,

SPP, OOP) on psychological distress was estimated to be different according to the specific dimension analyzed. Previous evidence suggested that these aspects of perfectionism showed different associations with indices of stress and evidence is mixed. For instance, SPP resulted to be consistently positively related to perceived stress (e.g., Smith et al., 2017). Results on SOP revealed non-significant associations with stress in some cases (e.g., Flett et al., 2016), otherwise some authors found that high SOP predicts high distress (Molnar et al., 2012). Evidence on OOP suggested that it did not play a significant role in stress (e.g., Aryani and Koesma, 2020) although other studies showed significant positive OOP-stress associations (Han and Park, 2019).

Basing on these findings, the present study aims to get some additional insights for answering the following questions:

- Which dimensions of perfectionism are related to psychological distress? In other words, considering the relative adaptiveness of SOP and OOP continues to be controversial (e.g., Molnar et al., 2012; Han and Park, 2019; Aryani and Koesma, 2020) should these dimensions be considered adaptive or maladaptive?
- Does psychological distress (i.e., stress experienced during the COVID-19 pandemic) mediate the relationship between perfectionistic aspects and disordered eating attitudes and behaviors, as indicated by previous evidence (e.g., Wang and Li, 2017)?
- Which dimensions of perfectionism are related to disordered eating attitudes and behaviors when we take into account the psychological distress? Systematic evidence shows that both perfectionistic concerns (i.e., SPP, OOP) and perfectionistic strivings (i.e., SOP) are relatively equally related to eating disturbances (see Limburg et al., 2017) but it is not clear whether this effect is direct or is fully mediated by other relevant variables like the impact of stress.
- Are there key cross-cultural differences in any of the associations described above in two distinct national cultures (Italy versus Spain)?

## MATERIALS AND METHODS

### Participants

The study involved three samples of participants: two recruited in Italy from April 26th to May 2nd 2020, and one recruited in Spain from April 26th to May 9th 2020. The first Italian sample (i.e., *psychometric sample*) included 360 participants (42.5% male; mean = 22.99 years; SD: 5.76; range: 18–77) recruited with the aim to validate the Italian short version of the Three-Factor Eating Questionnaire (TFEQ; Karlsson et al., 2000). The remaining main samples were recruited from Italy and Spain in order to test the hypothesized model and invariance across countries. The Italian main sample comprised 465 participants (35.9% male; mean = 36.76 years; SD: 12.86; range: 18–72), of which the 0.4% was tested and resulted positive for COVID-19 and the 6% was subjected to special restrictions related to their

health (e.g., mandatory quarantine). The Spanish main sample comprised 352 participants (31.5% male; mean = 38.05 years; *SD*:13.96; range: 18–71), of which the 1.1% was tested and resulted positive for COVID-19 and the 14.5% was subjected to restrictions related to their health. At the time of the survey, Italy had imposed a national lockdown for about 7 weeks, while Spain had set the lockdown for about 6 weeks. A greater portion of the Italian main sample reported to respect every day the provided restrictions (80.6%), compared to the Spanish one (74.7%). As detailed in **Table 1**, the two main samples resulted statistically different only on the education level ( $\chi^2 = 66.15; p < 0.001$ ), while no differences emerged on age [ $F_{(1,815)} = 1.89; p = 0.17$ ], gender composition ( $\chi^2 = 4.17; p = 0.12$ ), marital status ( $\chi^2 = 7.98; p = 0.16$ ), family income ( $\chi^2 = 0.64; p = 0.89$ ), as well as on Body Mass Index [ $F_{(1,815)} = 1.67; p = 0.2$ ].

### Procedure

All participants were contacted through a non-random convenience recruitment procedure: information related to the study and the link for filling the questionnaires in were spread through acquaintances, word of mouth and social media. The Italian-language version of the survey was identical in content to the Spanish-language version, and both were hosted on the same secure Internet-based survey-hosting platform (i.e., Survey Monkey). Participants were required to indicate

agreement with the informed consent document explaining the purpose of the study and highlighting the ethical principles (i.e., confidentiality of information, voluntary participation, withdrawal from participation at any time) before they could enter the survey. Participants were eligible to participate if: (1) they were living either in Italy or Spain at the time of the survey, and (2) they aged 18 or more years old. These inclusion criteria were set to ensure that participants adequately represented the two cultures understudy during the pandemic period. This study was conducted in accordance with the Helsinki Declaration and received approval from the Institutional Review Board of the Department of Psychology, Sapienza University of Rome.

### Instruments

All the respondents filled out the online questionnaire measuring the following key variables in Italian and Spanish language, respectively for both Italian samples and the Spanish sample.

### Socio-Demographic Characteristics

The questionnaire assessed participants' age, gender, marital status, education, family income, and information related to the COVID-19 pandemic.

**TABLE 1 |** Socio-demographic characteristics of the samples.

Characteristics	Italian psychometric Sample (n = 360) Mean (SD) Frequency (%)	Main samples		Main samples comparison	
		Italy (n = 465) Mean (SD) Frequency (%)	Spain (n = 352) Mean (SD) Frequency (%)	F $\chi^2$	P
Age (years)	22.99 (5.76)	36.76 (12.86)	38.05 (13.96)	1.89	0.169

### Multidimensional Perfectionism

Participants' perfectionism was assessed using the short version of the Hewitt and Flett Multidimensional Perfectionism Scale (HFMPs; Hewitt et al., 2008), consisting of 15 items, 5 items for each dimension, namely *self-oriented perfectionism* (SOP; e.g., "One of my goals is to be perfect in everything I do"), *socially prescribed perfectionism* (SPP; e.g., "The better I do, the better I am expected to do") and *other-oriented perfectionism* (OOP; e.g., "I have high expectations for the people who are important to me"). Items were rated using a 7-point Likert scale ranging from 1 (disagree) to 7 (agree), with higher scores indicating greater perfectionism. This brief version has previously validated for use in Italy (Lombardo et al., 2021), whereas for the Spanish sample we used the corresponding 15 items<sup>2</sup> from a previously validated Spanish long version of the scale (see Rodríguez Campayo et al., 2009). The reliability coefficients (i.e., Cronbach's Alpha) of the three HFMPs's sub-scales across the two main samples are reported in **Table 2**.

### Psychological Distress

The respondents' psychological distress was assessed using the Depression Anxiety Stress Scales (DASS; Lovibond and Lovibond, 1995), consisting of 21 items measuring three different aspects, namely *depression* (seven items, e.g., "I couldn't seem to experience any positive feeling at all"), *anxiety* (seven items, e.g., "I was aware of dryness of my mouth"), and *stress* (seven items, e.g., "I found it hard to wind down"). Respondents read statements about these constructs and record their answers using a 4-point Likert-type scale ranging from 0 (Did not apply to me at all) to 3 (Applied to me very much or most of the time). Past studies in Italy (Bottesi et al., 2015) and Spain (Daza et al.,

2002) have attested the validity and the reliability of the scale. The reliability coefficients (i.e., Cronbach's  $\alpha$ ) of the three DASS's sub-scales across the two samples of the present study are reported in **Table 2**.

### Eating Behaviors

Cognitive and behavioral components of eating were measured by the short version of the Three-Factor Eating Questionnaire (TFEQ; Karlsson et al., 2000), comprising 18 items with a 1–4 response scale. All item responses are dichotomized and aggregated into three sub-scales, namely *emotional eating* (EE, three items; e.g., "When I feel anxious, I find myself eating"), *uncontrolled eating* (UE, nine items; e.g., "Sometimes when I start eating, I just can't seem to stop") and *cognitive restraint* (CR, six items; e.g., "I consciously hold back at meals in order not to gain weight"). This short-form was validated for the use in Spain (Jáuregui-Lobera et al., 2014), whereas for the Italian version we provided a list of items selected from a previously Italian validated long version (Melchionda et al., 2003) and tested the factor structure in the first Italian subsample of the present study. Reliability coefficients (i.e., Cronbach's Alpha) of the three TFEQ's subscales across the three samples are reported in **Table 2**.

### Statistical Analyses

#### Reliability and Descriptive Analyses

Reliability and descriptive analyses as well as MANOVAs were carried out through the SPSS software (Statistical Package for the Social Sciences - IBM, 2017) version 25. More specifically, three MANOVAs were carried out to explore possible differences across countries (Italy vs. Spain) in participants' perfectionism, psychological distress, and eating behaviors.

#### Confirmatory Factor Analysis (CFA) of the Italian Version of the Tree Factor Questionnaire

In order to evaluate the factorial validity of the Italian 18-items Three-Factor Eating Questionnaire, using the data of the psychometric sample ( $n = 360$ ), a confirmatory factor analysis (CFA) was carried out using *Mplus* software version 7 (Muthén and Muthén, 2012) and the model parameters were estimated

<sup>2</sup>We preliminary evaluated the factorial structure of the Spanish short version of the HFMPs on the main Spanish sample using a Confirmatory Factor Analysis. The results showed that the three-factor structure of the scale fits the data almost well [ $\chi^2(87) = 401.013, p < 0.001$ ; CFI = 0.87, RMSEA = 0.10, 90% CI: from 0.091 to 0.111; SRMR = 0.095]. The standardized estimates of the factor loadings and other details can be provided on request by the first author. However, the factor loadings of each of the three latent variables assessed by the questionnaire were statistically significant ( $p < 0.001$ ) and were above 0.43.

**TABLE 2 |** Reliability coefficients and descriptive of the Key Measures across the Italian and Spanish main samples.

	Cronbach's $\alpha$		Mean (SD)		F	P	Partial Eta Squared
	Italy	Spain	Italy	Spain			
<b>Multidimensional perfectionism</b>							
Self-oriented perfectionism (SOP)	0.84	0.89	4.76 (1.25)	4.84 (1.29)	0.71	0.398	0.001
Other-oriented perfectionism (OOP)	0.75	0.77	4.18 (1.19)	4.05 (1.19)	2.25	0.134	0.003
Socially prescribed perfectionism (SPP)	0.73	0.75	3.81 (1.25)	3.52 (1.20)	10.87	0.001	0.013
<b>Psychological distress</b>							
Depression	0.89	0.86	0.82 (0.62)	0.62 (0.58)	21.58	<0.001	0.026
Anxiety	0.84	0.83	0.47 (0.49)	0.47 (0.54)	0.07	0.796	0.000
Stress	0.89	0.89	1.11 (0.62)	0.94 (0.69)	13.84	<0.001	0.017
<b>Eating behaviors</b>							
Emotional eating	0.85	0.85	2.12(0.83)	2.05(0.84)	1.44	0.230	0.002
Uncontrolled eating	0.86	0.90	2.05(0.60)	2.15(0.68)	4.80	0.029	0.006
Cognitive restrain	0.84	0.83	2.33(0.70)	2.28 (0.69)	0.95	0.331	0.001

using the default robust weighted least squares (WLSMV) estimation method with theta parameterization to account for the categorical nature of the 4-point response scale (Brown, 2015). The adequacy of the CFA was ascertained using a variety of indices measuring the degree of fit between input data and model-based estimates. The literature indicates the following as good fit model indices: TLI (Tucker-Lewis Index) or CFI (Comparative Fit Index) values close to 0.95 (Hu and Bentler, 1999), RMSEA (Root Mean Square Error of Approximation) values below 0.08 (Marsh et al., 2004) and WRMR (Weighted Root Mean Squared Residuals) values below 0.95 (close to 1.0 reasonable fit; Yu, 2002); a chi-square/df ratio below or equal to 3 (Kline, 1998).

### Measurement Invariance Analysis

Before testing the hypothesized model, the equivalence of the measurement model between countries (i.e., across the two main samples) is configured as a necessary condition for the comparison of psychological variables (Meredith, 1993). Although this was not the main purpose of our research, we considered it appropriate to conduct the measurement invariance separately for each of the three questionnaires we used for this study. In line with that, a series of multi-group confirmatory factor analyses (MGCFA) were modeled using maximum likelihood (ML) estimate, or the default robust weighted least squares estimate for ordinal data (WLSMV), via *Mplus* software version 7 (Muthén and Muthén, 2012), as follows (e.g., Meredith, 1993): (1) configural invariance, in which each common factor is associated with the same items across countries; (2) metric invariance, in which the items presented invariant factor loadings, but item intercepts are freely estimated across countries; (3) scalar invariance, in which both factor loadings and item intercepts (or thresholds for ordinal data) are constrained to invariance. According to Meredith (1993), the average item and scale scores are comparable across the two countries when scalar invariance is supported (Tomás et al., 2014).

For the purpose of the current study, the nested models of measurement invariance were compared against the configural invariance model using the change in CFI, TLI and RMSEA. Literature (Widaman, 1985; Cheung and Rensvold, 2002) states that a  $\Delta \leq 0.01$  for CFI and TLI, or  $\Delta \leq 0.015$  for RMSEA (Chen, 2007), indicates a not significant worsening of the fit model. The chi-square difference tests using the DIFFTEST command, in which a non-significant value ( $p > 0.05$ ) indicates good fit (Cheung and Rensvold, 2002), were also conducted to examine the ordinal data. However, if values exceeded these cut-offs criteria, partial invariance models were tested by releasing non-invariant parameters as stated by Byrne et al. (1989).

### Multi-Group Structural Equation Model (SEM) Analysis

Subsequently, we tested a model, across Italian ( $n = 465$ ) and Spain ( $n = 352$ ) main data, hypothesizing that perfectionism has direct and indirect effects (i.e., through its effect on psychological distress) upon eating behaviors (see **Figure 1**). Furthermore, the relations between these variables were tested controlling for the possible effect of participants' body mass index (BMI) on the

endogenous variables of the model (i.e., psychological distress and eating behaviors).

The hypothesized model was tested using a multi-group SEM analysis and the model parameters were estimated using the maximum likelihood (ML in *Mplus*) estimation method. More specifically, the multi-group analysis was carried out in order to evaluate firstly the model measurement invariance parameters across the two countries (i.e., Model 1- Metric invariance) and, subsequently, the extent to which the model's hypothesized relations held across them (i.e., Model 2-Covariances invariance and Model 3- Paths invariance).

In order to calculate the measurement indicators for the latent variables of the model, according to standard procedures for SEM analysis and following past studies (e.g., Lombardo et al., 2013), we used the three DASS's subscales (i.e., depression, anxiety, and stress) as measurement indicators of the latent variable psychological distress. Furthermore, an item parceling procedure (Kim and Hagtvet, 2003) was used for the other latent variables, in line with previous studies (e.g., Lucidi et al., 2014, 2019; Mallia et al., 2015). Specifically, the item parcels for each of these latent variables (i.e., self-oriented perfectionism, other-oriented perfectionism, social prescribed perfectionism, emotional eating, uncontrolled eating, and cognitive restraint) were created by randomly grouping the items of each scale into three separate item sets (parcels) and by averaging the item scores within each set.

For the multi-group analysis, the three models introducing the invariances (i.e., metric, covariances, and paths) across the two countries were compared against a configural invariance model using cut-offs listed above for acceptable change in CFI, TLI, and RMSEA. Finally, the indirect effects of the model were examined using bootstrapped confidence interval estimates (95% confidence interval with 5000 bootstrap resamples).

## RESULTS

### Reliability and Descriptive of the Key Measures of the Study

Overall, as reported in **Table 2**, all the key measures used in the present study showed acceptable internal consistency both in the Italian (Cronbach's  $\alpha \geq 0.73$ ) and in the Spanish (Cronbach's  $\alpha \geq 0.75$ ) main samples.

The MANOVAs results showed a significant multivariate effect of the country on the perfectionism [Wilks's  $\lambda_{(3,813)} = 0.976$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.024$ ], on the psychological distress [Wilks's  $\lambda_{(3,813)} = 0.947$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.053$ ] as well as on eating behaviors [Wilks's  $\lambda_{(3,813)} = 0.976$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.024$ ]. However, considering the univariate effects, as reported in **Table 2**, emerged a significant difference across the two countries only on the socially prescribed perfectionism dimension, on depression and anxiety, and on uncontrolled eating. More specifically, the Italian respondents reported higher levels of socially prescribed perfectionism, higher levels of depression and anxiety, and lower levels of uncontrolled eating when compared with the Spanish respondents.

### Confirmatory Factor Analysis of the Italian Version of the Tree Factor Questionnaire

The CFA conducted on the Italian psychometric sample showed that the three-factor structure of the Tree Factor Questionnaire fits the data well [ $\chi^2_{(132)} = 365.892, p < 0.001; \chi^2_e/df = 2.77, CFI = 0.96, TLI = 0.953, RMSEA = 0.070, 90\% CI: \text{from } 0.062 \text{ to } 0.079; WRMR = 1.23$ ]. The standardized estimates of the factor loadings are reported in **Appendix 1**. All factor loadings of each of the three latent variables assessed by the questionnaire were statistically significant ( $p < 0.001$ ) and were above 0.50.

### Measurement Invariance of the HFMPs, DASS, and TFEQ Measures Across Italian and Spanish Samples

We compared the fit of the three models to evaluate measurement invariance of the key measures of the study across the two countries. Scalar invariance, or at least partial scalar invariance, was achieved with several revisions necessary to satisfy the cut-offs criteria.

First, the HFMPs measure showed an acceptable fit of the model at the configural invariance step after correlating

the residuals of item 2 and 1, and of item 14 and 11 [ $\chi^2_{(170)} = 617.134, p < 0.001; CFI = 0.91, TLI = 0.89, RMSEA = 0.08, 90\% CI: \text{from } 0.073 \text{ to } 0.087; SRMR = 0.073$ ]. Changes in fit indices supported metric invariance ( $\Delta CFI = 0.001, \Delta TLI = 0.006, \Delta RMSEA = 0.002$ ), while they did not support scalar invariance initially ( $\Delta CFI = 0.072, \Delta TLI = 0.062, \Delta RMSEA = 0.021$ ). Inspection of the modification indices indicated that five item intercepts were non-invariant across countries (i.e., intercepts of item 12, 7, 11, 1, and 8). Thus, partial scalar invariance was supported after removing the equality constraints on these item intercepts ( $\Delta CFI = 0.013, \Delta TLI = 0.001, \Delta RMSEA = 0.001$ ) and testing the practical significance of differential item functioning (DIF) across countries. In the present study, the difference  $d$  was trivial ( $d < 0.20$ ; Chan, 2000).

Second, the DASS measure displayed an acceptable fit of the model at the configural invariance step [ $\chi^2_{(372)} = 997.743; p < 0.001; CFI = 0.97, TLI = 0.97, RMSEA = 0.064, 90\% CI: \text{from } 0.059 \text{ to } 0.069; WRMR = 1.604$ ]. Also, despite the significant chi-square difference, changes in the fit indices supported the metric invariance step [ $\Delta \chi^2_{(18)} = 36.625; p = 0.006; \Delta CFI = 0.006; \Delta TLI = 0.008; \Delta RMSEA = 0.008$ ], and the scalar invariance step [ $\Delta \chi^2_{(60)} = 594.922; p < 0.001; \Delta CFI = 0.012; \Delta TLI = 0.005; \Delta RMSEA = 0.004$ ].

Lastly, fit indices for the configural invariance step of the TFEQ measure fell within specified ranges [ $\chi^2_{(264)} = 725.688$ ;  $p < 0.001$ ; CFI = 0.97, TLI = 0.96, RMSEA = 0.065, 90% CI: from 0.060 to 0.071; WRMR = 1.752]. Moreover, changes in fit indices suggested that the fit of the metric invariance step was not significantly worse from that the configural model [ $\Delta\chi^2_{(15)} = 23.617$ ;  $p = 0.0719$ ;  $\Delta$ CFI = 0.002,  $\Delta$ TLI = 0.004,  $\Delta$ RMSEA = 0.004], but the scalar invariance step showed a deterioration in fit:  $\Delta\chi^2_{(51)} = 501.063$ ;  $p < 0.000$ ;  $\Delta$ CFI = 0.018,  $\Delta$ TLI = 0.01,  $\Delta$ RMSEA = 0.008. Inspection of the modification indices indicated that the main source of the misfit can be traced to one non-invariant threshold (item 1 threshold 2). Despite the chi-square difference was again significant [ $\Delta\chi^2_{(50)} = 358.191$ ;  $p < 0.000$ ], the changes in the fit indices compared to the configural model supported the partial scalar invariance by freeing this item threshold across countries ( $\Delta$ CFI = 0.012,  $\Delta$ TLI = 0.001,  $\Delta$ RMSEA = 0.001).

### The Relationships Between Perfectionism, Psychological Distress, and Eating Behaviors Across Italian and Spanish Samples

Table 3 shows the results of the multi-group analysis, which was performed to verify the metric invariance, the covariances invariance and, finally, the path invariance of the hypothesized model across the two countries. In particular, the baseline model (i.e., M0 – Configural invariance) showed a good fit, attesting that the hypothesized model fit well both the Italian and the Spanish data. Furthermore, the comparisons between the models introducing three different constrains/invariances across the two samples showed not significant differences, since all the observed  $\Delta$  CFIs are smaller than the recommended cut-offs (0.01). These results attested firstly that the factor loadings of the indicators used for each latent variable of the model resulted statistically equivalent across the two countries (i.e., metric invariance of the models). Additionally, the results attested also that the covariances between the latent variables of the model as well as the paths linking these variables resulted statistically equivalent across Italian and Spanish data (i.e., covariance and path invariance respectively). In particular, as reported in Figure 1, self-oriented perfectionism (i.e., SOP) showed a negative direct link both with emotional eating ( $\beta = -0.17$ ) and with uncontrolled eating ( $\beta = -0.14$ ). Other oriented perfectionism, instead, showed only indirect negative effects both

on emotional eating ( $\alpha\beta = -0.082$ ; 95% confidence interval: from  $-0.192$  to  $-0.007$ ) and uncontrolled eating ( $\alpha\beta = -0.072$ ; 95% confidence interval: from  $-0.166$  to  $-0.006$ ). Conversely, social prescribed perfectionism showed only indirect positive effects both on emotional eating ( $\alpha\beta = 0.177$ ; 95% confidence interval: from 0.109 to 0.300) and uncontrolled eating ( $\alpha\beta = 0.155$ ; 95% confidence interval: from 0.094 to 0.257).

## DISCUSSION

The present study investigated whether the psychological distress evaluated during the COVID-19 pandemic mediates the relationship between perfectionistic dimensions and problematic eating attitudes and behaviors in two samples drawn from the general population of Italy and Spain.

Findings showed that the psychological distress evaluated during the COVID-19 pandemic mediated the relationship between two perfectionistic dimensions and problematic eating behaviors in both the samples included. More specifically, results confirmed that psychological distress fully mediates the associations between the interpersonal aspects of perfectionism (i.e., SPP, OOP) and two of the three dysfunctional eating behaviors examined, namely emotional eating and uncontrolled eating. These results overlap with findings indicating that high perceived stress is associated with greater eating disorders symptoms (e.g., Klatzkin et al., 2019) as well as with components of perfectionistic concerns (i.e., SPP, OOP; Dunkley et al., 2016).

Path coefficients of each specific effect tested through the model indicated that participants with high SPP also show elevated psychological distress, that, in turn, is associated with greater levels of emotional eating and uncontrolled eating. This finding is consistent with previous results evidencing that maladaptive perfectionism positively predicts emotional eating through the mediation of stress (Wang and Li, 2017) and indicate that in the COVID-19 pandemic the link between perfectionism and eating symptoms is better explained by the mediation of the psychological distress. The role of SPP in predicting high psychological distress should be interpreted taking into account peculiarities of people with this perfectionistic aspect. Individuals with high SPP are prone to excessively concern over external expectations and pressures, and often engage in coping choices that did not match with the daily situational demands (Zhang, 2012). It is plausible that high SPP individuals may experience elevated stress in

TABLE 3 | Multi-group SEM: Models comparisons.

Model	Chi-square	df	CFI	TLI	RMSEA	SRMR	Chi-square/df	Comparison	$\Delta$ CFI	$\Delta$ TLI	$\Delta$ RMSEA
Model 0 (M0) – Configural invariance	894.195	384	0.944	0.933	0.057	0.054	2.32				
Model 1 (M1) – Metric invariance (i.e., factor Loadings)	977.527	405	0.937	0.928	0.056	0.051	2.41	M1 vs. M0	0.007	0.005	0.001
Model 2 (M2) – Covariances invariance	983.967	411	0.937	0.928	0.058	0.051	2.39	M2 vs. M0	0.007	0.005	0.001
Model 3- (M3) – Paths invariance	1041.644	430	0.933	0.928	0.058	0.057	2.42	M3 vs. M0	0.011	0.005	0.001

dealing with the provisions introduced by the governments in COVID-19 pandemic (i.e., social distancing), and that this stress is detrimental for eating behaviors. Moreover, previous evidence suggested that SPP is related to perceived loneliness and isolation (e.g., Harper et al., 2020). Recently, the importance of social connection is highlighted to mitigate negative psychological consequences of the COVID-19 pandemic (Tull et al., 2020). We speculate that the distress related to COVID-19 pandemic may facilitate people with high SPP in experiencing social disconnection, leading to eat more than usual (i.e., uncontrolled eating) and eating in response to emotional cues (i.e., emotional eating). This hypothesis is consistent with research on the association between eating behaviors and loneliness (Levine, 2012) that indicated the tendency to overeating as distracting from perceived social isolation and stress (Wansink and Payne, 2007).

Findings also showed that OOP negatively impacts psychological distress, that, in turn, positively predicts emotional eating and uncontrolled eating. These results evidence that demanding perfection from others (i.e., OOP) is associated with low psychological distress. Previous studies found a negative relationship between OOP and stress (Chang and Sanna, 2001), suggesting that, under certain circumstances, OOP could have adaptive effects (Hunter and O'Connor, 2003). Individuals with OOP are continuously concentrated on others' performance thus it is possible that the tendency to direct the attentive focus away from self-scrutiny, in some circumstances, is beneficial (as cited in Hunter and O'Connor, 2003).

Additionally, results evidenced a not significant SOP-psychological distress association and a direct negative effect of SOP on emotional eating and uncontrolled eating. The lack of association between SOP and psychological distress is consistent with previous findings (e.g., Flett et al., 2016) and confirms the intrinsic functional nature of SOP. The adaptiveness of SOP is also suggested by the fact that participants with high SOP experienced low disturbed eating behaviors, and this relationship is independent of their perceived distress. This finding contradicts the well-established positive association between perfectionistic strivings (i.e., SOP) and eating symptoms (see Limburg et al., 2017). Instead, results suggest that SOP may play a protective role for the negative consequences of distress on emotional and uncontrolled eating. This conclusion is consistent with previous evidence showing that positive perfectionism (an aspect of perfectionism comparable to SOP) was related to low emotional eating levels (Wang and Li, 2017). Taken together, these observations suggest that adaptive perfectionists (i.e., those who have high SOP) may be less vulnerable to the tendency to overeat and to eat in response to negative emotions. It is plausible that the typical motivation to be flawless of individuals with high SOP makes them less prone to engage in uncontrolled eating and in eating in response to emotional cues in high-stress conditions. Empirical evidence showed that, among all the perfectionism dimensions, only SOP was significantly related to the rigid adherence to strict dietary rules (Brown et al., 2012), thus it is possible that during the public emergency of COVID-19 pandemic, high SOP may have lead people to rigidly interpret and adhere to guidelines for healthy eating.

No significant association was found for cognitive restraint. This result is inconsistent with results of previous studies evidencing a positive association between cognitive dietary restraint and perfectionism (e.g., Cain et al., 2008), as well as between this eating behavior and levels of perceived stress (e.g., McLean and Barr, 2003). Social isolation measures introduced for the containment of the COVID-19 pandemic (including stay-at-home mandates) may make it difficult for people to restrict eating with the intention to lose or maintain weight. Staying at home could facilitate the engaging in unhealthy behaviors such as overeating (as cited in Buenaventura et al., 2020) rather than cognitive restraint due to the easy access to food reserves (e.g., Rodgers et al., 2020).

Several limitations of the present study should be acknowledged before concluding. First, its cross-sectional nature limited causal inferences. Further longitudinal studies are needed to examine whether perfectionistic dimensions prospectively predict changes in eating behaviors, and if this association would be mediated by psychological distress. Second, the mere use of self-report questionnaires may be subject to social desirability effects and recall bias. More specifically, future studies should control for the effect of social desirability as previous evidence showed positive associations between the motivation to distort one's responses in a favorable direction (i.e., social desirability) and both perfectionism and psychological distress (e.g., Lopez et al., 2006; Kung and Chan, 2014). Further studies should include a measure of perceived social isolation in order to analyze the extent to which each aspect of perfectionism could be related to the experience of loneliness during COVID-19 pandemic. Moreover, the current study should be replicated in other cultures to strengthen the generalizability of the results.

Despite these limitations, the present study provides further evidence for the roles of each perfectionism dimension in eating behaviors by considering the mediation role of psychological distress. Strengths of the present work include the use of multi-group SEM as a rigorous way to examine the degrees of goodness-of-fit for the proposed model and to simultaneously compare parameters across the two groups (Italian and Spanish). The multi-group SEM has been regarded as a powerful model and recommended in cross-cultural research especially when computing pairwise comparison between countries (Feskens and Hox, 2011). Moreover, the establishment of measurement invariance of all the scales used strongly supported the generality of the model and warranted comparisons between the two cultural groups studied.

In summary, results of the present research suggest that the OOP and SPP dimensions resulted to indirectly predict emotional and uncontrolled eating, whereas non-significant mediation result was found for SOP. Instead, SOP was found to negatively predict eating behaviors, supporting the adaptive nature of SOP in relation to emotional eating and uncontrolled eating and suggesting its potential protective role in conditions of stress and social isolation. These findings have theoretical implications for the perfectionism and eating symptoms literature. For example, the negative effect of SOP on eating symptoms may be the consequence of controlling for the common variance shared with other perfectionistic dimensions.

Previous studies demonstrate that when the covariance between perfectionistic strivings (e.g., SOP) and perfectionistic concerns (e.g., SPP) was controlled for, perfectionistic strivings show negative associations with maladaptive outcomes (e.g., anxiety; Stoeber et al., 2007). This mechanism may also pertain eating disorders (EDs) symptoms, as one past study demonstrated (Minarik and Ahrens, 1996). Further research should shed light on these processes by employing sophisticated statistical methods to more deeply explore the simultaneous effects of SOP, SPP, and OOP on problematic eating behaviors.

Findings suggest some clinical implications for future research and interventions aimed at reducing problematic eating behaviors. A growing literature supports that programs targeting perfectionism may be an effective treatment for EDs (e.g., Wilksch et al., 2008; Goldstein et al., 2014). Generally, these interventions address multiple components of perfectionism (e.g., concern over mistakes, personal standards; Wilksch et al., 2008) and result in a reduction of EDs symptoms (e.g., shape and weight concerns, Wilksch et al., 2008; drive for thinness, Levinson et al., 2017). In the present investigation, the interpersonal perfectionistic aspects (i.e., SPP, OOP) showed significant indirect associations with eating symptoms, suggesting that intervention protocols for individuals suffering from EDs should especially address these forms of perfectionism, as previous studies highlighted (e.g., Reilly et al., 2016). EDs treatment targeting perfectionism typically emphasizes changes in the patient's scheme for self-evaluation and includes cognitive-behavioral methods to address personal standards and self-criticism (see Egan et al., 2014 for further details). Results of this study may imply that future prevention and treatment for problematic eating behaviors should mainly aim on the reduction of aspects related to SPP (e.g., fear of failure) and OOP (e.g., excessive other-criticism) rather than aspects of SOP, although evidence on the efficacy of EDs treatment designed to decrease SOP is available in the literature (e.g., Lethbridge et al., 2011). Instead, the present findings highlighted the protective role of SOP in the development and maintenance of problematic eating behaviors.

Whereas the reduction of perfectionistic concerns (e.g., SPP) through the use of specific techniques (e.g., self-compassion strategies) should be recommended, the drive to excel related to SOP could be re-addressed to enhancing motivation for change and to serve recovery in EDs treatment (Wagner and Vitousek, 2019). On the other hand, clinicians should pay special attention to the reduction of perceived distress. More specifically, treating perfectionistic concerns may result in a relative reduction of patients' psychological distress, which, in turn, would decrease the likelihood to engage in emotional eating and uncontrolled eating behaviors. Further investigations of specific treatment strategies targeting these processes are required.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Institutional Review Board – Department of Psychology, Sapienza University of Rome. The participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

All the authors contributed to the study conception and design, and commented on previous versions of the manuscript. MV and ADM performed the material preparation, literature research, and data collection. ADM performed the statistical analyses with the supervision of LM. MV wrote the first draft of the manuscript. CL and LM read, corrected, and approved the final manuscript.

The BRICS Forum, an independent international organization encouraging commercial, political, and cultural cooperation between Brazil, Russia, India, China, and South Africa, was formed in 2011, and these countries have a significant influence on their regional affairs. These nations were hit by COVID-19 at different times, and all adopted home quarantine to reduce the spread of the virus. We present a comparative analysis of actions of psychology and potential outcomes during the COVID-19 pandemic in BRICS nations regarding five aspects: psychology in health policies, social roles of psychology, socioeconomic context, actions for the general population, and health professionals during stage 1 of the pandemic, and possible actions in stage 2. Various types of actions were taken by psychologists in BRICS, with different levels of coordinated cooperation with respective governmental and non-governmental organizations, multiple and parallel efforts from different scientific societies, and professional regulatory agencies. Scientific societies have had an important role in coordinating some of these efforts, especially because they congregate the psychologists from different parts of these countries, improving communication and access to key information. The aim of these actions varies from improving situational skills and competences to increase the accessibility of psychological services and provide psychoeducation and telepsychology. We will consider the social importance of these actions within these countries as a global opportunity for psychology to stage in a complex context involving human health. The way psychology in BRICS will face this challenging situation is likely to produce important regional influence, stimulate scientific contribution, and increase the accessibility of psychology.

**Keywords:** COVID-19, BRICS forum, psychology, telepsychology, actions, health workers

## INTRODUCTION

BRICS is the group composed of five major emerging countries: Brazil, Russia, India, China, and South Africa, which, together, represent about 42% of the population, 30% of the territory, 23% of Global Gross Domestic Product (GDP), and 18% of the global trade. Since 2009, these countries have sought to establish fairer international governance, developed sectoral cooperation in different areas, such as science, technology and innovation, economics, finances, business, education, and security (BRICS-Brasil, 2019). The BRICS is an economic group composed of designating countries considered to be emerging, which have the economic potential to overcome the great world powers. It is not an economic block or an international institution but an international mechanism with a diplomatic character, which promotes the collective economic and political actions by these countries. Currently, sectoral cooperation, which covers more than 30 subject areas, brings important concrete benefits to the populations of the five countries.

As a major global health problem, COVID-19 is a central theme on the BRICS agenda for having an impact on the capabilities of health infrastructure and global economies, in addition to the important discussion on political management that is associated with the development of efficient actions in these countries. Psychological scientific societies of these countries are aware of these impacts, concerned with consequences for the mental health of the general population and, in particular, health professionals, with psychosocial actions aimed at different vulnerable groups (children, the elderly, people in vulnerability, and victims of violence), taking into account sociocultural differences and the particular attempt to strengthen health systems in these developing countries.

In this sense, this perspective article discusses the actions of psychology as a science and profession, represented by several scientific societies and councils, governmental and non-governmental organizations, and universities, in combating the pandemic of COVID-19, in the countries that form the alliance of the BRICS. This proposal is important, given that we are among the 25 countries that most produce science in psychology, in a list of 173 countries (<https://www.scimagojr.com/countryrank.php?area=3200&year=2019>). If the BRICS were a country (adding up all the scientific production would be 8,118 documents in 2019), we would be third in the scientific production of psychology, behind the USA and the UK, well-ahead of Germany. Therefore, we present an analysis of actions of psychology and potential outcomes just after the outbreak of COVID-19 in the BRICS nations regarding five aspects: psychology in health policies, social roles of psychology, socioeconomic context, actions for the general population, and health professionals during stage 1 of the pandemic, and possible actions in stage 2. Finally, we consider a comparative analysis of these actions. Before this analysis, we characterize the psychology in the BRICS countries.

## Characterization of Psychology in the Brics Countries

### Brazil

There are 350,000 registered psychologists in Brazil today (<http://www2.cfp.org.br/infografico/quantos-somos/>), working

in individual practice, healthcare, education, organizations, and research. Profession and formation have been regulated by Federal law No. 4,119 since 1962. Federal Council of Psychology (FCP) has been the organization responsible for professional registration and regulation since 1972. Brazilian Society of Psychology (BSP) has congregated all areas of scientific and professional psychology since 1971 (Williams and Hubner, 2014) and joined the International Union of Psychology Science (IUPsyS) in 1957.

In 2016, there were 626 courses of psychology (in public and private institutions) with 22,985 enrolled students, after the Higher Education project that intensified the expansion, democratization, interiorization, and internationalization of Higher Education (Dantas et al., 2019). Extensive supervised training during 5-year courses is mandatory in different areas of professional psychology. Therefore, universities and faculty are part of the public mental care service. Parallel to professional growth, scientific knowledge is produced in about 90 graduate courses and published internationally and by dozens of open-access national scientific journals linked to universities and scientific societies of different subfields of psychology.

Regarding mental health, SUS and Unified Social Assistance System (SUAS) have become important devices for the integration of professional psychologists in public policies since the 2000s. Both were responsible for the insertion of psychologists to the most diverse municipalities and locations in the country to a contingent, estimated in 8,000 psychologists in Reference Centers for Social Assistance (CRAS and CREAS) and 40,000 psychologists in SUS (Macedo et al., 2011). Unified Health System (SUS) serves more than 70% of the population. It works in regionalized care networks, integrating different levels of care complexity, from community Basic Health Units (UBS) to hospitals. The characteristics of the service provided vary according to the different regions of the country. In recent years, there has been an expansion of the inclusion of psychology in primary care, especially in the Family Health Strategy (ESF) and in Family Health Support Centers (NASF), where psychologists perform socio-educational activities, home visits, and clinical care. However, there is no clear role of psychology in health teams (Seidl et al., 2019), which contrasts with the traditional formation of psychologists and expectations of the users (Seidl et al., 2019).

### Russia

In Russia, more than 200 universities are engaged in the training of psychologists. Currently, according to the reports of the respected ministries, about 60,000 psychologists work in the field of education, in the healthcare sector, more than 30,000 psychologists; in the structure of law enforcement agencies, about 40,000 psychologists; in the system of social protection, more than 25,000 psychologists; in the HR system of organizations, about 50,000 psychologists; and more than 95,000 psychologists conduct individual practice.

The largest and oldest organization that unites professional psychologists in Russia is the Russian Psychological Society (RPS), one of the oldest psychological societies in the world, which was founded in 1885. The purpose of the creation of RPS was the development of “psychology, in its compositions, applications, and history, and the spread of psychological

knowledge in Russia (RPS).” Members of the society were world-famous scientists who have made substantial contribution to the formation and development of psychological science: L. S. Vygotsky, A. R. Luria, A. N. Leontiev, P. Ya. Galperin, and other leading scientists of the Russian Academy of Sciences and the Russian Academy of Sciences, leading psychologists of the largest scientific and educational organizations. Together with the Federal Educational and Methodological Association in the Field of Higher Education, RPS organizes scientific and methodological support for the preparation of federal state educational standards of higher professional education and basic professional educational programs in the field of psychological education.

## India

Psychology as a discipline started in 1916 when the first department of psychology was established at the University of Calcutta, India. Later, departments of psychology were established at the University of Mysore in 1924, University of Madras (1943), University of Kerala (1957), Utkal University (1958), University of Bombay (1959), Allahabad University (1961), and the University of Delhi (1964). Psychology was also introduced in the various Indian Institutes of Technology and Management setup later. During the years, various psychology associations were formed, and it is difficult to give the exact number of associations in the country. The Indian Psychological Association was established in 1925, Indian Psychoanalytic Society in 1922, and later on, Indian Association of Clinical Psychology, National Academy of Psychology (NAOP), Indian Academy of Applied Psychology, and several other associations focusing on health, school psychology, community psychology, counseling and guidance, and about 20 regional associations in the different states, besides numerous local chapters. The idea of a federation of associations has been mooted and felt important and announced in 2014, but much needs to be done. The focus of these associations has been more on academic work and awareness generation than psychological services, except for a few. The National Academy of Psychology (NAOP) is a member of the International Union of Psychological Sciences and participates regularly and actively in its programs. It is also a member of the Asia Pacific Association of Psychology and engages in collaborative endeavors, including programs in disaster management.

The Rehabilitation Council of India (RCI) regulates the professional programs in clinical and rehabilitation psychology (Brazilian Federal Government, 2020). Psychologists work in close association with professionals in allied disciplines, such as psychiatry, pediatrics, education, social work, nursing, rural development, rehabilitation, defense, and management. It may be noted that, with the realization of the complexity, the move is more toward multi- and trans-disciplinary initiatives. In India, there is no registry of psychologists in the country; hence, an accurate count is difficult. Manickam (2016) suggests that there may be more than 300 master-level programs of psychology with different specializations in the country and, perhaps, more than 100,000 psychologists based on the number of training centers

and the intake at each center (p. 5). This number may have increased in the last 4 years.

India has several institutions working for the mental health and well-being of its citizens. In 2017, the country passed a progressive Mental Healthcare Act, 2017 (The Mental Health Care Act, 2017) “to provide for mental healthcare and services for persons with mental illness and to protect, promote, and fulfill the rights of such persons during delivery of mental healthcare and services and for matters connected therewith or incidental thereto” (Government of India, 2017). The act also outlines the responsibilities of other agencies such as the police concerning people with mental illness as well as attempts to tackle the stigma of mental illness and its amelioration. Many current mental health-related services happening in the country are in the backdrop of this act. NIMHANS (National Institute of Mental Health and Neuro Sciences) is the major center for mental health and neuroscience education in the country. The institute provides a large number of mental health and well-being-related services. Several other institutions both in the government sector and the private sector are providing their services for mental health care, including many mental health professionals and clinical psychologists in various medical institutions and hospitals in the country. These institutions during COVID times are providing counseling and mental health facilities for the public as well as special groups like children, migrants, elderly, etc.

## China

Psychology as a discipline was established in China around the 1920s with several milestones achieved at that time, such as the first psychology laboratory (1917, Peking University), the first psychology department (1920, Nanjing Normal College), the Chinese Psychological Association (1921, the predecessor of Chinese Psychological Society, CPS), and the first research institute (1929), Institute of Psychology, Academia Sinica (the predecessor of Institute of Psychology, Chinese Academy of Sciences, IPCAS) (Han and Zhang, 2007). CPS is one of the earliest (seventh) national academic organizations in the world. It has 36 divisions and 12 committees for special task forces. Two other national associations of psychology are the Chinese Association of Social Psychology (1982) and the Chinese Association for Mental Health (1979).

CPS joined the International Union of Psychology Science (IUPsyS) in 1980, and the International Association of Applied Psychology (IAAP) in 1984. CPS hosted the 28th International Congress of Psychology, held in Beijing on August 8–13, 2004, under the auspices of IUPsyS. CPS and CAMH, jointly in cooperation with Beijing University (Department of Psychology), held the fifth World Congress of Psychotherapy in Beijing in October 2008. In 2 years, CPS will host the 30th International Congress of Applied Psychology in Beijing, July 2022.

Psychology is taught in China at both undergraduate and postgraduate levels, in 815 universities and institutes that offer postgraduate programs, 114 have master programs in psychology (psychology, mental health education) and 30 universities have doctoral level programs in psychology in 2020 (China Education online).

In 2002, the China Ministry of Labor and Social Security launched a certification for psychological counselors, based on the National Standards on Psychological Counseling. The new certification was given to 1.2 million counselors who fulfilled the basic requirement, took the training, and passed a national examination. It enables private psychotherapy practice and psychological counseling in general public settings, such as hospitals, universities, primary and secondary schools, entrepreneurs, and communities.

### South Africa

Regulation of the practice of medicine and allied professions in South Africa dates back to the late nineteenth century when the then Colonial Medical Council of the Cape Province was established in terms of Section 18 of the Medical and Pharmacy Act of 1891. At that time, the Cape Province was nominally under the British colonial rule, which lasted until 1910, when the Union of South Africa was formed in 1910. In 1928, the South African Medical and Dental Council (SAMDC) was appointed in terms of Act Number 13 of 1928, which was amended in 1974 (Health Professions Council of South Africa, 2020). Through a series of amendments, the SAMDC was subsequently replaced by the Health Professions Council of South Africa (HPCSA). The HPCSA consists of 12 professional boards, with the Professional Board for Psychology being one of them. The Professional Board for Psychology has the mandate to, among others, 1. Control and to exercise authority in respect of all matters affecting the education and training of persons in, and the manner of the exercise of the practices pursued in connection with, any health profession falling within the ambit of the professional board; 2. Maintain and enhance the dignity of the profession and the integrity of the persons practicing the profession (Health Professions Council of South Africa, 2020).

To practice in South Africa, a psychologist has to register with the HPCSA under any of the following categories: clinical, counseling, educational, industrial, or research. Besides, the HPCSA has provided for the registration of psychometrists and registered counselors who can be categorized as mid-level psychology professionals. Psychologists are expected to adhere to their scope of practice as outlined in the Regulations Defining the Scope of the Profession of Psychology.

One of the challenges that South Africa faces is the acute shortage of psychologists and other mental health professionals. A study by Docrat et al. (2019) has found that there were only 0.97 psychologists per 100,000 uninsured population in South Africa, between the years April 2016 and March 2017. Information obtained from the HPCSA indicated that, as of May 2, 2018, 8,773 psychologists were servicing a total population of ~57.78 million people in South Africa (Stats, 2019).

Apart from the statutory Professional Board for Psychology, there are several psychological associations operating in South Africa. The Psychological Society of South Africa (PsySSA) is the largest of these associations, with over 1,000 members (Psychological Society of South Africa, 2020). The society was formed in 1994 through an amalgamation of various psychological bodies that were in existence at that time.

## SECTIONS ASSESSMENT OF POLICY/GUIDELINES OPTIONS AND IMPLICATIONS

We present a comparative analysis of actions of psychology and potential outcomes during the COVID-19 in the BRICS nations regarding five aspects: psychology in health policies, social roles of psychology, socioeconomic context, actions for the general population, and health professionals during stage 1 of the pandemic, and possible actions in stage 2.

### Psychology in Health Policies Brazil

In Brazil, the first case of COVID-19 was reported around February 26, and quarantine began in several cities in March. By May, some cities enacted lockdown due to a high number of deaths. Since then, 349,113 cases have been confirmed, and 22,165 deaths occurred until May 24, 2020 according to the Brazilian Ministry of Health (2020b).

The Ministry of Health issued an ordinance n 639 on March 31, 2020, named “Brazil counts on me” (Brazilian Ministry of Health, 2020c) for recruiting health professionals, including psychologists, to work in cities with a shortage of workers. The TeleSUS made available information and guidance about COVID-19, using chat, apps, a telephone, and WhatsApp, aiming at increasing quarantine of potential cases or risk groups (<https://aps.saude.gov.br/apecoronatelesus>) but did not provide psychological care. Quarantine, lockdown, or other measures of social distancing were recommended at the discretion of governors and mayors but not by the Ministry of Health. In a controversial attitude, the Brazilian president not only did not recommend social distancing but also stimulated social gathering on public appearance in front of the official presidential palace, visiting shops and buying from street vendors in Brasília with national media coverage. These mixed messages concerning the severity of the pandemics were considered as a menace by the international community (The Lancet, 2020).

This was the first time that the Brazilian government has called on psychologists through “Brazil counts on me” (Brazilian Ministry of Health, 2020c). The Brazilian public health system hires psychologists to work in primary care in the Family Health Strategy (ESF) and in Family Health Support Centers (NASF), as mentioned above. However, until then, there was no work organized to serve the population at different levels of health care in biological disasters and aimed at the general population, patients, and healthworkers. Also, we did not have a tradition of online psychological care for health or training for psychologists in this field.

Brazilian psychologists have completely changed their professional activities, turning to online services. On March 26, the Federal Council of Psychology published a national resolution (Federal Council of Psychology, 2020a), reducing bureaucracy for psychologist’s registration for practice mediated by information and communication technologies. For instance, during COVID-19, psychologists can make use of information and communications technology to assist people during crises or

emergencies, which was forbidden before. Despite these changes, some limitations to online care were maintained so far, such as psychological assessment (Federal Council of Psychology, 2019), mainly concerning the use of some psychological tests, and, for some cases of forensic assessment, face-to-face service must be provided (Federal Council of Psychology, 2020b). The pandemic crisis has many potential sources of psychological distress (large-scale deaths, economic recession, unemployment, urban violence, lack of protective equipment, fear of contracting the virus, stigmatization). The provision of psychological services for mental health for the population, health professionals, and patients was a fundamental condition in this period (Torales et al., 2020).

Changes in regulation of telepsychology were crucial to the implementation of health policies, such as psychological care offering to the community, especially to health professionals. One of the first initiatives aimed at telepsychology to the population with mental suffering was a partnership between the Brazilian state of Rio Grande do Norte and the Federal University of Rio Grande do Norte.

Universities are providing teleservices [e.g., University of Juiz de Fora ([calmanessahora.com.br](http://calmanessahora.com.br)); State University of Londrina ([www.uelcontracoronavirus.com](http://www.uelcontracoronavirus.com))]. Federal University of Rio Grande do Sul associated with the Ministry of Health organized a call center to offer psychological support to health professionals involved in COVID-19 (<https://sites.google.com/hcpa.edu.br/telepsi/>), using an open platform for training and research. In the same way, Oswaldo Cruz Foundation of Brasília (Fiocruz), a research institution linked to Ministry of Health, produced a series of e-books about coronavirus (<https://www.fiocruzbrasil.fiocruz.br/coronavirus/saude-mental-em-tempos-de-coronavirus/>). From this material, an online course was created for several health professional categories, including psychologists. After completing this training, professionals will be allowed to use a telepsychology platform provided by Fiocruz.

COVID-19 associated with quarantine has produced changes in the psychological practices, bringing new challenges for professionals in Brazil. Researchers from the Brazilian Society of Psychology (BSP) have produced guidelines for psychologists (<https://www.sbponline.org.br/enfrentamento-covid19>) to guide evidence-based practice during the pandemic and a resource hub to provide links to different kinds of material related to psychological effects of COVID-19 produced by other scientific societies, researchers, and international health organizations.

## Russia

The COVID-19 pandemic has led to significant changes in the lives of Russians. To date, according to the official information (<https://xn--80aesfpebagmfb1c0a.xn--p1ai/>), more than 280,000 people are ill, 2,631 died. At least half of the cases detected in the capital of Russia, Moscow city, with a population of more than 12 million and over 17 million people live in the suburbs.

The self-isolation regime announced on March 30, 2020, during which, the majority of the population was compelled to stay at home, raised challenges that required a response from psychological science and practicing psychologists. Though, currently, in some regions, self-isolation regime is taken off in

Moscow, and in regions with detected high numbers of infected, it was prolonged until the end of May. During the last 15 years, Russian Psychological Society became deeply integrated with the education (elaboration of the educational standards for school- and university-level education). However, a lack of legislation on psychological help in the country due to the absence of specific regulations is probably the major challenge faced before and during pandemic, when the qualification of the service of volunteer psychologists became a relevant issue.

Rise in emotional reactions associated with the virus (fear of getting sick, anxiety for oneself and relatives, etc.), changing living and working conditions (cabin fever, violation of family structure, etc.), a situation of uncertainty about both the virus, and life at the end of the pandemic regime were detected.

## India

The first case of COVID-19 in the country was reported on January 30, 2020. This has increased to a total of 112,359 cases, 3,435 deaths in the country until May 21, 2020. So far, the majority of the cases had been reported in big cities, e.g., Mumbai, Ahmedabad, Chennai, Pune, Delhi, Jaipur. The COVID-19 outbreak was linked to people coming from outside the country initially, but, soon, it spread to many parts of the country. The Prime Minister of the country on March 22, 2020 asked the people to observe a Janta Curfew (voluntary public curfew), which found a massive support. This was a precursor to the forthcoming lockdown period. On March 24, 2020, a lockdown of the entire country was announced for 21 days, affecting the entire 1.3 billion population of India. On April 15, lockdown 2 was announced, extending the earlier lockdown until May 3, 2020, which was further extended to May 17, 2020 (lockdown 3). The Government decided to divide the country into three zones: Green Zone, Red Zone, and Orange Zone, having varying degrees of relaxations. We are now having another lockdown 4, until May 31, with more relaxations. During the lockdowns, various efforts were made by government agencies to make essential supplies available to people so that some of their hardships were taken care of.

The government launched a smartphone application called “Arogya Setu” to contain the spread of COVID-19 as well as to do contact tracing. The app intends to spread awareness of COVID-19 and to connect essential COVID-19-related health service to the people. The Ministry of Health and Family Welfare of India has created a separate section for behavioral health related to COVID-19 on its official website. The officials have actively been posting several audiovisuals, addressing the issues of social stigma related to COVID-19, stress management, depression, tobacco and alcohol consumption/addiction, practical tips on handling mental health during the lockdown, and taking care of the mental health of children as well as elderly. The Ministry early on undertook the role to create greater awareness of important issues, such as how to handle social isolation and has provided some practical tips to handle emotional problems, addressed “psychosocial issues among migrants during COVID-19,” among others. These efforts came as early as the last week of March, the week when the lockdown was announced for the first time in India. More and more resource material is actively being added to

the repertoire. A toll-free helpline number has also been issued, specifically to deal with psychosocial difficulties/issues (Ministry of Health Family Welfare Government of India, 2020).

A relatively young Ministry of AYUSH established in 2014 has also been playing an active role in the dissemination of information such as how to boost immunity and has provided simple ayurvedic procedures for cough and sore throat (Ministry of AYUSH, 2020). Ayurveda has for long played a central part in many people's beliefs and attitudes toward health issues in India. Positive informative messages from an official government ministry at a national level can help in boosting people's sense of security in these uncertain times.

The National Disaster Management Authority of Government of India on their home page created a subsection "COVID-19: Positive Stories" wherein various uplifting stories of generosity, positive developments in handling the COVID-19 virus, among others, are continuously published (National Disaster Management Authority, 2020a). Among the plethora of advisories from various ministries and departments of Government, the need to create social support and take care of the mental health of frontline workers was not forgotten (National Disaster Management Authority, 2020b).

However, government measures in dealing with mental health issues beyond providing resource materials and advisories are minimal. The fact that such issues have been acknowledged by the government is a positive step but still insufficient. The biggest concern in India is the well-being of the large section of the population, who are at the periphery. These include women, children, minority groups, other deprived groups based on caste and class as well as the physical and mentally challenged persons. Psychological associations face the biggest challenge to provide mental health services to this section. Several NGOs have also been very active. During COVID-19 times, these vulnerable groups have been worst impacted, challenging the unorganized psychological services in the country in many ways.

Using the Ministry of Health and Family Welfare's data source, NDMA created a list of COVID-19 warriors that total to 13,968,832. Among these are psychologists subsumed under allied and healthcare professionals at a paltry number of 532 and psychosocial care personnel that include M.Sc. psychology students and master of social welfare students with a total number of 1,163,46 (National Disaster Management Authority, 2020c). These figures do indicate that there is scope to further accept and strengthen the role of psychology in mental health services during these times.

## China

The CPS developed its Registry System for the Chinese clinical psychologists (RSCP) and set up criteria for qualification, continual education and training, and ethical standards (published in 2007, revised 2018) (Clinical Registration System of the Chinese Psychological Society, 2018). Soon after the COVID-19 breakout in early January of 2020, Chinese psychologists actively provided three levels of psychological assistance. At the first level, suggestions were provided to government agencies to take necessary actions to prevent public panic and promote psychological relief from the beginning of

the blockage. The psychological intervention has been integrated in the national emergency administration from the early stage. On January 26, China CDC issued the guideline of emergency psychological crisis intervention during the coronavirus outbreak. On 5th March, National Health Commission and the Ministry of Civil Affairs jointly issued a guideline to call for psychological assistance and social services for patients of the COVID-19, quarantined persons and frontline workers in epidemic prevention and control (Zhengkui et al., 2020).

Health administration and civil affairs departments in severely affected regions should organize professional teams to provide online and offline psychological assistance for frontline medical workers and disease-control personnel, as well as those who stick to their posts, including traffic police, logistics, and community workers, according to the guideline. On March 18, the State Council interagency task force issued "psychological counseling for those affected by COVID-19 (Jia et al., 2021), which called for sustained psychological counseling services, especially for COVID-19 patients, their families, families of fallen patients, vulnerable groups, health workers and those fighting the virus in the front line, including police officers and community workers. The psychological services (including lectures for general populations, individual counseling, and online self-helping programs-APPs) are mainly provided remotely via the internet or mobile phones (Li et al., 2021). Two weeks after the quarantine of Wuhan, the epidemic center of the COVID-19 breakout, on February 7, the National Health Commission released the guideline for psychological intervention hotlines during COVID-19, guiding the hotlines' setup, counselor training, and supervision. The guideline also addressed the importance of ethics in the distance counseling. Psychologists (especially those in the CPS Division of Clinical Psychology) have been working closely with governmental officials and psychiatrists and social workers at different levels. It is necessary to incorporate psychological support into the planning and construction of social governance and social psychological service system. Mental health of common civilians and the needs of a stable and harmonious society continue to drive the development of psychology in China.

From the nature of different subjects and a country's requirements of social psychological service system, group-oriented and individual-oriented social psychology are inevitably apart in many aspects, as service recipients, service concepts and ideas, service implementation, etc. It is recommended to build the social psychological service and social governance system based on social psychology, instead of only from the perspective of individual psychological health.

Traditional Chinese culture emphasizes more on group rather than individual. It is easier for group-oriented social psychology to study and design the construction of the social governance and social psychological service system from a macro level. Praise to the Traditional Chinese Medicine, together with the western medicine, the COVID-19 pandemic had been actually contained in Wuhan (and all around China) in late March 2020. However, the home quarantine policy had been strictly, whenever required. Psychological supports have been provided systematically throughout China at the community level, with

focuses on arch hospitals and schools/universities, mainly via online services.

All the above highlight and reinforce the importance of group-oriented social psychology in the construction of social governance and social psychology service system.

## South Africa

As of May 23, 2020, the total number of people infected with COVID-19 was 21,343. This survey is updated regularly on the South African government website that was launched specifically to communicate information about the pandemic [see SA Coronavirus (n.d.)].

On March 15, 2020, the South African Minister of Cooperative Government and Traditional Affairs declared a National State of Disaster in terms of the Disaster Management Act Number 57 of 2002. Through the National Disaster Management Center, which is provided for in the Act, the government is required to “promote an integrated and coordinated system of disaster management, with special emphasis on prevention and mitigation by national, provincial, and municipal organs of state, statutory functionaries, (and) other role players involved in disaster management and communities” (Department of Cooperative Governance and Traditional Affairs, 2002).

Informed by this Act, the South African national government has welcomed the involvement of individuals and professional groups that have offered to assist the government in its response to COVID-19. Consequently, psychologists in South Africa have individually and collectively come forward and are now involved in efforts spearheaded by the government to contain the pandemic. For instance, the Psychological Society of South Africa is one of the organizations that have formed what is known as “HealthCare Workers Care Network (HWCN),” an organization made up of psychologists, psychiatrists, anesthesiologists, medical doctors, and other health professionals. This multi-stakeholder initiative aims to support health care workers during the COVID-19 pandemic and beyond (Psychological Society of South Africa, 2020). Currently, this organization provides training, webinars, and psychoeducational information for healthcare workers. It also uses volunteers to offer individual and group support to healthcare workers. All mental health initiatives that are influenced by the Disaster Management Act are likely to have important psychosocial benefits for vulnerable groups, such as homeless people, the elderly, children, and those exposed to violence, drugs, and substance abuse.

At the beginning of May 2020, the country transitioned into Level 4 of the five-stage risk-adjusted response, with Level 3 due to start on June 1, 2020. As shown in **Table 1**, Level 4 provides for extreme precautions to limit community transmission and outbreaks, while allowing some activity to resume. Some of the activities that were allowed during this level were limited wholesale, retail, manufacturing, and agricultural and health activities. While less severe, Level 3 will still impose restrictions on work and social activities to address the high risk of transmission. Some high-density settlements will be declared hotspots during Level 3. A hotspot is defined as “... an area that has more than five infected people per 100,000 people or

where the new infections are increasing at a fast pace” (President Ramaphosa speech, May 24, 2020).

Due to the restrictions imposed on individuals during the pandemic, the Health Professions Council of South Africa (HPCSA) had to revise its guidelines on the provision of online health services. In its original General Ethical Guidelines for Good Practice in Telemedicine, the HPCSA discouraged health practitioners from routinely servicing their patients virtually (Health Professions Council of South Africa, 2020). In a recent notice issued on March 26, 2020, in response to COVID-19, the HPCSA pronounced that “telehealth is only permissible in circumstances where there is an already established practitioner-patient relationship, except where telepsychology and/or telepsychiatry is involved; in which case, telehealth is permissible even without an established practitioner-patient relationship” ([https://www.hpcs.co.za/Uploads/Professional\\_Practice/FAQ\\_Professional\\_Practice.pdf](https://www.hpcs.co.za/Uploads/Professional_Practice/FAQ_Professional_Practice.pdf)). This new development provides an opportunity for psychologists to explore new avenues for providing mental health services for their clients, now and possibly, in the future. As a result of this reform, many telehealth platforms are now inviting health professionals to attend webinars that offer some form of training on how to provide telehealth services, including a teletherapy and counseling (for example, see [www.ezmed.solutions](http://www.ezmed.solutions) and [www.cgm.com/za](http://www.cgm.com/za)). The medical insurance companies have also come out in support of telehealth services by assuring psychologists and other health professionals that they will reimburse the service providers for this alternative service [for example, see *Discovery Health* (n.d.)].

It is important to register that 26 years after the demise of a colonial government that guaranteed more privileges for a minority community of European descent when compared with indigenous African communities, the majority of South Africans continue to have little or no access to mental health services. One of the key focus areas of the Psychological Society of South Africa before COVID-19 has been to actively strive for social justice by opposing policies and practices that deny individuals or groups access to mental health services.

## Social Roles of Psychology Brazil

The COVID-19 pandemic has exacerbated social inequalities (Dorn et al., 2020) in different countries, and Brazil is no exception. Considering that one-third of households do not have adequate sewage collection, 15.1% do not have running water (Brazilian Institute of Geography and Statistics, 2018) and the high number of homeless people and prisoners who cannot be in social isolation, basic preventive care is not available to everyone. Besides hampering basic care, inequality *per se* tends to intensify during the pandemic. Prejudice (Bavel et al., 2020) and domestic violence (Marques et al., 2020) are expected, among other implications. In this sense, psychologists should be able to offer psychosocial support to those facing inequalities during this period. CRP and its regional councils advised psychologists on the importance of psychosocial support for different vulnerable groups, such as homeless people (Regional Council of Psychology-São Paulo, 2020) and prisoners (Regional Council of Psychology-Bahia, 2020; Regional Council

**TABLE 1** | Summary of alert levels in South Africa [adapted from SA Coronavirus (n.d.)].

Alert level	Level 5	Level 4	Level 3	Level 2	Level 1
Objectives	Drastic measures to contain the spread of the virus and save lives	Extreme precautions to limit community transmission and outbreaks, while allowing some activity to resume	Restrictions on many activities, including at workplaces and socially, to address a high risk of transmission	Physical distancing and restrictions on leisure and social activities to prevent a resurgence of the virus	Most normal activity can resume, with precautions and guidelines followed at all times. Population prepared for an increase in alert levels if necessary

of Psychology-São Paulo, 2020). Moreover, scientific societies, universities, and different groups of psychologists have mobilized to deal with other social problems, such as prejudice, domestic violence, and fake news.

### Prejudice

Prejudice is a hostile attitude toward groups or individuals for being part of certain groups (Allport, 1954). During the pandemic, hostility toward Chinese has grown, even promoted by some Brazilian politicians (Globo, 2020). There are also reports of health professionals being stigmatized (Markman, 2020). Seeking to reduce the occurrence of prejudice and discrimination, the Brazilian Psychological Society prepared a document with guidelines for facing stigma and prejudice during the pandemic (Peucker and Modesto, 2020).

### Domestic Violence

Domestic violence has been one of the consequences of social distancing (Chandan et al., 2020). In Brazil, it is estimated that, in March (when social distancing measures were announced in the country), the increase in domestic violence was 17% (Marques et al., 2020). Seeking to reduce the problem, scientific societies and groups of researchers have sought to inform psychologists and the general population about the different types of domestic violence (Curia et al., 2020), conflict mediation strategies in the family (Soares and Modesto, 2020), as well as channels to Brazilian institutions that offer psychosocial support (Mello and Modesto, 2020).

### Fake News

Besides social inequality, the spread of fake news in social media became another problem for public health in Brazil (Thomas et al., 2018; Waszak et al., 2018). Also, the Brazilian president took a stand against social isolation and minimized its consequences, which has been a problem for the country, according to an editorial in *The Lancet* (2020). Brazilian researchers analyzed the influence of fake news on prevention behaviors during the pandemic and found out that belief in fake news was associated with less social distancing (Modesto et al., submitted)<sup>1</sup>, although political polarization has a more robust effect than fake news (Modesto et al., 2020). Many scientific societies in Brazil have shared WHO, PAHO recommendations, as well as producing accurate material that aims to confront fake news.

<sup>1</sup>Modesto, J. G., Keller, V. N., Rodrigues, C. M. L., and Lopes, J. L. S. (2020). The moderating role of belief in a just world on the association between belief in fake news and prevention behaviors during the Covid-19 pandemic (Manuscript submitted).

### Russia

While organizing psychological assistance in the usual ways (in person) is not possible, the possibilities of online counseling are widely used. The Russian Psychological Society, the Russian Academy of Education, Faculty of Psychology, Lomonosov Moscow State University organized several hotlines for psychological assistance [including a united 24/7 hotline on the website of COVID-19, organized by the Russian Government (<https://xn--80aesfpebagmfb0a.xn--p1ai/>)]. In total, more than 1,000 psychologists participate in the work of hotlines of federal and regional significance.

### India

The role of psychology is immense in these circumstances. Several psychologists, as well as NGOs involved in elderly care, homeless people, and vulnerable sections of the population, are actively participating in providing relief and mental health services. Psychology associations are playing an active role as well as psychologists and healthcare professionals associated with medical institutions. For instance, a relatively new Association of Health Psychologists (AHP) took an active initiative in extending its services during the time of COVID-19. It was the first professional organization to launch online counseling in the first week of April 2020 for anyone directly or indirectly affected by COVID-19 or the lockdown-related psychological issues. The first initiative was in Hyderabad under the banner of “SERV,” an acronym for “Social Emotional Rehabilitation of Virus Victims.” This was launched in collaboration with UNICEF, Action Aid, Dr. Reddy Foundation-School Improvement Programme, APTS Social Service Forum, and Asha Hospital. Counselors with the highest academic background and years of experience are available on a helpline 24 × 7. Encouraged by the response, the AHP started similar helplines in collaboration with Sri Padmavathy Mahila University Thirupathy, Andhra Pradesh, Orissa Central University, Koraput, Odisha, Calcutta University, West Bengal and Bangalore, Karnataka in collaboration with UNICEF. The counselors attended thousands of calls from different parts of the country as well as a few calls from Indians residing in other countries. In initial months, the calls related to general anxiety of the “fear of unknown”; insomnia; interpersonal conflicts due to home confinement leading to a situation called “home crowding”; the anxiety of frontline health care workers; the psychological distress of people in quarantine centers; panic attacks of people of all ages, gender, and geographical location; anxiety of students due to uncertainty of examination schedule; financial problems; non-availability/accessibility of regular medicines due to lockdown; precipitation of pre-existing

mental health problems; issues related to migrant labor; and also calls from victims of domestic violence, to name a few. Apart from COVID-19/Lockdown-related problems, the helpline has been receiving calls related to other psychosocial problems. Because of this, the helplines are continuing through, and the number of COVID-19-related calls has been gradually reducing.

Several initiatives were taken by other associations as well (which will be discussed in a later section); however, looking at the population of the country, the problems are immense and can be tackled only with the combined efforts of all. More and more psychologists should be involved by the government in these times as in when there is a second wave of COVID-19 later in the year, mental health concerns are going to become pivotal. Many people have lost their jobs, and as time passes and they do not get economic relief, mental health concerns are going to become acute. It is not to say that mental health concerns are not important now. The concerns because of lockdown are related to fear, anxiety, social isolation, lack of human stimulation, working from home, and making the fine balance between home and work. Once the lockdown is lifted, as no society can be in a state of complete lockdown, the fear is related to a surge in cases of corona infections, disease, death; all of which may lead to serious mental health concerns. Psychology associations should make the government start focusing more on mental health issues of the most vulnerable sections of the society.

### **Fake News**

News items and images not related to COVID-19 times were shared and created fear and panic among citizens. The government is tackling the problem of fake news by requesting social media platforms to remove and not promote messages that will weaken the government's efforts during these times. The media is continuously being requested to play a very responsible role and help in countering fake news. Some news channels are doing a commendable job of alerting people to fake news. In these times, responsible sharing of news has to be followed, but, as is the current situation, fake news is rampant. Irresponsible forwarding of messages on social media should be avoided. The Government of India has recently issued a directive, asking social media companies to voluntarily curb fake news and misinformation related to the coronavirus on their platforms. This is considered as an important step to prevent the community transmission of the disease. A lot of psychology research shows that, in times with a lot of uncertainty, rumors and propaganda of various kinds have easy acceptability among the masses. Stern and prompt actions are needed; otherwise, it will play havoc with people's life and health. Together with the government, it is also important that we, citizens, not only exercise caution but debunk such messages.

## **Socioeconomic Context**

### **Brazil**

About 13 million Brazilians live in favelas. Hygiene recommendations are near impossible to follow in these environments because of the high demographic density and lack of treated water. Communities in favelas have organized themselves to implement measures on their own (The Lancet,

2020). The prevalence of deaths and contamination by Sars-Cov-2, inconsistent government measures of social isolation, quarantine and lockdown, and their long-term impact will widen such existing socioeconomic disparities. Therefore, the impact of COVID-19 on mental health is also greater in economically disadvantaged populations (Frasquilho et al., 2016; Mental Health Foundation, 2020; Nações Unidas Brasil, 2020). The universal income program Bolsa Família was established in 2003, and today, it serves 13.1 million families (40.8 million people), who receive an average benefit of R\$ 188.86 per month. In the crisis caused by COVID-19, an emergency aid (R\$600, equivalent to U\$100, for 3 months) was made available to informal workers, individual micro-entrepreneurs, self-employed, and the unemployed; 60 million citizens requested it (<https://www.gov.br/pt-br/servicos/solicitar-auxilio-emergencial-de-r-600-covid-19>).

Brazil has a large informal employment sector, with many sources of income no longer an option (The Lancet, 2020). Considering the economic impact of the pandemic in Brazil, a survey carried out by the National Confederation of Industry (CNI) in May 2020, with 2,005 people over the age of 16, in 27 states, found out that Brazilians lost their purchasing power; 23% of respondents lost their income, and 17% had losses in their monthly income, which represent almost 40%. The fear of losing a job was reported by almost 80% of the respondents, and 9 out of 10 people rated the impact of COVID-19 on the Brazilian economy as significant. According to the data, 40% of the respondents reported having overdue accounts in the last 40 days (Agência Brasil, 2020).

With around 55% of the entire global population without access to social protection, these losses will harm many sectors, such as education, human rights, and in the most critical cases, basic food security and nutrition. Hospitals with limited resources (i.e., lack of personal protective equipment for health professionals), deficient health systems are expected to collapse. This could worsen with a peak in the number of cases since up to 75% of the population in the least developed countries do not have access to hygienic supplies. Other social conditions, such as precarious urban planning and overpopulation, deficient waste management services, and even traffic jams that prevent access to health care, can contribute to drastic growth in the number of cases of COVID-19 (Nações Unidas Brasil, 2020). In this context, it is crucial to take into account the broad socioeconomic consequences of pandemic crisis, which will have serious impacts on mental health by increased rates of unemployment, financial insecurity, and poverty (Barr et al., 2015; Holmes et al., 2020).

Many private companies have decided to help various segments of society, with hygiene items, food, clothing, and water donations, supported by the tax incentive laws. One example of organized action of the private sector is Todos pela Saúde (<https://www.todospelasaude.org>).

COVID-19 initially reached large urban centers in Brazil, concentrated in the industrialized state of São Paulo. However, it has advanced rapidly across the country, hitting badly the states of Amazonas and Pará and extending to indigenous territories in the Amazon. Amazonas is the Brazilian state with the largest number of indigenous people. According to the IBGE, the state has 183,514 indigenous people; of which, 70% live

in villages. Many communities are lacking basic hygiene items (soap, treated water) to reduce the risk of contagion. People also live in villages and share utensils, which increases the chance of contamination. Indigenous communities also live in areas where there is limited access to healthcare, particularly intensive care beds (BBC News, 2020). Federal government has been ignoring or even encouraging illegal mining and logging in the Amazon rainforest, and, now, these loggers and miners risk bringing COVID-19 to remote populations (The Lancet, 2020). As contingent action, the Federal Government sent financial aid to the State of Amazonas. By the end of May 2020 will be inauguration of the first health area dedicated to the care of indigenous patients with COVID-19 in the State of Amazonas. It will have 53 beds, 33 clinical beds, 10 Intensive Care Units (ICU), and five Intermediate Care Units (ICU). There will also a space for spiritualization destined to shamans—spiritual leaders of indigenous peoples (Ministério da Saúde do Brasil, 2020).

### India

One of the major social problems that have been highlighted during COVID-19 times is the sharp divide between the haves and the have-nots, the rural and the urban, and the privileged and the vulnerable sections of the society. This divide was already there but got highlighted during this time. Visuals on television of thousands of migrants fleeing from major cities to their villages are very disturbing. With factories and workplaces shut down, many migrant workers were left with no food, money, and shelter. There was thus a mass exodus from big cities. Because of the lockdown, this was a major issue. The government has been arranging relief camps for these people, announced an economic package for them and requested companies/employers to pay the workers their salary during the lockdown period. Unemployment has risen and lots of migrant workers had no choice but to return to their homes. There are some apprehensions associated with this exodus to the rural areas. As a large number of migrant laborers are returning from big cities which are the hot spots for COVID-19, the fear of the pandemic in rural areas is frightening as health infrastructure is insufficient in these areas. The lived realities of the past few months were tumultuous and catastrophic for most migrant workers, especially women, and, unfortunately, mental health, and psychological services available to them are at the bare minimum, except those provided by some NGOs. What is of utmost importance in the Indian scenario is to compile data related to psychological services and psychology professionals, as, at present, in the absence of such documentation, it becomes difficult to comment on the role of the psychological associations during this pandemic.

### South Africa

The South African government imposed a national lockdown that lasted for 6 weeks, starting on March 26, 2020. In his address to the nation, President Cyril Ramaphosa pointed out that the national lockdown is one of the five alert levels of the South African government's risk strategy to respond to the spread of COVID-19. As reflected in **Table 1**, alert Level 5 of the national lockdown was the most stringent measure that entailed the closure of schools, businesses, and recreational facilities,

except essential services. This alert level had a significant negative impact on the health, social, and economic lives of individuals and communities. For instance, a national survey by the Human Sciences Research Council (HSRC) found out that between 45 and 63% of those surveyed reported that the lockdown would make it difficult to pay bills, debts, earn income, feed their families, and keep their jobs (Human Sciences Research Council, 2020). The restrictions on people's movements also meant that some patients who needed to receive medical and psychosocial services could not access these, as public transport was not readily available.

The national government put in place some socioeconomic measures that were aimed at individuals, families, and businesses to mitigate against negative impact of COVID-19. At individual and family levels, the interventions introduced included payment of a social relief grant, a distress grant to the unemployed, and an increase in the social grant amount paid to the indigent, among others. For businesses, the government introduced tax relief, economic stimulus measures, and employment-related measures, such as the employment tax incentive that encourages employers to hire young unemployed job seekers. While these measures have assisted greatly in minimizing the negative impact of the pandemic, there have been several challenges associated with these government initiatives. These include a lack of capacity on the part of national and local governments to roll out so many socioeconomic measures in a short space of time.

## Actions of Psychology for the General Population and Health Professionals During Stage 1 of the Pandemic Brazil

The Conselho Federal de Psicologia, the regulatory agency or professional psychology, registered psychologists for online practice and provided basic professional guidelines for work during COVID-19 (e.g., to provide services in ventilated places, allowing a distance of 1 to 2 m between people). If a professional chooses to provide online psychological services, he or she must follow previous guidelines (CFP Resolution No. 11/2018) and register to do so in the respective Regional Psychology Council.

The Brazilian Society of Psychology (BPS) constituted a Working Group of professional researchers who sought to base their actions on developing strategies for training and supporting this professional category in coping with the situation of COVID-19. The work was developed using scientific and technical criteria, using evidence to support their decisions and guidelines. The first step was to publish fascicles, available free online at the SBP homepage (<https://www.sbponline.org.br>). Moreover, links with relevant information about the pandemic from reliable sources were also made available by SBP.

So far, 10 topics have been developed with updated information to contribute to the professional practice of psychology. The texts are brief and objective and seek to help understand the context, identify the concepts involved, learn about alternatives, and monitor interventions. The first edition addresses the technical guidelines for the work of psychologists in the context of the COVID-19 crisis and contextualizes the

pandemic and provides guidelines for psychologists to work with health professionals. The second topic entitled “Stress in Health Professionals Who Care for Patients with COVID-19,” defines stress and presents clinical examples of professionals who work with patients with COVID-19. It identifies its possible manifestations, individual and institutional management, as well as the monitoring of the interventions performed. In the third topic, the three Ds are addressed: despair, helplessness, and hopelessness in health professionals. Key D concepts, individual reactions, and examples of verbalizations of fear, despair, helplessness, hopelessness, and suicidal ideation are defined. They present factors that determine the way people face a crisis (previous experience of crisis, support system, and history of mental disorders) and the first psychological aids: welcoming and active listening, psychoeducation, helplessness approach, focuses on despair, coping fear, focus on hope, problem-solving, assessment of ideation, and suicide risk. The fourth topic deals with the stigmatization of health professionals. It contextualizes the problem, defines stigma (internal and external), and provides management strategies, such as access to information, awareness, and ethical posture. In the fifth topic, recommendations are presented for the on-line and online professional practice of psychology in the face of the COVID-19 pandemic. It addresses the alternatives on how to offer the first psychological help to health professionals working in hospitals. It guides through how to proceed with online, voluntary, in-person, and hospital care. The sixth topic deals with mourning and reviews the concept, demonstrating the physical and emotional reactions experienced in this process and the alternatives for the psychologists to address this theme. In the seventh topic, issues related to the management of conflicts in the family are presented. It discusses how isolation predisposes to the appearance of conflicts and presents strategies for handling the situation, with steps for resolving conflicts. The eighth topic discusses the management of sleep disorders in the context of coping with COVID-19. It demonstrates how the pandemic can predispose to sleep disorders and identifies management strategies. The ninth topic presents the theme of psychological support for parents of children from 0 to 11 years old during the COVID-19 pandemic. It seeks to provide support for the psychologists to work with parents and provides behavioral management strategies during isolation. The 10th topic addresses issues related to violence against women. The different forms, phases, and consequences of this type of violence are defined. Alternative actions are presented, as well as techniques and devices that are usually used in the situation.

The TelePSI Project (<https://sites.google.com/hcpa.edu.br/telepsi/>) is an initiative of the Ministry of Health of the Brazilian Government, in partnership with the Hospital de Clínicas de Porto Alegre, which received the support of several academic institutions and societies, including the Brazilian Society for Psychology. In TelePSI, contracted psychologists and psychiatrists offer psychological and psychiatric consultations to manage stress, anxiety, depression, and irritability in health professionals and students, teachers of all levels of education, and professionals of essential services. They receive specific

online training and supervision, and data are collected to compare the effectiveness of different interventions are clinical and scientific supervision group for evaluating different types of psychotherapy for emotional problems during the pandemic, and disseminating psychoeducational materials. Oswaldo Cruz Foundation of Brasília (Fiocruz) planned a similar teleservice provided by trained volunteer psychologists.

## Russia

### *Psychoeducation*

Psychologists have been actively involved in informing the public about how to organize their lives in conditions of self-isolation with children, the elderly, alone, etc. RPS has elaborated recommendations for various groups of the population on organizing the activities during the period of isolation (<http://xn--n1abc.xn--p1ai/news/themes/8462/>), as well as their promotion through Federal and regional media regularly. During 2 months, representatives of the Russian Psychological Society made more than 150 interviews to the media and more than 30 interviews on Federal and Regional TV channels in the frame of talk shows, expert talks, etc., making recommendations for the public concerning the organization of the daily routine, coping with anxiety and stress, organizing activities for children, and exposing relevant fake news.

Starting from March 16, 2020 students of all higher educational institutions in Russia were urgently transferred to distance learning, which created a lot of organizational and psychological difficulties and became a source of stress for all the participants of the educational process. This shift toward distant learning was successful due to such well-established platforms as [distant.msu.ru](http://distant.msu.ru), [webinar.ru](http://webinar.ru), etc.

Due to anonymity, online education at the university led to cases of cyberbullying, cybertrouling, spamming, which became the reason for the development by the RPS of recommendations addressed to university teachers on how to behave properly in such situations to protect themselves and students from cyber interference.

A separate task for psychologists in the field of education was maintaining the motivation of students who were torn out of the usual educational context. The recommendations developed by the RPS allowed teachers to support the students' engagement in distance learning situations. At the same time, the psychological services of the universities monitor the psychological state of teachers who find themselves in a situation of increased stress.

No less challenging was the situation and the organization of the distant educational process at schools and preschools. The transition to distance learning became possible, thanks to the previously introduced Russian Electronic School (<https://resh.edu.ru/>), Moscow Electronic School (<http://mes.mosedu.ru/present-en/>), which is an official all-Russian resource for schooling as well as other resources, such as Yandex.Uchebniki (<https://education.yandex.ru/home/>), «Advance», «iSpring», «InternetUrok.ru», «Unicraft», etc. The actual collision of the norms of family life and the norms of the school in the situation of the distant organization of the educational process led to conflicts between teachers and parents, and increased stress. RPS has developed relevant

recommendations for both teachers and parents to optimize the organization of the educational process and normalize relations between family and school.

### **Work With Medical Staff**

In April 2020, psychologists faced the challenge of implementing psychological assistance for medical personnel experiencing a high workload and stress. Representatives of the Russian Psychological Society provided methodological assistance in the systemic psychological support of management, medical personnel, patients, and their relatives in medical institutions for patients with COVID-19. Telepsychology was organized both for medical personnel and for patients and their relatives. However, in special cases, offline work was organized.

Leading specialists of the Faculty of Psychology of the Lomonosov Moscow State University, the Russian Academy of Education, and the Russian Psychological Society, together with the Federal Medical Biological Agency of Russia, and, personally, its head, Veronika Skvortsova, had developed “psychological thermometers” for adult patients and patient-children and medical staff who provide medical care for patients with COVID-19 ([http://fmbaros.ru/psikhologicheskaya-podderzhka/detail/?ELEMENT\\_ID=38750](http://fmbaros.ru/psikhologicheskaya-podderzhka/detail/?ELEMENT_ID=38750)).

With the help of such “psychological thermometers,” one can independently measure emotional state in an online format and get instant feedback on self-help measures, the required support from colleagues, and, also, the need to seek professional psychological help in the respected psychological service of the hospital or medical center where the person is working or receives treatment.

## **India**

As already mentioned earlier, the major psychology associations are making significant contributions furthering the role of psychology as a science and profession in the country. We have three major associations: National Academy of Psychology, India (NAOP, India), which represents India in the IUPsyS; the Indian Association of Clinical Psychology (ICAP); and Indian Academy of Applied Psychology (IAAP). As discussed by Manickam (2016), together these three associations may have a membership of over 4,000 psychologists, which, certainly, do not match the vast requirements of the country. The Indian Association of Clinical Psychology has been making pioneer contributions during COVID-19 times. Indian Association of Clinical Psychology (IACP) has taken an initiative to form a “COVID-19 Psychological Support Group.” This initiative is providing free telephonic/online counseling for people in emotional distress. As a part of this program, they are training volunteers so that they can help in providing psychosocial support for the callers. The association is also providing psychoeducational tips for parents/caregivers of person with disabilities. Modules on how to handle emotional and behavioral problems, behavioral management, and coping with COVID-19-related stress are also being provided for the general public. The association is also providing various kinds of psychological support for migrant workers who are facing difficult times as well as frontline workers (doctors, nurses, police personnel,

etc.), who are working hard under difficult circumstances to provide health care. The Indian Academy of Applied Psychology (IAAP) has been providing online support, educating people with authentic information about COVID-19, extending help, counseling, and giving appropriate referral services to manage stress. In addition, the association is organizing special events like essay competitions and other activities related to the psychological impact of COVID-19 to increase awareness about the disease. The National Academy of Psychology (NAOP, India) has been extending support by disseminating information related to prevention and protection through webinars on issues related to pandemic and vulnerability during these times. Online support is also being provided through counseling. Besides these major associations of the country, a large number of NGOs and other associations are also contributing significantly in terms of providing mental health services, training the counselors to provide help for those who are in desperate need of assistance.

India’s experiences in the pandemic of COVID-19 have shown that a better public health system with special programs based on various sections of the society is needed (Kumar et al., 2020). Though it started as a disease in urban areas, the fear of the disease spreading to rural areas is a big one. In a country like India, where 65–68% of the population live in rural areas and these areas already have the highest overall burden of disease and accompanied lack of health facilities, it is a major risk factor. As Kumar et al. (2020) argue there is the need to take immediate steps to control the spread and its aftereffects and to use this opportunity to strengthen and improve its primary health care system in rural India. The health care system is not adequate or prepared to contain COVID-19 transmission in the rural areas because of the shortage of doctors, hospital beds, and equipment, especially in densely populated states (Mitra, 2020).

As Nayar et al. (2020) posit, it is important to understand the forms of emotional disturbances among the different age groups as well as different sections of the society. A new form of “othering” is seen in society. Who is the other is being redefined. The same colleague, domestic help, and neighbor are now seen as the other due to the suspicion that they may be potential carriers of infection. There is a kind of dichotomized world view that is prevalent (Nayar et al., 2020), which has altered the fabric of the society where everyone is fearful of getting infected, despite the “not me” syndrome. Additionally, scores of people have lost their sources of income. For most people, priorities in life are changing, putting an additional burden of stress.

## **China**

The Clinical Psychology Registration Work Committee of the Chinese Psychological Society (hereafter referred to as the “Registration System”), as a self-regulated professional organization of clinical and counseling psychology, devoted itself to the psychological aid after the outbreak of the COVID-19 pandemic and explored effective approaches and methods for psychological aid!

1. Speak up as professionals. The Registration Work Committee started to work on January 23 and issued a written proposal to all the psychological professionals across the nation on January 26, and advocated that all the psychological aid should

be integrated in the national framework in fighting the COVID-19, and underlined the need of multi-department cooperation. It reaffirmed the professional ethics and strongly emphasized that all the psychological aid should be conducted scientific orderly and conform to professional standards.

2. Set up an organizational structure. The Registration Work Committee set up the organizational structure on January 25 and established several working groups with different functions to ensure orderly development, including the supervision group, the popular science dissemination, the information resource acquisition, and so on.

3. Give full play to the superiority of the Registration System members. A group of 161 registered clinical psychology supervisors, who were willing to supervise, was released to the public on the WeChat Official Account, providing free supervisory resources for counselors, and psychotherapists.

4. Enhance the competencies in psychological aid. The sudden outbreak of the COVID-19 emerged in a fast spread and affected widely, and as a result, most psychological aids were conducted through hotlines, including the popularization of the medical knowledge of the COVID-19. The Registration Working Committee decided to work in a pyramid model due to the specialties of the COVID-19, referring to training registered psychology supervisors and providing guidelines and approaches for them to supervise counselors and therapists who work in the front line. From January 28 to May 20, a total of 32 training sessions and supervision have been arranged for registered supervisors with a total of more than 1,600 participants. Nearly 10 million people received training and supervision focused on hotlines, psychological stress, and crisis intervention provided by the trained supervisors.

5. Timely release professional guidance documents as a leading professional organization. Guidelines for Psychological Aid Hotline under the Contagion Fight, Guidelines for Online Psychological Aid under the Contagion Fight, Ethics for Psychological Hotline (First Draft), and Ethics for Online Counseling (First Draft) were released continuously from January 31, leading professionals to conduct within competencies and comply with the ethics.

6. Cooperate with governmental officials and peer colleagues from other professionals (social workers, psychiatrists, etc.). To cooperate with the National Health Commission, the competent government department for psychological aid during the COVID-19 pandemic. The Registration Work Committee put forward targeted psychological aid policies for the country and the specific population affected by the epidemic, for e.g., timely proposing the overall plan of psychological aid construction for the Arch hospitals built in Wuhan. Besides, it joins hands with other academic organizations, such as the Chinese Association for Mental Health, China Association of Social Psychology, in fighting against the COVID-19 pandemic to share resources and joint proposals.

7. Promote the popular science on the major media. Make knowledge dissemination of audio or videos programs on how to promote mental health in the pandemic period and provide the public with knowledge and methods on mental health to adjust the mentality and be positive and optimistic.

## South Africa

At the beginning of May 2020, the country transitioned into Level 4 of the five-stage risk-adjusted response, with Level 3 due to start on June 1, 2020. As shown in **Table 1**, Level 4 provides for extreme precautions to limit community transmission and outbreaks, while allowing some activity to resume. Some of the activities that were allowed during this level were limited wholesale, retail, manufacturing, and agricultural and health activities. While less severe, Level 3 will still impose restrictions on work and social activities to address the high risk of transmission. Some high-density settlements will be declared hotspots during Level 3. A hotspot is defined as “... *an area that has more than 5 infected people per 100,000 people or where the new infections are increasing at a fast pace*” (SA Coronavirus, n.d.).

Due to the restrictions imposed on individuals during the pandemic, the Health Professions Council of South Africa (HPCSA) had to revise its guidelines on the provision of online health services. In its original General Ethical Guidelines for Good Practice in Telemedicine, the HPCSA discouraged health practitioners from routinely servicing their patients virtually (Health Professions Council of South Africa, 2014). In a recent notice issued on March 26, 2020, in response to COVID-19, the HPCSA pronounced that “telehealth is only permissible in circumstances where there is an already established practitioner-patient relationship, except where telepsychology and/or telepsychiatry is involved; in which case, telehealth is permissible even without an established practitioner-patient relationship” (Health Professions Council of South Africa, 2020). This new development provides an opportunity for psychologists to explore new avenues for providing mental health services for their clients now and, possibly, in the future. As a result of this reform, some telehealth platforms are now inviting health professionals to attend webinars that offer some form of training on how to provide telehealth services, including teletherapy and counseling (for example, see [www.ezmed.solutions](http://www.ezmed.solutions) and [www.cgm.com/za](http://www.cgm.com/za)). The medical insurance companies have also come out in support of telehealth services by assuring psychologists and other health professionals that they will reimburse the service providers for this alternative service [for e.g., see Discovery Health (n.d.) and GEMS (n.d.)].

## Possible Actions in Stage 2

### Brazil

There is a COVID-19 Clinical Care Protocol for Primary Care, which does not provide psychological care for these patients (Brazilian Ministry of Health, 2020a), despite the number of psychologists in SUS. Currently, psychologists working in primary care (UBSs) interrupted their routine care (e.g., guidance groups) and performed only welcoming, referring patients who required mental health care to the Psychosocial Care Centers (CAPS) (Brazilian Ministry of Health, 2020b).

CAPS also changed their routine during the pandemic. There is a dispensation of psychiatric medication with a longer term (e.g., for 3 or 6 months, depending on the characteristics of the patients), constant monitoring (weekly or fortnightly) by

the technicians (e.g., psychologists), weekly individual attendance for severe cases only (with personal protective equipment) (only one patient and one companion at a time) or home care, after screening for COVID-19 symptoms.

Health institutions (e.g., hospitals) started to provide psychological care for families of inpatients or those who died as a result of COVID-19 and health professionals who care for these patients. Networks were organized to provide psychological assistance for health professionals by universities, associations, and groups of psychologists. Besides, starting in May 2020, online psychological care by SUS is foreseen for health professionals (FIOCRUZ, 2020), which is already happening in some teaching hospitals in the country.

It is expected that, in the second phase of the pandemic, Brazilian Society for Psychology and other scientific societies will continue to support the work of psychologists facing the new challenges. The aim is to improve professional skills and competencies, providing training and supporting the development of technologies and service protocols. Moreover, the scientific production in psychology in the context of COVID-19 must reach the professional psychologists and benefit the population. Communication about the professionals' practice and increased accessibility to psychological services through psychoeducation and telepsychology should be sought.

### Russia

Representatives of RPS, as well as researchers all over the world, are actively engaged in monitoring the mental conditions of various population groups across Russia, identifying factors that are crucial to the successful accommodation to the period of self-isolation and building strategies for future. RPS, in collaboration with the leading Russian universities supported by The Ministry of Science and Higher Education of the Russian Federation, has started a project "Research at Home." The purpose of this research is to assess psychological well-being among the student population ( $N = 6,550$ ) to develop evidence-based recommendations to decrease negative effects and increase positive consequences of self-isolation. The results obtained showed no differences in the levels of psychological well-being, significantly lowered levels of depression, anxiety, and stress during the period and higher levels of anxiety and stress during the period. It was shown that studying the impact of the pandemic on the mental health of students requires attention to possible dynamics of their mental state within relatively short periods and gender differences.

### India

In this stage of the pandemic, the focus is more on dealing with the pressures of the situation, which are mostly socio-structural. In the coming months, the focus has to shift to the psychological needs of people. The emotional impacts of what migrant workers are going through may be a major issue to deal with. The people are walking back to their villages in groups. The social, emotional, and economic costs are far more serious in developing countries like India as compared with developed nations. In the

next few months, these vulnerable sections of the society will need more psychosocial support. The government has to seriously look at the role of psychologists in providing the psychosocial and emotional support. The psychology associations have to come forward in providing more mental health-related services and training of psychologists to improve situational skills and competences to increase the accessibility of psychological services.

### China

The COVID-19 pandemic in China has gone through two phases. The first phase is for protecting and saving lives. Medical treatments are more important than psychological service. But, in the second phase, about 2 months later, psychological reaction or even psychological symptoms, or even mental disorders, especially PTSD, have emerged. For example, those who have witnessed the loss of lives, especially for medical doctors and nurses who had been working in arch hospitals. They knew how vulnerable humankind was in facing the virus. So Division of Nursing Psychology and Division of Medical Psychology, of the CPS, have been working very hard to provide services for medical staff, especially in the first 2 months.

In the first month, it is quite normal for people to react either mentally or behaviorally in stress. Then, in the second month, the third month and, now, the fourth month, upon the relief of the lockdown in May, life returned to the normal schedule in China. So it is a good time for us to reflect on our work, reflect on ourselves, to consider what psychologists can be of help in a future situation like this.

The CPS has done a lot since the lockdown because of COVID-19, the beginning of the pandemic. In the past 4 months, the Standing Committee of the CPS have met twice to make the strategic plans and arrangements of psychological support at the national level, during the lockdown, and after it was relieved.

Wenchuan earthquake in 2008 provided experience in psychological support in crisis intervention. Mental and behavioral reactions to a crisis like SARS and COVID-19 pandemic are varied but normal. In the second phase, trauma-related symptoms emerged and can become prominent. Therefore, CPS developed a three-level strategy for psychological service in the COVID-19 pandemic. The three-level-responding strategy to the pandemic brought up by the CPS included the following aspects. (1) Firstly, recruit psychologists with competence. CPS developed competence-enhancement programs for clinical psychologists right after the lockdown, in the end of January. The registration system of CPS has kept training registered psychologists, especially for crisis intervention to improve their competence in providing qualified services for all those in need. (2) Secondly, developing a response system in cooperation with governmental agencies. CPS work together with government agencies, NGOs, and foundations. They try to make sure that the strategic plans are active and sustainable. (3) Thirdly, target key groups in need of psychological service. CPS work with hospitals, schools, and community staff to find the key groups who have psychological problems, mental disorders, or even PTSD.

All institutions have voluntarily done their work. Psychologists set up hotlines, sent out teams working on the frontline, especially Wuhan City. And some of them edited books, developed apps and online programs for psychological services and counseling, and online psychotherapy and teletherapy.

Psychological services have been mentioned by China President Xi Jin-ping in his talks three times since the lockdown. Psychologists have been integrated in the work team for crisis intervention at both the national level and the provincial level. Medical teams were recruited in other provinces and sent to Wuhan or other cities in Hubei Provinces, and psychologists were included in those teams. Ten psychologists had been recommended and included in the National Team of Crisis Intervention, leading by the China Ministry of Crisis Intervention.

Psychological support has been provided in many ways. Counseling or psychotherapy has been provided for free all around China, especially for inhabitants in Wuhan City. Both Division of Personality and Division of Counseling or Clinical Psychology of CPS are affiliated to Central China Normal University, which is located in Wuhan City. Many colleagues working in the School of Psychology there have become the key team members working in the epicenter ever since the lockdown. Almost all universities with a department or school of psychology set up hotlines; for e.g., ShanDong Normal University, located in Ji'nan City, the capital of Shandong province, provides hotline service for the general population in Shandong province. A similar case holds for almost all capital cities of provinces across China.

For knowledge dissemination, many books have been edited, and many web pages have been developed. These can provide psychological knowledge and skills, helping people to adjust and cope with the COVID-19 pandemic. Technology was also employed to assist mental health. Different self-help apps have been developed to help general population online. Also, a wearable wristband with real-time physiological data acquisition, was used by nurses and doctors who work in frontline hospitals. The wristband recorded physical health parameters, mental health parameters and physical activity, providing a quick screening assessment of their (mental) health status.

The COVID-19 outbreak happened during the spring festival, which is a very unique opportunity for family members gathering together. And family dynamics have become a very strong basis of coping with the pandemic. The interpersonal relationship has never been so intensively tied. In this context, CPS has launched a Peace Mind Program, initiated by the Division of Crisis Intervention and Division of Psychological Institutions, together with the Institute of Psychology, Chinese Academy of Sciences. The Peace Mind Program has begun on January 28, right after the Spring Festival. They provided 94 lectures for either professional psychologists or for common civilians to disseminate psychological knowledge and skills. Online psychological assistance was also provided for different groups and professions, especially for policemen, medical professionals, and social workers in communities. We provide a hotline

where people can find help or counseling for themselves or for their relatives.

Another initiative, so-called "Thousands of Psychological Institutions for the Peaceful Mind," is a volunteer recruiting program. The program has recruited about 3,000 psychologists, and more than 400 institutions were involved in the program.

Altogether, 454 organizations were recruited in the Peace Mind Program to provide service in different settings. More than 1,300 medical staff received psychological services, including group therapy, an audio program for stress management. Two thousand four hundred sixty-three institutions have been provided psychological counseling services. More than 4,220 counseling sessions have been provided for individuals. Colleagues in China have composed more than 5,330 essays for knowledge dissemination to the public. For hotlines, nearly 100,000 counseling calls have been received; 77,000 online counseling inquiries have been provided. One hundred seventy-five thousand joined the 1-week program through the APP we developed, with 70% of the users finished the whole program. We also developed a self-evaluation questionnaire, and 187,000 individuals finished the online evaluation. For the video and audio program, we published online, there are more than 1 million views for the lectures, and more than two million play for the audio programs.

Research and project funding has been provided for those initiatives. All work we have done is to find the key groups in need. We realized that there is, still, a lot of work to be done. We hope that international communication and cooperation will give us more understanding of the mental and behavioral reaction to the COVID-19 pandemic and to the crisis in general.

For psychologists, we need to study more on mental and behavioral reactions in a crisis like this and how to provide effective services in the future. For psychologists in China, teamwork, especially work with government agencies and NGOs at different levels from national, provincial, city, and community levels, is very important.

Psychology as a profession in China needs legislation. Psychology as a discipline is very well-developed, but the legal status of the professional psychology profession is not quite stable. We have two kinds of mental health services: one is represented by psychiatrists and the other one is represented by clinical psychologists. These two versions of mental health services, of course, differ in many ways.

## South Africa

As part of the comprehensive national response, the South African government is implementing an eight-stage process to manage the COVID-19 pandemic (see **Table 2**). The eight stages are: preparation; primary prevention; lockdown; surveillance and active case-finding; hotspots; medical care (for the peak period); bereavement and the aftermath; and ongoing vigilance (SA Coronavirus, n.d.). The first two stages (i.e., preparation and prevention preceded the lockdown (Stage 3), which also coincided with alert Level 5 of the risk-adjusted response. What is to be done during Stage 4 (surveillance and active case-finding) coincides with alert Level 4 of the risk-adjusted response. During

**TABLE 2** | Eight-stage process to manage the COVID-19 pandemic [adapted from SA Coronavirus (n.d.)].

Stage	Stage 1: preparation	Stage 2: primary prevention	Stage 3: lockdown	Stage 4: surveillance and active case-finding	Stage 5: hotspots	Stage 6: medical care (for the peak period)	Stage 7: bereavement and the aftermath	Stage 8: ongoing vigilance
Actions	<ul style="list-style-type: none"> <li>Community education</li> <li>Establishing lab capacity</li> <li>Surveillance</li> </ul>	<ul style="list-style-type: none"> <li>Social distancing &amp; hand-washing</li> <li>Closing schools and reduced gathering</li> <li>Close the borders to international travel</li> </ul>	<ul style="list-style-type: none"> <li>Intensifying curtailment of human interaction</li> </ul>	<ul style="list-style-type: none"> <li>The Community response: door-to-door screening, testing, isolation and contact tracing</li> <li>The Community response: door-to-door screening, testing, isolation and contact tracing</li> </ul>	<ul style="list-style-type: none"> <li>Surveillance to identify &amp; intervene in hotspots</li> <li>Spatial monitoring of new cases</li> <li>Outbreak investigation &amp; intervention teams</li> </ul>	<ul style="list-style-type: none"> <li>Surveillance on case load &amp; capacity</li> <li>Managing staff exposures and infections</li> <li>Building field hospitals for triage</li> <li>Expand ICU bed and ventilator numbers</li> </ul>	<ul style="list-style-type: none"> <li>Expanding burial capacity</li> <li>Regulations on funerals</li> <li>Managing psychological and social impact</li> </ul>	<ul style="list-style-type: none"> <li>Monitoring Ab levels</li> <li>Administer vaccines, if available</li> <li>Ongoing surveillance for new cases</li> </ul>

this stage, currently in place during the month of May 2020, the focus is on the community, intending to conduct door-to-door screening, testing, isolation, and contact tracing.

As from the beginning of June 2020, the country will transition into Stage 5, which coincides with alert Level 3 of the risk-adjusted response. Looking at **Table 2**, it is evident that psychologists will have a big role to play in Stage 7 (bereavement and the aftermath). With psychologists mobilized to play a role through structures, such as the HWCN, it does appear that the population will be able to receive some form of psychological services into the future as the pandemic continues to escalate.

## DISCUSSION/CONCLUSION

COVID-19 provided the context for the first comparative analysis of psychology status in the BRICS nations. As directors of national scientific societies, the authors have worked for the past 3 years to develop BRICS Union of Psychologists, before COVID-19. We have also worked on international communication and cooperation ever since the outbreak of COVID-19. For example, we have participated in the zoom meeting hosted by American Psychological Association at least twice a week, which aims at collecting information from colleagues around the globe.

In the comparative analysis of the actions of psychology in the BRICS countries, the first question that stands out is that the political and economic management of each country influenced the modus operandi of each representation of psychology. Psychological societies received support, encouragement, and even a direct political call for public policy actions for crisis management, psychoeducation, first psychological aids, and active listening directed to the public (population, health professionals, and patients). Moreover, all societies have engaged in confronting COVID-19 in public health at various levels, considering the impacts on mental health.

Although psychology acts to promote mental health in BRICS, only in Russia that psychology had a strong role in remote education in these early months of COVID-19. On the other hand, psychology in China was quickly organized, and this will

speed up the required legislation and professional preparedness. In China and Russia, the scientific societies worked closer and integrated with the government. In Brazil, psychologists are integrated into the public health system, and a large number of psychologists are registered in a federal regulatory council of their own, but telepsychology is underdeveloped; state governments are working with Federal and State Universities to provide telepsychology during COVID-19. In India and Brazil, there is a prevalent sense of dichotomized world view, in contrast with the strong interpersonal strengthening described in China.

Countries with large social inequalities faced more socioeconomic gaps that affect mental health, further straddling the health system weaknesses, as shown by Brazil, India, and South Africa. The interface between the socioeconomic and political moment might have contributed to the exacerbation of mental health issues in the early months of COVID-19. The various psychology organizations in these countries have tried to organize themselves independently or seeking to sensitize governments to articulate actions in favor of minority groups (indigenous people, people in situations of socioeconomic vulnerability, and people in rural areas). In general, interventions introduced included payment of a social relief grant or of a distress grant to the unemployed and an increase in the social grant amount paid to the indigent. Also, technological and/or socioeconomic inequalities in countries like Brazil, India, and South Africa did not allow online services (health, mental health, and education) to reach everyone (rural, indigenous population, the poorest, and the most vulnerable), in contrast to online education in Russia and hotlines, apps and wearables in China.

Despite this deficient access to online services in some of the BRICS nations, the expanded and extensive insertion of the telepsychology happened in all of them. The guidelines on this modality of online intervention were different for each nation and had to be reformulated due to the situation. In Brazil and South Africa, there were regulations being discussed under pressure, reformulated and adapted to the context of COVID-19.

Psychology has different roles in their societies, and the pandemic exacerbated the strengths and exposed some of the weakness. In a long and continuous tradition of Russian psychology, the government actions have a place for education, mental health, and refined identification, and intervention is possible, for instance, in emerging cyberbullying. China, the first country of the epicenter of the pandemic, has been working in this crisis, using previous experience and an organized psychological intervention in many levels of psychological care contextualized, with the support of integrated and expanded political and economic management that helped in facing the emotional issues. India has a prolific amount of actions and a recent mental care policy that will probably catalyze the experiences during the pandemic into better mental health services. Psychology in South Africa has a strong regulatory link with other health professions; as a result, the strategies were set for all health professions, and psychology benefited from that despite the low contingent of psychologists. In contrast, despite of the high contingent of psychologists in Brazil, telepsychology was not stimulated, and the strong public health system did not offer telepsychology to the general population; universities and scientific societies are leading the actions in mental health during COVID-19 in independent initiatives amid a complex political context. In general, psychology in BRICS has been making pioneer contributions during COVID-19 times.

Psychoeducation of the general population and building competencies of psychologists to work during and after the crisis are the main aims in BRICS. The different approaches of each country are related to the role of psychology in society, equity, and social context. The use of digital platforms and telepsychology has been one important resource that gives visibility to psychology and expands mental health care. In general, it is expected that there will be an increased role of psychologists in providing cultural sensitive intervention and information on socioemotional skills.

COVID-19 (Coronavirus disease 2019) is a novel coronavirus which was first detected in late December 2019 in the Wuhan Province of China. This novel coronavirus, caused by a zoonotic beta-coronavirus (SARS-CoV-2), is described as highly infectious. The World Health Organization (WHO) named the novel coronavirus as COVID-19 on February 11, 2020, and declared it as a “pandemic.” Almost all countries have undertaken wide-scale precautions so as to prevent or limit the spread of the virus, with most having practiced some form of “lockdown” along with “social distancing,” as well as dispensed recommendations for proper hand washing, avoiding touching the face, wearing facemasks, and using disposable tissues when either coughing or sneezing. Whereas it is well known that slowing the spread of this new epidemic requires the cooperation of all citizens, some people still seem to willfully disregard the rules and guidelines, and thereby ignore the health risks posed to both themselves and to others they come into contact with. People have responded differently to lockdown rules and social distancing practices. Whilst the majority follow the rules and recommendations with great care, others are more lax or simply refuse to comply. These differences might be accounted for according to a number of factors including personal, social, cultural, mental, and economic variables. Being persuaded to comply with preventive rules, especially those concerned with health-related behaviors, also bring certain other factors into play. Fear is one of those factors, and is one of the most powerful. It is well known that fear-based appeals can be effective in inculcating health behaviors, with many theories having been developed in this area. However, both the content of the message (the level of the fear it contains) and certain personal variables can determine the persuasive power of the fear appeal. It can even have an adverse effect if not properly applied. Many theories have been developed to address the persuasive effectiveness

of the fear appeal (e.g., fear-drive theory, protection-motivation theory), and this study aims to discuss these individual differences in precautionary and preventive measures for the COVID-19 pandemic within the framework of the basic assumptions of these theoretical approaches.

**Keywords:** COVID-19, fear appeals, protection-motivation theory, fear-drive theory, extended parallel process model, pandemic, health behavior, health psychology

## INTRODUCTION

COVID-19 (Coronavirus disease 2019) is a new type of coronavirus which was first detected in late December 2019 in the Wuhan Province of China. This novel coronavirus, caused by a zoonotic beta-coronavirus (SARS-CoV-2), is described as being highly infectious. It affects the lower respiratory tract and can also manifest as pneumonia. Its most common clinical symptoms are reported as fever, fatigue, myalgia, dry cough, and dyspnea (Zhong et al., 2020). Coronavirus disease 2019 is regarded as a relative of SARS (Severe Acute Respiratory Syndrome) and also MERS (Middle East Respiratory Syndrome) (Sohrabi et al., 2020). The novel coronavirus outbreak was declared a Public Health Emergency of International Concern on January 30, 2020 and The World Health Organization (WHO) called for collaborative efforts worldwide in order to prevent the rapid spread of COVID-19 (World Health Organization, 2020b). The WHO named the novel coronavirus (2019-nCoV) as COVID-19 on February 11, 2020, and later declared it as a “pandemic,” meaning an epidemic on a global scale. Tedo Adhanom Ghebreyesus, the current serving President of the WHO, stated that the name COVID-19 is derived from the CO of “corona,” the VI of “virus,” and the D of “disease,” followed by the 19 of “2019” being the year of the disease’s official categorization.

The COVID-19 pandemic spread very quickly worldwide, with the virus having reached 215 countries and territories as of March 27, 2021, with 125,781,957 confirmed cases and 2,759,432 deaths attributed to the disease, according to the WHO (World Health Organization, 2020a). The economic and psychosocial consequences of this new epidemic have been wide-ranging, far-reaching, and unprecedented on a global scale; having caused not only significant death and serious health issues, but also severe economic problems, psychological pressures, and significant changes to daily life affecting human life worldwide. Negative psychological and economic consequences have also become another epidemic emerging alongside and as a result of the COVID-19 pandemic. The new pandemic and related economic recession has been found to be correlated with a 10-60% increase in deaths of despair in the United States alone (Socin, 2021). The COVID-19 pandemic, as a global crisis, has resulted in disruptions to both the supply and demand of various commodities in the world economy (Chudik et al., 2020). Unemployment rates have increased, and the International Monetary Fund (IMF) described the 2020 global economy as having shrunk to an extent not seen since the Great Depression of the 1930s<sup>1</sup>. COVID-19 has not only affected

the global population’s physical health, but has also been the cause of heightened anxiety, depressive symptoms, and stress; for example in China (Cao et al., 2020; Wang et al., 2020), Turkey (Bakioğlu et al., 2020), Israel (Tzur Bitan et al., 2020), Germany (Bendau et al., 2021), the United States (Taylor et al., 2020; Twenge and Joiner, 2020), Italy (Mazza et al., 2020), and Egypt (Arafa et al., 2021).

Numerous campaigns have been conducted in many countries to inform about the existence of COVID-19, its symptoms, means of transmission, the most at-risk groups, and the recommended precautions and preventative measures that should be taken. In order to prevent or limit the spread of the virus, governments worldwide announced new public policies such as social distancing, self-isolation, and self-quarantine (Anderson et al., 2020). People have been warned not to leave their homes (“lockdowns”), as well as being recommended how to properly wash their hands, to avoid touching their face, to use facemasks, adhere to social distancing advice, and to use only disposable tissues when coughing or sneezing. The global rates of those infected as well as numbers of deceased from COVID-19 are systematically announced through different channels of the media, with medical experts and government officials continuously warning of the serious risks presented by the virus.

Some countries have been shown to have quickly and successfully reduced infection rates, whilst some have been less responsive or effective (Hyland-Wood et al., 2021). It has been observed that not all campaigns have resulted in notable increases in effective preventive health behaviors, with individuals responding differently to lockdown rules and social distancing measures. While the majority follow these measures with great care, some largely ignore the advice and refuse to alter their behavior. These differences may be explainable through a number of determinants, including personal, social, cultural, educational, mental, and economic variables.

On the other hand, it is well known that “knowledge and attitudes toward infectious diseases” are highly associated with the level of panic emotion and, by association, with preventing the spread of communicable diseases such as COVID-19 (Zhong et al., 2020). It is therefore important to understand the public’s attitudes toward the disease, not only for helping them psychologically and physiologically, but also to help in persuading them to comply with the recommended preventive behaviors. Gerhold (2020) conducted a study with a German sample and found a negative correlation between age and the prediction of COVID-19 risk, and that females were more concerned about the new epidemic than their male counterparts. Research has shown that there has been a significant increase in

<sup>1</sup><https://www.bbc.com/news/business-51706225>

the levels of depression, anxiety, general stress, and posttraumatic stress related to COVID-19 (Fitzpatrick et al., 2020; Huang and Zhao, 2020). This increase has been found to be higher for those with pre-existing depressive or anxiety disorders (Asmundson and Taylor, 2020; Bendau et al., 2021). Also, recent studies have revealed certain gender-based differences in the fear experienced in relation to the COVID-19 pandemic. Females have significantly reported higher levels of fear of COVID-19 (Humer et al., 2020; Korukcu et al., 2020; Liu et al., 2020; Qiu et al., 2020; Reznik et al., 2020; Trnka and Lorencova, 2020; Tzur Bitan et al., 2020; Koçak et al., 2021; Pak et al., 2021), depression, anxiety, and stress (Mazza et al., 2020) than males.

The rapid spread of COVID-19 has caused substantial human psychological effect worldwide, as previously mentioned (Torales et al., 2020). One of these strongest psychological effects is fear (Pakpour and Griffiths, 2020). Traumatic life events such as the emergence of new endemic diseases can cause significant fear in many people, and as such has been evaluated as a “normal” and “functional” reaction (Witte, 1992; Ahorsu et al., 2020; Harper et al., 2020; Khan et al., 2020); however, in extreme cases, this fear may lead individuals to take extreme action and even to commit suicide (Bhuiyan et al., 2020; Dsouza et al., 2020; Griffiths and Mamun, 2020; Sher, 2020).

On the other hand, fear is also known to be an effective means of persuasion, if applied properly (Witte and Allen, 2000). According to the literature on the topic of persuasion, “fear appeals” are highly associated with dealing with risk-based health behaviors, and as such have been widely used to instill attitudinal change and for different goals (e.g., coping with addiction or preventive health behaviors) (Tannenbaum et al., 2015). Recent research has established that fear is positively related to compliance with COVID-19 preventative behaviors (e.g., Bashirian et al., 2020; Cypryńska and Nežlek, 2020; Winter et al., 2020). Harper et al. (2020) found that fear was the main predictor of positive behavior changes associated with the prevention of spreading COVID-19 (e.g., guidelines on social distancing and personal hygiene). Koniak and Cwalina (2020) found that fear of COVID-19 leads to more positive and supportive attitudes toward proposed restrictions than may have initially existed.

In the circumstances of the current global outbreak, healthcare professionals and social scientists have been guiding governments in developing policies to slow down the spread of the virus and to limit its impact. At this point, it is extremely important to issue informative and persuasive messages to the population in order to ensure a higher level of virus-mitigating behaviors are adopted so as to limit the spread of the virus, and thereby to protect both their health and the health of the community at large. Persuasive messages are created and sent to society through public service announcements and similar media in many countries. Undoubtedly, the use of fear appeals is seen as one of the most effective strategies applied to increase the strength of messages in health-related persuasive communication campaigns.

In the current study, the relationship between fear and persuasion will be discussed, and then basic theoretical approaches to fear appeals will be examined in detail. In this context, complying with preventive health behaviors will be analyzed based on each of these theories’ statements. In addition,

current research findings that address the relationship between fear appeals and adherence to recommended behaviors to protect against COVID-19, and thereby prevent the rampant spread of the virus, will be examined. In light of these theories and current research findings, the effects of health policies and fear-based communication campaigns that have been implemented since the beginning of the pandemic will be discussed. Finally, based on these theories, suggestions will be put forward on how to best apply messages containing fear in the most effective way in order to address the global impact of the COVID-19 pandemic.

## FEAR APPEALS

Fear is an adaptive emotional response to a real or a perceived physical or emotional threat that serves to stimulate the person to deal with potential risks (Gullone, 2000). Although it is considered as a negative emotion, under certain circumstances, fear can also be defined as “essential” and “functional”, as with anxiety. The optimal level of fear allows us to avoid vital or life-threatening dangers, as well as helping us adapt to the environment and to survive. For this reason, researchers working on persuasion presume “fear” to be an effective tool in replacing risk-inherent health-related attitudes (addictions, avoiding regular health checks, not adopting preventive health behaviors) with recommended attitudes and practices. In a recent study, Zettler et al. (2020) determined that the HEXACO personality domain of emotionality, which is described as excessive levels of fear, was associated with a higher level of acceptance of the restrictions aimed at slowing down the spread of COVID-19.

Fear appeals are persuasive efforts that intend to arouse fear by stressing the negative consequences (danger and/or harm) that could occur if individuals do not change their attitudes and/or practices in line with the official recommendations (Perloff, 2009; Tannenbaum et al., 2015). A fear appeal is typically structured as follows; “If you do not adopt the behavior recommended (purchasing, voting, believing, supporting, learning, stopping, etc.), you will encounter extremely negative or dangerous results.” For example, it is said that “smokers will contract chronic obstructive pulmonary disease if they do not give up the habit” or “people who do not brush their teeth regularly will soon lose their tooth if they do not develop this habit.” Considerable research has been undertaken on the persuasive effects of fear appeals (e.g., Rogers and Mewborn, 1976; Liberman and Chaiken, 1992; Eagly and Chaiken, 1993; Rogers and Prentice-Dunn, 1997; Das et al., 2003).

Although it seems a simple premise to awaken fear in people, research has shown that the same fear-arousing content does not necessarily have the same effect for all. Sometimes, a fear appeal could be less scary than the researcher’s expectation; whilst sometimes it is the opposite, with participants’ fear having become too exaggerated to take it seriously. As a result, research has shown the necessity of determining what scares who and to what extent. It is ineffectual to scare people more than necessary, just as it is to scare them too little (Morris and Swann, 1996).

Therefore, it is important to examine the variables that determine this during the current pandemic. Basic fear appeal theories provide explanations that serve this purpose. In the current study, as previously mentioned, it is aimed to make inferences in light of both the relevant theories and current research findings.

Many different theoretical approaches have been developed on fear appeals, with the following five approaches leading the literature; Health Belief Model, Fear-Drive Theory, Protection-Motivation Theory, Terror Management Theory, and Extended Parallel Process Model.

## Health Belief Model

The Health Belief Model (HBM: Hochbaum et al., 1952; Hochbaum, 1958) is one of the most commonly implemented approaches to preventive health behaviors (Rosenstock and Kirscht, 1979). It endeavors to predict health behavior in terms of certain specific belief patterns.

There are two main elements of health behavior: threat, and outcome expectations (Gehlert, 2006). The threat consists of the perceived susceptibility to health risk and also the perceived seriousness of that illness. In the case of the risks associated with being infected with COVID-19, the threat would involve believing that one was susceptible to acquiring the virus, and also that it was as serious as the health authorities portray it to be. The outcome expectations are the perceived benefits of a suggested behavior, such as using facemasks as a measure to prevent the transmission of the virus, and the perceived barriers to showing that behavior. Another element that has been added later as a separate concept is self-efficacy, which relates to confidence in one's ability to take action (Champion and Skinner, 2008).

The combination of these factors affects the probability of the behavior happening. According to this model, fear appeals will be more persuasive if they underline a person's perceptions about subjective susceptibility, benefits, barriers, and self-efficacy (Laranjo, 2016). The person will be more likely to adopt preventative behaviors if they perceive the health threat to be serious, that they perceive themselves to be vulnerable, and where the benefits of following the suggested behaviors outweigh the costs. If a person perceives that there is a severe threat to their health, and the perceived benefits outweigh the perceived barriers, then they will probably prefer to act in line with the recommended preventive health action.

## Fear-Drive Theory

According to Janis' Fear-Drive Theory (Janis, 1967), fear is a driver state that motivates individuals to adopt recommendations expected to mitigate a negative state. In the case of the fear aroused in response to a message, a need for fear reduction occurs that results in an attitudinal change (Walton, 2000). According to the drive theory, the more fear that is aroused, the greater the likelihood that the fear appeal will be successful. According to this model (Janis, 1967), there is an inverted U-shaped relationship between fear and attitudinal change. In this model, it is claimed that fearful messages create a motivational urge to attitudinal change; yet, on the other hand, in the case of causing excessive fear, the expected attitudinal change will decrease.

Janis (1967) argued that the undesired high level of tension that emerges as a result of a threat motivates individuals to ignore their fears instead of changing their attitudes and adopting the proposed attitudinal change. If the recommended new attitude suggests a certain way to avoid the frightening outcome, it is possible to reduce that fear by taking the recommended route. When attitudinal change is regarded as being powerful enough to reduce or end the fear, it can be perceived as a reward, and the individual motivated to act in line with the proposed new attitude. However, if the recommended attitude is perceived as ineffective in reducing the fear, the individual will likely choose to ignore the frightening result or to reject the fear message.

To summarize, according to this theory, it is critical to find the optimal level of fear appeal at which the likelihood of attitudinal change is maximized. If the level of fear is inadequate, the corresponding fear arousal will be insufficient to initiate the expected change. On the other hand, if the resultant level of fear is considered too high, the fear appeal may cause defensive processes such as message denial or threat derogation (Manyiwa and Brennan, 2012).

Persuasion literature on fear appeals, especially those related to health-related attitudes and behavioral changes, show that when the dose of fear is misaligned, people go into defensive mode and the effect of "unrealistic optimism" appears. The term "belief in a just world" inspires this effect; where the world is perceived as just, where people live in a world in which everyone gets what they deserve. Accordingly, good things always happen to good people and bad things only happen to bad people (Lerner, 1980). Thus, the misconception that "nothing happens to me," which is commonly observed, comes into play and forms a kind of defensive shield (Perloff, 2009). As a result, individuals who receive a fear appeal will show very little care about recommended attitudinal changes if they consider the likelihood of the fearful results to be negligible, especially when the dose of fear is significantly high. On the other hand, optimism bias can also be considered as a functional defense to cope with increased anxiety, stress and depression, especially among vulnerable groups in this process. In a meta-analysis study based on research conducted over a period of almost 70 years, it was revealed what qualifications a fearful message should contain in order to be considered persuasive (Nabi et al., 2008, 191). It was shown that such a message needs to address an important hazard through the optimal level of fear (i.e., high enough to convince the individual, but low enough not to cause undue anxiety or trigger defense mechanisms such as message denial or threat derogation) and to inform the receiver about the appropriate behavior/attitude that will enable them to avoid the risk.

The persuasiveness of fear appeals related to COVID-19 are also related to the main domains of fear. Several studies have explored these domains (e.g., Schimmenti et al., 2020; Taylor et al., 2020; Trnka and Lorencova, 2020) which include fear of contamination, fear of economic consequence, coronavirus-related xenophobia, fear of the body, fear of significant others, and fear of inaction, etc.

Fear is a subjective emotion and reactions to fear may vary from one individual to another (Mertens et al., 2020). There are apparent individual differences in tolerance for fear and

risk (Lunn et al., 2020). It is extremely difficult to determine which level of fear will have what effects on which individual, to estimate the optimal dose of fear appeal, and to generalize it within the process of a global health crisis such as the current pandemic. Such messages should be supported with empathic content in order to avoid leading to perceptions of “despair” and “an inevitable end,” fed with an anxiety-reducing positive content, and emphasize that it is possible to protect oneself from the mentioned risk by taking simple measures. Perceived self-efficacy also plays a critical role in the persuasiveness of fear appeals (Peters et al., 2018; Bavel et al., 2020).

Nevertheless, debate on the persuasive power of fear appeals has continued for many years. Empirical research on fear appeals has revealed conflicting results; and whilst many studies have shown fear arousal to be persuasive (e.g., Rotfeld, 1988; LaTour and Pitts, 1989; Miller and Millar, 1998), others have concluded just the opposite (e.g., Hovland, 1959). These conflicting results may be explained by the mediating effect of “efficacy” (Manyiwa and Brennan, 2012), and Rogers’ Protection-Motivation Theory (1975) draws attention to this emphasis.

## Protection-Motivation Theory

Rogers’ Protection-Motivation Theory (PMT) (Rogers, 1975) was first developed to form a conceptual explanation of the effect of fearful messages. Rogers (1985) then went on to expand the theory with a more comprehensive version that highlighted the cognitive processes underlying attitudinal change and added extensive explanation with regards to persuasive communication.

According to this theory, individuals will choose one of the adaptive or maladaptive coping strategies after receiving the message or risk encountering significant health issues. Motivation for protection from the danger (protection motivation) occurs as a result of the perception of the danger and the corresponding evaluation of the recommended coping strategies. The greater the elicitation of protection motivation, the greater the attitudinal change.

The perception of danger represents the perception of the probability of encountering the negative experience (risk), and of its seriousness. The evaluation of coping strategies includes two elements; “response (behavioral) efficacy” and “self-efficacy.” Response efficacy is about the capacity of the new attitude/behavior suggested in the message in order to be disconnected from the danger. Self-efficacy, on the other hand, relates to the self-confidence of the individual in successfully performing the proposed attitude/behavior (Norman et al., 2005).

Perceiving health hazards and assessing the efficacy of coping strategies can lead to “adaptive behaviors” (protection motivation) or “maladaptive responses.” Maladaptive responses are behaviors that will lead to health risks for the individual. Such responses include behaviors with negative consequences (e.g., consuming too much alcohol, avoiding regular health checks for serious health issues like heart diseases and cancer). According to this theory, fear appeals can change attitudes (individuals more motivated to protect themselves from danger) under only four conditions (Rogers, 1975);

- Perceived severity/noxiousness of the danger/risk,
- Perceived likelihood of the dangerous event’s occurrence, and the perceived probability of personal damage (vulnerability/susceptibility),
- Perceived effectiveness and power of the proposed attitudinal change (measures) to prevent the risk (response efficacy), and
- Perceived self-efficacy to successfully enact the measures and practicability/applicability of the proposed new attitude.

Rogers stated that the first two conditions deal with warning individuals to change their attitudes in order to protect themselves (protection), whilst the other two are about persuading them (motivation) that they can actually achieve what is required of them. Rogers indicates that this is largely dependent on the individual’s self-belief in their own skills and perceived behavioral control perception of the severity of an epidemic plays an important role in the attitudes exhibited toward, for example, the COVID-19 pandemic. It is of the utmost importance to accurately explain the seriousness of the situation, as well as its individual, social, and even global risks to the public without any time being wasted. This perception is one of the main determinants of whether or not individuals will adopt the recommended attitudes or exhibit the advised preventive behaviors.

Consistent with this assumption, a recent study by Kuper-Smith et al. (2020) revealed that the majority of the population in both the United States, the United Kingdom, and also in Germany underestimated the possibility of being infected, did not classify themselves as being within an at-risk group, or being a carrier/transmitter of COVID-19 compared to others. They reported that individuals exhibited an “optimism bias” which led them to mitigate the probability of becoming infected themselves or infecting others. In other words, it was seen that they assumed the notion that “nothing will happen to me.” It was also observed that there was a negative correlation between the perception of “the possibility of getting infected from others” and the perception of “the possibility of participating in hygiene-related behaviors (e.g., hand washing, and social distancing).” These results could be interpreted as there being a positive correlation between the low level fear of transmission and risk-inherent social behaviors.

The second condition, in short, concerns whether or not an individual sees himself as being at risk, and is also defined as a good predictor of the recommended preventive behaviors. Wise et al. (2020) reported that with COVID-19, especially during the initial stages of the epidemic, feeling personally at risk of infection was a greater predictor of engaging in preventive behaviors such as social distancing and handwashing practices. This is closely related to the “ego-involvement” emphasized in the long-established Social Judgement Theory (Sherif and Hovland, 1961; Sherif et al., 1965). The first campaigns on AIDS (Acquired Immune Deficiency Syndrome) was acknowledged not to have worked well largely due to low levels of perceived ego involvement (Larson, 1995). At that time, it was believed that

only practicing homosexuals and those from certain races were the at-risk groups, and that individuals who did not categorize themselves within these risk groups simply did not care about the messages or change their attitudes as a result. However, after the subsequent comprehension that “everyone is in the risk group,” the impact of the AIDS campaigns increased and more significant changes in attitude were seen.

The third condition answers the question, “which mitigation measures/recommended attitudes are available?” At this stage, it is extremely important to ensure that the goal of the recipient is to focus on the recommended solutions and to manage the crisis rather than focusing on their fears. If the epidemic is portrayed as a situation from which there is no escape and no remedy, individuals will panic due to high levels of anxiety and fear. Then, fear control takes over and they are unable to focus on the actual recommendations being put forward.

The final condition of “perceived self-efficacy” is concerned with the evaluation of the target person’s own ability to successfully enact the recommended measures. Encouraging people through persuasion tools such as “positive attributions” and “high expectations” can be a good solution. It is functional to state that they are believed to be able to achieve the task, and to emphasize feelings of unity so as to underline the importance of the social dimension of the spread. As reported by Harper et al. (2020), combining an acceptable level of fear with messages emphasizing personal capability can prompt safety-promoting behaviors such as personal hand hygiene and social distancing.

Using the PMT to predict preventive/protective behaviors, it may be said that those with high levels of perceived vulnerability, perceived severity of the virus, perceived effectiveness of the recommended behaviors, and perceived self-efficacy will be most likely to comply with the recommended COVID-19 protective behaviors. On the contrary, those who have a low perception of their risk, the seriousness of the virus, the effectiveness of the recommended behaviors, or their capability to following through with recommended behaviors will be less likely to engage in preventive or protective behaviors. Recently, several studies have attempted to predict the adoption of COVID-19 preventive behaviors based on PMT (e.g., Al-Hasan et al., 2020; Chong et al., 2020; Jørgensen et al., 2020; Kowalski and Black, 2021; Rui et al., 2021). Their findings have shown that efficacy beliefs predict compliance with recommended preventive behaviors in the case of COVID-19 (Chong et al., 2020; Jørgensen et al., 2020). Ezati Rad et al. (2021) found significant positive correlations between preventive behaviors for COVID-19 and perceived vulnerability, perceived severity, response efficacy, self-efficacy, and protection motivation. Kowalski and Black (2021) found that perceived severity and perceived effectiveness, and also the power of the proposed measures in preventing or reducing the risk (response efficacy) significantly predicted engagement and adherence with the recommended behaviors. Al-Hasan et al. (2020) found that higher levels of threat appraisal, coping appraisal, and intensity related to COVID-19 knowledge positively influenced social distancing adherence. Some studies have revealed that the best predictor of protective behaviors among the PMT variables is perceived severity (Anaki and Sergay, 2021; Rui et al., 2021).

## Terror Management Theory

Terror Management Theory (TMT) (Greenberg et al., 1986) asserts that mortality salience increases the potential for experiencing existential anxiety and creates a feeling of terror that negatively affects a person’s psychological wellbeing. Humans have developed two distinct buffers to cope with such feelings of terror and to feeling a sense of control over the unavoidable reality of our own mortality; and these are our cultural worldview, and self-esteem. These buffering systems alleviate existential terror by providing a sense of being a valued individual living within a meaningful world (Pyszczynski et al., 2021).

According to the model, death-related thoughts can lead individuals to either exhibit the suggested health behavior or to deny and avoid it when focused on thinking about it consciously. Proximal defenses are aroused in order to suppress such thoughts, or to push death away into the future by refusing to accept vulnerability to the risks, or motivating them to begin to act healthier in terms of their behaviors so as to ensure a longer life; namely, they lead to attempts to remove them from the consciousness. Nevertheless, in the case of thoughts about death, these are located on the fringes of our consciousness, distal defenses, which push the individual to maintain self-esteem and to cling to one’s own cultural worldview, which results in increased or decreased compliance to the proposed health behavior (Pyszczynski et al., 2021).

TMT is undeviatingly functional to understand individual responses to the current pandemic (Pyszczynski et al., 1999). According to Pyszczynski et al. (2021), the roots of the multidimensional costs (personal, social, economic, and political) of the COVID-19 pandemic are clearly based on the risk of dying from the virus.

In the COVID-19 case, the possibility of death or serious illness caused by the virus is extremely salient. Rapidly increasing mortality and intubation rates, as well as images of overburdened hospital wards make this even more evident. As such, it has been extremely challenging to manage this form of terror. Economic chaos, social isolation, human rights violations, contradictory and confusing explanations given from governments and/or scientists, as well as an infodemic spread by the mass media have also reinforced the existential anxiety and impaired our primary coping resources (FitzGerald et al., 2020).

Especially in the media, the constant informational flow regarding the virus has led to a proximal form of defense. This situation has led to an increase in problematic behaviors such as eating disorders (Ammar et al., 2020), and an increase in alcohol consumption (Furnari, 2021). Underestimating and trivializing the threat is, in a sense, another result of this defense. Dealing with positive illusions, such as not seeing one’s own age group or race at risk, evaluating the pandemic as a kind of political conspiracy, or underestimating its fatality or contagiousness, have all been exhibited. The proximal defense was also manifested by adaptive responses; compliance with recommended guidelines to avoid infection (such as maintaining social distance, hand washing, and the wearing of facemasks). Despite the ongoing information bombardment, death-related thoughts are not always at the center of consciousness. At this

point, efforts to embrace the cultural worldview or to increase our self-esteem may come into play. The high correlation between political orientation, taking the virus seriously, and adhering to recommended behaviors (Funk et al., 2020) can be considered as an indicator of distal defenses.

## Extended Parallel Process Model

The Extended Parallel Process Model (EPPM: Witte, 1994) could be described as an integration of the main theoretical perspectives on fear appeals such as Fear-Drive Theory (Janis, 1967), Protection Motivation Theory (Rogers, 1975; Maddux and Rogers, 1983), and Leventhal's Parallel Process Model (Leventhal, 1970; Leventhal et al., 1983). This theory was developed in order to illustrate the pathways that people use to appraise fear appeal messages, and the strategies they employ in response to the emotions evoked by such appeals. Although it is very similar to the Protection Motivation Theory, it contains differences in certain dimensions. Protection Motivation Theory suggests that maximum attitude change will be reached when both threat and perceived efficacy are high (Rogers and Prentice-Dunn, 1997). However, in the Extended Parallel Process Model, there are two separate types of motivation responses identified; "protection motivation response" and "defensive motivation response." Protection motivation responses result in the acceptance of fearful messages, whilst defensive motivation responses cause rejection of the message (Timmers and van der Wijst, 2007).

According to the Extended Parallel Process Model, we face two distinct sets of appraisals when confronted with fear appeals; "threat appraisal" or "response appraisal" (Witte and Allen, 2000). In the threat appraisal, as Rogers (1975) mentioned "susceptibility," we assess the possibility of facing a threat (e.g., "How likely am I to contract COVID-19?") and the severity of results connected to that threat (e.g., "How harmful is the transmitted virus?"). This step is about evaluation of the effectiveness of the fear component in the fear appeal. If the likelihood and the severity are evaluated as being low, the fear appeal largely fails and the target person stops processing the message. However, if they are both high, fear leads the target to proceed to the second step, response appraisal. This step involves the evaluation of two efficacies; "response efficacy" and "self-efficacy." Response efficacy is conceptualized as perceptions of the effectiveness of protective/preventive behaviors, whilst self-efficacy is about people's beliefs in their own abilities to properly perform the protective/preventive behaviors (Witte, 1994).

In the case of threat appraisals and efficacy appraisals being higher than necessary, danger-control responses are triggered, and the target is motivated to engage in the recommended behaviors contained in the fear appeal message in order to protect themselves. However, if the threat appraisal is high but the efficacy appraisal is lower, fear-control responses will occur and the target will engage in maladaptive coping strategies such as denial, delay, or defensive avoidance in order to control the tensions provoked by the fear appeal.

This model also suggests that when individuals are confronted with a fearful message, one of two parallel processes (or different mechanisms) will affect their attitude; "danger control" or "fear control" (Witte, 1994). Danger control is the process that takes

place when an individual believes that they can cope with the frightening result being emphasized in the message if they apply the recommended attitudinal change. For example, belief that following a recommended diet in order to cope with health problems caused by diabetes will work and succeed as desired. Fear control, on the other hand, is the process that happens when the individual focuses on how to cope with the fear that they are experiencing, instead of how they will actually deal with the frightening result they are facing.

An effective fearful message must include two main components; "danger" (a danger/risk/problem that the individual may encounter) and "detailed information about the solution" (what to do in order to deal with the problem). Such a message should first frighten the individual to a sufficient level and warn against existing dangers, and should include two different kinds of information;

- "Severity information" – E.g., Smoking can lead to a heart attack,
- "Susceptibility information" – Warning individuals about at-risk groups (e.g., All smokers are at risk of having a heart attack at an early age).

In order to achieve this, two types of information should be included; information about what they are at risk from, and the solutions they should follow.

In addition, they need to believe that these solutions will actually work and that they themselves can achieve it. In order for this to happen, two kinds of information must be included;

- "Response efficacy" – Information that emphasizes the effectiveness of the recommended attitude (e.g., Quitting smoking considerably reduces the risk of having a heart attack),
- "Self-efficacy" – Information that motivates the individual that they can cope with the problem (e.g., You can quit smoking. Millions of people have succeeded, and you can do it too).

In line with this information, the individual will enter into one of these two "parallel processes." As previously explained, if the individual believes that they can cope with the danger, they will feel better able to face it and focus on the required solutions when executing the "danger control" process. However, if the individual believes that they are faced with serious or insurmountable danger, then they will more likely focus on their fear rather than the solution, and will enter the "fear control" process in order to try and cope with the fear rather than the danger.

To summarize, there are four basic variables in this theoretical perspective; with two related to evaluations about the threat, and two related to efficacy. In the case of the COVID-19 pandemic, the questions we need to face in terms of measuring these variables can be exemplified with the following:

Threat variables:

- Perceived severity – How serious do you think the consequences will be if you become infected with COVID-19?

- Perceived susceptibility – How possible is it that you might contract COVID-19?

Efficacy variables:

- Response efficacy – How effective do you think the recommended solutions are, such as social distancing, using a facemask, and proper handwashing at preventing COVID-19 infection?
- Self-efficacy – How confident do you feel that you could successfully follow the recommended solutions to avoid contracting the virus?

In 2006, within the Communication for Healthy Living (CHL) Project in Egypt (2003-2010), a national communication strategy was developed in order to prevent the spread of Avian Influenza (H5N1). In the campaign, the Extended Parallel Process Model was employed to persuade people to conform to certain health recommendations (Health Communication Capacity Collaborative, 2015). The study observed that whilst individuals perceived the threat posed by Avian Influenza as remaining high over time, their perceived efficacy to deal with the threat increased substantially.

The extent to which a person feels threatened by a health problem determines their motivation to act; while their confidence to efficiently decrease or prevent the threat defines the action taken.

It could be said that, in the case of a perceived threat being greater than the perceived response efficacy and self-efficacy, the probability of enacting behavioral change will likely decline. Therefore, it is extremely important to form a message that maintains balance between these two components. Message recipients must recognize that they are at risk, but at the same time understand that there are effective ways of coping with the risk and that they are capable of taking the necessary action (Witte and Allen, 2000).

Zhang (2021) found that severity and response efficacy were positively related to compliance behaviors. Increasing severity and response efficacy perceptions may be key in promoting compliance behaviors. Lithopoulos et al. (2021) conducted a test that applied EPPM in the context of the novel coronavirus disease (COVID-19) on a Canadian sample that consisted of 1,055 participants. Intentions to follow government recommendations, physical distancing, and fear control responses (i.e., negative and defensive reactions) were predicted using EPPM (perceived threat and efficacy). Consistent with the EPPM, they explored that individuals with high perceived threat and perceived efficacy scores had high intentions to comply with the recommended protective acts, physical distancing, and low fear control. Perceived efficacy was seen as the strongest predictor in their study's analysis.

## DISCUSSION

Individuals react to risks in many different ways; some immediately follow the recommended behaviors, whilst others opt for more harmful reactions including ignoring the reality of

the risk and continuing to exhibit risk-inherent behaviors (Taylor, 2019). Although being aware of the risks of unsafe health-related behaviors, some people prefer to disregard messages designed to motivate them into changing their attitudes and choose instead to maintain their existing habits despite the warnings (e.g., Smoking Kills!) (Martin and Kamins, 2010). This personal difference is related to many variables including individual, sociopolitical, and cultural differences. A clear example of this has been seen with the COVID-19 outbreak, and which has been witnessed closely across societies on a global scale. As emphasized in detail in the current study, the use of fear appeals have effectively persuaded many people to avoid unnecessarily health risk behaviors and to practice more appropriate preventive behaviors deemed useful in dealing with global health problems such as the current pandemic.

Recent studies have revealed a relationship between fear and COVID-19 prevention behaviors (e.g., Chang et al., 2020; Harper et al., 2020; Anaki and Sergay, 2021). For example, Harper et al.'s (2020) study revealed that people who are more fearful about COVID-19 engage more with the recommended preventive health behaviors such as regular hand washing and social distancing practices. As previously noted, Zettler et al. (2020) found that the emotionality domain (i.e., having extreme levels of fear, anxiety, and reactivity) of the HEXACO personality was positively correlated with an agreement with government-mandated restrictions.

It is well known that fear is an adaptive response in the presence of a threat. On the other hand, it is more liable to become chronic or acute rather than adaptive in extraordinary situations such as pandemics (Mertens et al., 2020). At this point, as assumed in all five of the aforementioned theories, it is vitally important to set the correct level of fear when issuing fear appeals to individuals who are perceived to be in a vulnerable emotional state. As previously mentioned, according to the Fear-Drive Theory, there is an inverse U-shaped relationship between fear and attitude change; fearful messages create a drive to attitudinal change, but, in the case of excessive fear, the expected change in attitude actually decreases. On the other hand, a low dose of fear may also cause individuals not to take the situation seriously enough, not see themselves at risk, and therefore not to heed the warnings or to obey the rules. According to terror management theory, sometimes fear appeals based on severe health risks can encourage people who gain self-esteem from risky behaviors to continue to exhibit those same errant behaviors. Then there is the “boomerang effect” (or “forbidden fruit effect”), which comes about through an increase in undesired risky behaviors, instead of following the recommended practices (Wolburg, 2006). Briefly, the necessity of adjusting the dose of fear is a well-proven concept.

It is also critical to prevent the spread of misinformation, which can lead to underestimation of the criticality of an epidemic (e.g., “nothing will happen if your immunity is good,” or “nothing will happen to individuals in the younger age group”) and blocking the transmission of incorrect messages explaining how to cope with the epidemic can prove very difficult, or even impossible in today's multimedia online world. In the fight against COVID-19, it has been observed that many countries have placed too much emphasis on certain risk groups, and

announcing that young people face a much lower level of risk has resulted in a significant reduction in their compliance with the recommended guidelines and imposed rules.

We could say that fear appeals on COVID-19 should include not only threats and risks, but also efficacy variables in light of the theories discussed in this review. The level of fear should be determined carefully in order that it does not unnecessarily lead the target audience to “fear control” rather than “danger control.” Creating effective public service announcements that include solution-oriented messages can be very persuasive if sufficient attention is paid to the level of fear aroused, and in motivating citizens that it is possible to protect themselves and society as a whole.

The significance of following the recommended measures and the other preventive behaviors must be underlined, not only as a personal health decision but also as an act of social responsibility. It should be openly declared that a pandemic requires a general community-wide approach if the mitigating actions are to achieve the desired effect. Coping with the presence and ubiquitous spread of COVID-19 requires handling as a collective aspiration rather than a set of personal goals. Researching the factors underlying the attitudes and behaviors of those who do not follow the rules is thereby also crucial.

The self-related appraisals about future events are generally optimistically biased: we consider that negative events are less likely to happen to us than to others, while the positive may be more likely. As previously mentioned, Kuper-Smith et al. (2020) argued that this bias leads people to perceive the possibility of them becoming infected, or infecting others as asymptomatic carriers, as lower than for other people. In the same study (Kuper-Smith et al., 2020), it was seen that participants from all three countries in their study (the United Kingdom, Germany, and the United States) shared optimism bias. In this process of managing a global pandemic, being aware of such biases, and exploring the underlying causes and their consequences, can help guide those responsible to form and issue persuasive messages that will further increase compliance with the recommended preventive behaviors.

On the other hand, the cultural differences observed in terms of compliance with the authorities should not be ignored when examining this kind of attitudinal change and or levels of compliance. In some countries, citizens seem to follow social isolation and lockdown rules more readily than elsewhere. For example, Anaki and Sergay's (2021) research found that people in the United States and Europe reportedly adopted less COVID-19 related precautionary behaviors than people in Asia. Current and future research on this situation will also provide significant benefits to these and similar struggles faced by today's national and international authorities in tackling the COVID-19 pandemic.

Being an individualistic or a collectivistic culture determines the sense of unity, interdependence, and compliance with social norms (Triandis, 2001). In individualistic cultures, the bonds between the members are considered loose; as they generally only look after themselves and their immediate family. But in the collectivist culture, people are considered interdependent, with large interconnected extended family structures, where

the interests and decisions of the collective group come first based on their shared interests. Individualism tends to predominate in developed and Western countries, whilst collectivism predominates Eastern countries (Hofstede, 2011). Civics of the collectivistic eastern countries have innate cultural characteristics such as a greater tendency toward the obedience of authority, endurance, and self-discipline, and they succeed in remaining calm despite being subjected to far-reaching and often draconian restrictions in the fight against the pandemic.

Coronavirus disease 2019 protection behaviors appear closely related to the dependency/independency dimension of each culture. Interdependence cultures such as in many Asian societies afford priority to social rather than individual goals, and instill a naturally high sense of duty and communal responsibility. The importance given to social norms and the suppression of individual interests has been seen to result in greater levels of compliance with rules in such cultures (Bavel et al., 2020).

Similarly, being a tight or a loose culture also seems to be very decisive at this point. According to Gelfand (2020), it is highly related to having a “tight” or “loose” society. Tight societies are represented with strong norms and a low tolerance of deviant behavior. On the other hand, loose societies have relatively flexible social norms and a high tolerance for undesirable behaviors. Tight societies are the rule-makers, whilst loose societies are the rule-breakers. Typical “tight” societies such as Japan, Singapore, and Hong Kong have shown effective responses to COVID-19. In these countries, regularity is part of daily life, and strict, robust laws and social coordination have been shown to save lives when faced with health-related hazards such as a pandemic, especially during the early initial spread of a virus. These countries often have significant experience living with the threat or recent history of wars, natural disasters, and epidemics. Loose countries, on the other hand, like the United States, Italy and Spain are well known as more being permissive and have a softer rule-based society; and as a result face significant difficulties in managing crises such as a pandemic (Gelfand et al., 2011). Tightness-looseness indicates the extent to which social norms are pervasive, clearly defined, and reliably imposed (Gelfand et al., 2011). According to Gelfand (2018, 3), being tight or loose “not only explains the world around us but actually can predict the conflicts that will erupt—and suggests ways to avoid them.” So it could be seen as an important predictor of the ability to manage crises such as a global pandemic.

Tight cultures have generally encountered more historical epidemics, warfare, and natural disasters such as earthquakes, and the importance of applying strict rules, low tolerance for deviant behavior, and acting together in such cases has been experienced in terms of survival (Dong et al., 2021). However, in loose cultures, where freedom and individuality are highly valued when threats such as epidemics arise, it may be more difficult to become organized as a society in order to act collectively, and the restriction of freedoms is questioned far more. It is known that tight cultures such as Singapore, Japan, and China have strict social norms, and that rule violations are punished more severely in such cultures, while loose cultures such as the United States, Italy, and Brazil are more permissive (Bavel et al., 2020).

Dong et al.'s (2021) study revealed that cultural tightness is a protective factor against psychological disorders in the COVID-19 pandemic. It moderates the positive relationship found between the risk perceptions of COVID-19 with psychological disorders. Additionally, the same study showed that in these cultures people are protected from psychological disorders by the high levels of perceived protection efficacy. In another recent study, Zhang (2021) applied Hofstede's cultural orientations (collectivism, power distance, long-term orientations, and indulgence) to examine the Extended Parallel Process Model (EPPM) (severity, susceptibility, self-efficacy, response efficacy, and compliance behavior) variables. The study's findings showed that different fear appeal variables work differently according to certain cultural orientations. These results could be used as a functional guide to psychological prevention, and to predict compliance with protective behaviors such as those recommended in tackling the COVID-19 pandemic, and also for future probable outbreaks.

Hofstede (1980) asserted that all individuals are culturally "coded" from early childhood, and that our behaviors are generally culturally determined. Cultures also differ in their avoidance of uncertainty. A society's tolerance for ambiguity indicates the extent to which a culture programs its members how to feel (comfortable or uncomfortable) in unexpected circumstances. It seems that avoiding cultures attempt to reduce the probability of such situations by forming strict behavioral codes, laws and rules, and an almost inbuilt disapproval of deviant beliefs and actions (Hofstede, 2011). New studies, therefore, that examine the individual differences observed in coping with COVID-19 based on culture may also prove eminently functional for our future understanding of the subject and how best to tackle it.

According to International Human Rights Law, every human has the right to the highest available standard of health. Governments have a responsibility to prevent all kinds of threats to public health, and likewise to provide medical care to those in need. It also emphasizes that, in cases of severe public health threats such as pandemics, careful attention should be given to human rights, and applications should be neither arbitrary nor discriminatory, but based on human dignity (Human Rights Watch, 2020). At the same time, it also declares that in cases of serious public health threats such as pandemics, restrictions can be justified when they are rigidly necessary, based on legal grounds and scientific data, respectful of human dignity, and proportionate to reach the goals (Amon and Wurth, 2020). In processes invoked in response to COVID-19, it has been seen that inappropriate policies have led to numerous human rights violations such as ageism, discrimination, and stigmatization (Mykhalovskiy et al., 2020), and more recently in terms of inequalities seen in access to COVID-19 vaccines. Public messages and health politics related to COVID-19 should be constructed based primarily upon a human rights approach. It is essential to combat stigma and discrimination, to respect privacy, to avoid blaming those who do not comply with the recommended measures, and fight inequities in the access to healthcare and vaccines (Mykhalovskiy et al., 2020). In addition to all of these human rights violations, there are other

ethical issues to consider in the communications regarding protective measures: social distancing, the wearing of facemasks, restricted public gatherings and even private gatherings, as well as personal hygiene such as handwashing (Guttman and Lev, 2021). Handwashing and hygiene-related measures invoke certain ethical issues due to the reality of global inequity of having access to a clean and reliable water supply. Suggestions for maintaining social distance and distance-learning educational practices have brought about other examples of inequality. The suggestion to "stay at home" and to "work from home" is not readily applicable to individuals of many trades or all professions. There are also inequalities in terms of access to the necessary technological tools and infrastructure needed in terms of working or studying from home, communicating with significant others via online means, or to attending compulsory schooling through distance education.

Multidisciplinary rather than solely medical approaches are needed in order to cope with the rapid spread of a pandemic such as with COVID-19. It is essential to understand the human behaviors, attitudes, and underlying beliefs and rationales in order to be able to develop policies that are more effective on the ground. Only such an approach can contribute to the understanding of why different people have responded so diversely to the calls made by health and political authorities in the case of COVID-19 to reduce physical interaction levels and thereby the spread and impact of the disease.

In order to explain human behavior in a multidimensional context and to develop persuasive communication strategies, support is needed to be drawn from the social sciences; more specifically, from the disciplines of psychology, sociology, anthropology, and social psychology. New research is needed from the scholars of these disciplines in order to explore why people have responded so differently. Examining global health problems such as the current pandemic from the social psychological perspective could benefit not only the general public, but also politicians, educators, scientists, policymakers, and health authorities. Therefore, it is important to analyze these problems not only by conducting empirical research, but also in discussing the results according to both the traditional and contemporary theoretical perspectives. These issues should be discussed based on different theoretical approaches and from different disciplines' perspectives in order to gather the most appropriate practical solution suggestions to cope with the COVID-19 pandemic.

## RECOMMENDATIONS FOR AWARENESS CAMPAIGNS

From the beginning of the COVID-19 pandemic, images and text-based messages with exaggerated and/or sensitive content with the potential to cause psychological trauma started to spread on a global scale, in newspapers, televisions, and through the ubiquitous world of social media. It was seen that pictures of individuals who had died from the virus, were hospitalized and intubated in intensive care units, and publicity shots that emphasized how the disease was rapidly progressing and had a

significantly high mortality rate were shared. It has since been revealed that these messages increased the fear, anxiety, and stress levels of many people, and for some triggered seriously traumatic emotions (Dong and Zheng, 2020). Research has shown that individuals over the age of 65 years old were faced with ageist attitudes and stricter restrictions, whilst various group members identified as being “vulnerable” (e.g., healthcare providers or those already suffering from a chronic illness) were confronted with these negative outcomes to a much greater degree (Tzur Bitan et al., 2020; Trnka and Lorencova, 2020).

Although considerable evidence exists regarding the relationship between fear appeals and attitudinal change in general when it comes to disease prevention behaviors, this relationship is by no means simplistic or clear-cut. Sometimes, contrary to what is supposed in the theories, independent from the level of fear awakened, the fearful message can also be ignored, leading to defensive avoidance, or it may be so ineffective that no significant behavior change occurs (Heffner et al., 2021).

During the current pandemic, fear appeals used in health communication messages (e.g., public service announcements, posters, social media posts) have utilized graphic images and scary language to stimulate fear and to underline the negative consequences of not following the recommended behaviors (Stolow et al., 2020). However, depicting alarming and shocking scenarios can have a harmful effect, especially among those considered to be vulnerable (Lin et al., 2020; Trnka and Lorencova, 2020). Messages underlining the gravity of the pandemic could exacerbate pre-existing mental health problems such as anxiety and stress. In order to avoid such unwanted results, public messages must be designed in a way that explains appropriate ways to cope with the risks, and to increase self-efficacy in the population (Stolow et al., 2020).

The theories discussed in the current study emphasize how to deal with unwelcome negative consequences of using fear appeals. For example, in line with the EEPM's explanations about protection motivation, public messages that support the power of the proposed measures, besides the severity of the risk, such as “The COVID-19 virus is dangerous, but do not worry, it is easy to protect you and your loved ones; wear a facemask, keep your distance from others, and wash your hands often” could be effective. It has been revealed that fear appeals are more effective when the message includes efficacy, emphasizes the severity and vulnerability of the risk, but clearly underline the applicability and functionality of the recommended measures (Tannenbaum et al., 2015). Recent studies have shown that public health messages that focus on the severity of the virus and the efficacy of the preventive behaviors are deemed to be more effective (Anaki and Sergay, 2021; Kowalski and Black, 2021; Lithopoulos et al., 2021; Rui et al., 2021).

However, some researchers oppose this method to avoid unintended consequences, which may cause the “fear control” mentioned in the fear-drive theory, and some negative socio-behavioral outcomes such as distrust in health authorities, skepticism of health messaging, and resistance to engaging in the recommended behaviors (Stolow et al., 2020), and also “news avoidance” (Tunney et al., 2021).

According to Guttman and Lev (2021), appealing to positive values such as compassion and solidarity can be an effective communication approach in cases like epidemics, where the welfare of the individual depends upon collective actions. In collective threat situations, it is useful to impart messages to the general public regarding the need to stand together and to emphasize the ethos of “Together, we can overcome this.” This strategy could prove especially efficient in the case of the COVID-19 pandemic in ensuring that individuals who are in the low-risk group comply with the restrictions and support the more vulnerable members of society by considering the general population as a community (Guttman and Lev, 2021). Many different examples of this have been witnessed; for example, the United Nations' COVID-19 Response Creative Content Hub contains a variety of materials on prosocial acts including messages such as “Together we can overcome,” “Save people, donate to fight COVID-19,” “Follow the instructions, relax and donate,” and “Spread positive ideas, stay hopeful, stay safe” (United Nations, 2021).

Using war-type terminology (e.g., beating, fighting, enemy, weapons, victory) to motivate people to comply with the recommended COVID-19 related measures is another common communication strategy employed by political leaders (for example, former US President Trump), and also the mainstream media (Bates, 2020). Although this rhetoric seems to serve to stimulate a sense of unity against a common enemy, it is a tactic used to justify strict measures of human rights violations. On the other hand, although it seems that it aims to create solidarity, it also triggers othering, discrimination, and stigma (Venkateswaran, 2020).

There is some evidence that prosocial persuasive appeals could be more effective than fear appeals (Shen, 2011). According to Heffner et al. (2021), appeals that use prosocial language to underline the positive results of recommended behaviors can trigger positive emotions such as hope and joy, and therefore could be more effective than fear appeals in enhancing perceived efficacy.

For example, Heffner et al. (2021) used a fear appeal in their research, which included the severity of the virus and the vulnerability: “The coronavirus is coming for you. When it does, your healthcare system will be overwhelmed. Your fellow citizens will be turned away at the hospital doors. Exhausted healthcare workers will break down. Millions will die. The only way to prevent this crisis is social distancing today.” In the same research, another appeal that focused on self-efficacy and response efficacy was given to the participants with a prosocial language: “Help save our most vulnerable. Together, we can stop the coronavirus. Everyone's actions count. Every single person can help to slow the crisis. We have the tools to solve this problem. Together, and by self-isolating, we can save millions of lives.” Their findings showed that both threat and prosocial messages were equally able to stimulate compliance with the recommended COVID-19 preventive behaviors. Therefore, considering the findings show that restrictions increase clinical mood disorders, it seems more reasonable to choose public health messages that activate positive emotions instead of fear appeals

in order to increase compliance with restrictions and other preventive health behaviors. They also should be accurate, based on real data, and be transparent. They should be empathetic, and not include blaming or shaming; far from a paternalistic and authoritarian orientation, they should emphasize trust in the public, describe the rules in simple and easy-to-follow language, and highlight their practicality, ease of application, and their functionality.

Stolow et al. (2020) also proposed the use of supportive and evidence-based health communications over fear-based that explain step-by-step what can be done in order to protect themselves and society as a whole. They advised on innovative alternative strategies such as using appeals by opinion leaders and celebrities, education-based entertainment, and humor as

means that could be employed as alternatives to fear appeals for the avoidance of the aforementioned unintended results. According to Guttman and Lev (2021), communication strategies should be based on the essential principles of human rights, including autonomy, equality, dignity, and privacy (Guttman and Lev, 2021). Appeals to prosocial values could be used as well as or instead of the fear appeals in light of the positive psychological perspective.

Given the high mortality of the coronavirus disease 2019 (COVID-19), having severe COVID-19 may be a life-threatening event, especially for individuals at high risk of complications. Therefore, in the article we try to answer two questions that are relevant to public mental health: Can we define groups who are at higher risk of developing pandemic-related PTSD? How can health specialists prepare for it? Given the results of previous research on PTSD in epidemic (e.g., SARS) survivors, we suggest that mental health professionals in countries touched by the pandemic should prepare for an increase in the PTSD prevalence, specifically in: individuals who have had severe COVID-19; family members of these patients and of patients who have died; and frontline healthcare workers witnessing COVID-19 patients' sudden deaths, or numerous life-threatening situations. We postulate that these groups at risk should be routinely screened for PTSD in primary medical and pediatric care. Mental health services should prepare for providing therapeutic interventions for individuals with PTSD in the vulnerable groups, and support to their families, especially children.

**Keywords:** coronavirus disease, post-traumatic stress disorder, severe acute respiratory syndrome, prolonged grief disorder, family, healthcare worker

## INTRODUCTION

The COVID-19 pandemic covered 223 countries, 136,291,755 individuals with confirmed infection and 2,941,128 deaths as of April 13, 2021 (1). Globally the case mortality rate from COVID-19 is 10.4 deaths per 100,000 inhabitants but it varies widely by region and country, with as high as 84.9 in Belgium, 67.5 in Andorra, and 64.3 in the United Kingdom (2). Age is the main risk factor for complications and death as a result of COVID-19;

the disease death rate varies from 0.2% for individuals aged 10–39 years to 21.9% in people over 80 years. Death rate also increases in patients with pre-existing comorbid conditions, such as history of metastatic solid tumor (57%), myocardial infarction (47%), cerebrovascular disease (39%), congestive heart failure (37%), hemiplegia (34%), malignant neoplasm (27%), diabetes (20%), dementia (20%), chronic pulmonary disease (16%), hyperlipidemia (11%), and hypertension [8.4%; (3–5)]. Given the high COVID-19 mortality, the severe disease may be life-threatening and as such may be considered a traumatic event, especially for individuals at high risk of complications and death (6–8).

People who are exposed to traumatic events can develop post-traumatic stress disorder (PTSD). PTSD is a serious mental disorder that can develop in persons exposed not only to actual or threatened death, who directly experienced the traumatic event(s), but also in those who witnessed such an event personally, learned that the accidental or violent event occurred to a close family member, or friend or experienced repeated or extreme exposure to aversive details of the traumatic event personally. Such an event is criterion A for PTSD in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [DSM-5; (9)]. PTSD causes severe distress or impairment in psychosocial functioning and is marked by four main types of symptoms that last for at least a month, being, respectively, the criteria B, C, D, and E for the disorder: (i) intrusions associated with the traumatic event, e.g., involuntary distressing event-related memories, dreams, and flashbacks, or physiological reactions to cues that resemble the traumatic event; (ii) avoidance of event-related stimuli, i.e., internal (memories, thoughts, and feelings) or external (people, places, situations) reminders; (iii) negative alterations in event-related cognitions, and/or mood, e.g., inability to remember an important aspect of the event, distorted cognitions about the event leading to blaming himself or herself or others and/or persistent negative emotional state and inability to experience positive emotions, diminished activities, and/or detachment from others; and (iv) event-related increased arousal and reactivity, e.g., difficulty sleeping and concentrating, reckless or self-destructive behavior, and being easily irritated and angered (9). PTSD individuals are 2–5 times more at-risk of suicidal ideation, suicide attempt, and deaths by suicide (10). Previous research indicates that about 80% of individuals with PTSD have at least one other comorbid disorder, in particular: depressive and anxiety disorders, as well as substance use disorder (11, 12).

Given the exceptional epidemic situation we are facing now, can we define groups at high risk of developing pandemic-related PTSD? What steps can mental health specialists take to prepare for it? In the following paper we will briefly address these issues.

## WHAT GROUPS HAVE HIGH RISK OF DEVELOPING PANDEMIC-RELATED PTSD?

We believe that mental health professionals in pandemic countries should be prepared for an increase in the PTSD

prevalence in three specific groups during COVID-19 pandemic and later: (i) individuals who have had severe COVID-19 and who feared imminent death from the disease; (ii) family members of these severely touched patients or patients who have died as a result of the disease; and (iii) frontline healthcare workers (HCWs) witnessing COVID-19 patients' sudden deaths, or life-threatening situations.

## Severe COVID-19 Survivors

Among COVID-19 individuals, those with a severe course of the disease are particularly at risk of developing PTSD (6–8). Patients who had to undergo medical interventions to maintain or restore vital functions experience particularly intense traumatic stress (13, 14). A very traumatically stressed subgroup may also include individuals with severe disease who were refused health care as a result of health service failure during a pandemic (15, 16). The meta-analysis of 35 studies involving 79,170 people with COVID-19 (17) showed that almost a quarter of them (23%) develop a severe form of the disease (35 studies, 79,170 patients) which requires close monitoring. The total percentage of patients admitted to the intensive care unit was 11.0% (39 studies, 80,487 patients), with no significant differences between various countries or regions (17). The life of many of these individuals is threatened and many of them may experience high levels of fear of imminent death, which creates a traumatic event.

The effects of the current as well as of past epidemics on the mental health of survivors can help predict the psychopathological consequences of a severe life-threatening viral disease. Two Italian studies on recovered severe COVID-19 survivors reported that the prevalence of PTSD is 10.4% (8) and 30.2% (7), respectively. Additionally, in survivors of the severe acute respiratory syndrome (SARS) during the epidemic that covered 29 countries in 2002/2003, infecting 8,096 individuals, of whom 774 died PTSD was present in 39% of patients 10 months after discharge (18), and over time the frequency of PTSD even increased, ranging from 42 to 54.5% after 31–51 months from discharge (18–20). Given that an estimated 3.6% of U.S. adults had PTSD in the former year, and the lifetime prevalence of this syndrome being 6.8% (21), the cited studies indicate that PTSD is a common chronic mental health problem following a virus disease with high mortality (22).

It should be added that COVID-19 infected persons most often develop less severe symptoms such as fever (78.8%), loss of smell and/or taste (from 19.0 to 73.6%), cough (53.9%) and malaise (37.9%), and sometimes diarrhea (9.5%), rhinitis (7.5%), and abdominal pain and vomiting (4.5%) (17, 23, 24) which are usually not life-threatening and are treated at home with over-the-counter medications. Infection may also be asymptomatic (25–27). Such cases are not likely to develop PTSD as COVID-19 infection in most of the cases does not lead to symptoms severe enough to be life threatening and these individuals do not meet the A criterion for PTSD (9). However, some persons, although not hospitalized, may experience severe symptoms of COVID-19 and fear of imminent death, thereby experiencing a traumatic event, and can develop PTSD; high levels of fear of death during

the event, not the type of medical treatment, are the hallmark of a traumatic stressor.

## Families of Severe COVID-19 Survivors and of Persons Who Died of the Disease

The second group at risk of developing pandemic-related PTSD are the families of people whose lives were at risk due to severe COVID-19 as well as the families of those who died of the disease under emergency circumstances. Being a witness to the threat to the life of another person, especially a loved one in the course of COVID-19, can be a traumatic event (9). The family's situation becomes even more complicated when a loved one has died in the course of the disease. Bereaved persons can then be obliged not only to deal with the traumatic events of life-threatening viral disease and the death of a loved one, but also with intense grief symptoms. The sudden death of a loved one and the inability to prepare for the death—which often occurs during a pandemic—is a risk factor for prolonged grief disorder (28). Grief of family members may be additionally difficult and complicated due to the circumstances surrounding death and mourning during a pandemic, e.g., quarantine of the dying persons, and delayed and very modest funerals. Grief and mourning in this time, due to accumulation of death and difficulties with recognizing individual bereavement and pain during pandemic, especially after loss of an elderly with chronic diseases, can be disenfranchising and therefore additionally complicated (29).

## Frontline Healthcare Workers

The third group at risk of developing PTSD during a pandemic are healthcare professionals who experience traumatic stress in the context of witnessing patients' dying and their lives being threatened, especially in cases of insufficient or inadequate intensive medical equipment. Furthermore, shortages of protective or medical equipment (30, 31) can be potentially traumatic if they lead the HCWs to fear of contamination and own imminent death. Own severe course of the disease and being a witness to the threat to life or death of other people may lead to the accumulation of traumatic stress in HCWs. Studies showed that after the SARS epidemic in 2002/2003, PTSD developed more often in infected HCWs than in non-HCWs (20, 32). We may predict that other professional groups such as employees of nursing homes and of other long-term care facilities also may experience some of these above mentioned traumatic stress factors (33).

## WHAT STEPS CAN BE TAKEN TO PREPARE FOR PANDEMIC-RELATED PTSD?

A systematic approach to services to prevent, diagnose, and treat PTSD in risk groups is needed (34). First of all, mental health experts should be aware of the risk of developing PTSD in severe COVID-19 survivors who feared imminent death from the disease, their family members and family members of patients who have died as a result of the pandemic, as well as frontline

HCWs witnessing patients' sudden deaths, or life-threatening situations. Information about PTSD and its symptoms should be made available to all HCWs and to mental health patients and their families during and in the months following the pandemic.

Second, we postulate that the three groups at risk described above should be routinely screened for PTSD in the months following the onset of the disease as the usual window of PTSD onset lies between 1 and 6 months after a traumatic event. Screening should be done in primary medical and pediatric care if resources are immediately available for timely follow-up by mental health professionals with specific expertise in PTSD assessment, and—in optimal circumstances—treatment of this disorder. Screening should distinguish between other mental health problems vs. PTSD. Measurement should begin with screening first for traumatic events, i.e., directly experiencing or witnessing death or imminent threat of death due to the pandemic (or other concurrent or previous incidents) being criterion A of the disorder according to DSM-5. PTSD symptoms should be screened only if potentially traumatic events are identified. For example, non-symptomatic individuals who test positive for COVID-19 are not at risk and should not be screened for PTSD, although they may develop other mental disorders such as depressive or anxiety disorder (35). Co-occurrence of PTSD and other disorders [see (7, 8)] is associated with high levels of distress, burden and reduced quality of life (11, 12), thus special clinical attention should be paid to individuals with PTSD experiencing additional mental health problems.

Bereaved surviving close ones who died unexpectedly as a result of the pandemic should be screened not only for PTSD but also for prolonged grief disorder, for example with the Prolonged Grief Disorder-13-Revised scale (36). PGD measurement should be carried out 12 months after the loss, as—according to DSM-5-TR—this is the time after which the persistence of severe grief symptoms, if they interfere with the psychosocial functioning, indicates the presence of this disorder (37).

Third, mental health services should prepare to provide evidence-based therapeutic interventions for individuals with PTSD such as prolonged exposure therapy, and cognitive processing therapy (38). It would be worth training clinicians in various countries in delivering these evidence-based interventions online, as well as to test their effectiveness in individuals with pandemic-related PTSD. Moreover, mental health professionals should be encouraged to: (i) share their experiences on the adjustments to be made in order to tailor these interventions to the current situation, e.g., necessity to provide interventions online and to acknowledge the specificity of the clinical picture of symptoms in severe COVID-19 survivors and their families (including the bereaved), and HCWs; (ii) define frameworks to effectively implement evidence-based interventions in mental health services in various countries (in particular in low income countries); and (iii) prepare accessible and easy-to-follow online trainings for professionals from various countries on evidence-based therapeutic interventions for PTSD.

Finally, studies indicate that the severity of PTSD symptoms in parents is associated with an increase in behavioral and emotional problems in their children (39, 40). Therefore, one should be

prepared to prevent such cascading effects of the pandemic by considering psychological support for children of parents who have developed PTSD due to the pandemic. Again, one of the challenges would be providing support for children and their families through online services.

The issue of the full prevalence of pandemic-related PTSD remains a matter of future research as symptoms may develop up to 6 months after the traumatic event. Research showing the full scope of pandemic-related PTSD prevalence will be possible only a few months after the end of the outbreak. Former studies indicated a large prevalence of PTSD in survivors of the earlier coronavirus epidemic (SARS), especially in HCWs, therefore we suggest that mental health professionals should prepare for the frequent occurrence of PTSD in this high risk groups. Families of survivors of severe diseases with high mortality and those who died from the pandemic, as well as frontline HCWs who were not infected but have witnessed numerous deaths and life-threatening situations—although not included in such systematic studies as survivors—may also experience traumatic stress during the outbreak and develop PTSD. Notwithstanding, we suggest that health care policies should consider routine screening for the presence of PTSD symptoms in the three groups at risk described in this paper,

together with preventive and treatment strategies of PTSD, and related risks such as suicide.

## AUTHOR CONTRIBUTIONS

MS wrote the first draft of the manuscript. All authors edited it, wrote parts of the reviewed manuscript, and accepted its final form.

## FUNDING

The research is financed by the funds from the Faculty of Psychology at the University of Warsaw, and the Department of Psychology at the Maria Grzegorzewska University awarded by the Polish Ministry of Science and Higher Education in the form of a subvention for maintaining and developing research potential in 2020.

## ACKNOWLEDGMENTS

The very first form of the manuscript have previously appeared online as a preprint: <https://psyarxiv.com/bnkve/>.

Chinese emergency department (ED) staff encountered significant mental stress while fighting the coronavirus disease 2019 (COVID-19) pandemic. We sought to investigate the prevalence and associated factors for depressive symptoms among ED staff (including physicians, nurses, allied health, and auxiliary ED staff). A cross-sectional national survey of ED staff who were on duty and participated in combating the COVID-19 pandemic was conducted March 1–15, 2020. A total of 6,588 emergency medical

personnel from 1,060 hospitals responded to this survey. A majority of respondents scored above 10 points on the PHQ-9 standardized test, which is associated with depressive symptoms. Those aged 31–45, those working in the COVID-19 isolation unit, and those with relatives  $\leq 16$  or  $\geq 70$  years old at home all had statistically significant associations with scoring  $> 10$  points. Depressive symptoms among Chinese emergency medical staff were likely quite common during the response to the COVID-19 pandemic and reinforce the importance of targeted ED staff support during future outbreaks.

**Keywords:** COVID-19, depression, emergency medicine, PHQ-9, China

## INTRODUCTION

At the end of December 2019, a new respiratory infection outbreak, later termed coronavirus disease 2019 (COVID-19), was first reported in Wuhan, China (1). Unfortunately, COVID-19 has continued to rampage throughout the world. According to the World Health Organization (WHO), there have already been hundreds of millions confirmed cases and several million deaths (2). The prevention and containment of COVID-19 have become issues of worldwide concern. Among a variety of control options, social distancing was recommended by the WHO to reduce the possibility of infection (3). Unfortunately, medical staff, particularly those on the frontlines of healthcare in emergency departments (EDs), have taken the brunt of the effort in the fight against COVID-19. They are unable to follow recommendations on social distancing and must work in areas that are high risk for COVID-19. According to data from the National Health Council of China, as of April 1, 2021, thousands of medical staff have been infected and many have died (4). ED staff are not only exposed to a higher risk of infection but also suffer the physical and mental strain of tiring work schedules, difficult triage decisions, fears of infecting family members, and the anguish of losing patients and colleagues to COVID-19 (5).

Previous studies showed that infectious disease pandemics, such as severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) can impact negatively on the mental health of different groups of people, including healthcare workers (6, 7). COVID-19 also likely results in psychological problems, such as stress, anxiety, and depressive symptoms, among frontline medical workers. Recently, several studies have reported that the prevalence of anxiety and depression among healthcare workers is higher during the COVID-19 pandemic (8, 9). However, research exploring the mental health problems of frontline medical workers in the ED is limited. The aim of this project was to examine the prevalence of depressive symptoms among ED medical personnel in China during the early (and most severe phase so far for China) of the COVID-19 pandemic.

## MATERIALS AND METHODS

### Study Design and Participants

This was a national cross-sectional survey conducted between March 1 and March 15, 2020. The study was approved by the Ethics Committee of Peking Union Medical College Hospital, and all participants provided informed consent. Chinese ED

staff (including physicians, nurses, allied health, and auxiliary ED staff) between 18 and 80 years of age who were on clinical duty in areas designated to receive COVID-19 patients between November 1, 2019, and March 15, 2020, were invited to participate. Only those able to complete informed consent were eligible for inclusion. Anyone previously diagnosed with any mental illness, those taking any antipsychotic medications, or those participating in other clinical trials were excluded. Due to the sudden outbreak of COVID-19 in China, some retired medical staff participated in the fight against the pandemic, so our study included medical staff over 60 years old (the normal retirement age in China). Finally, since nearly all ED staff on clinical duty in China during this period participated in fighting against the COVID-19 pandemic work, a concurrent control group of ED staff who did not participate in the fight against the pandemic was not feasible.

### Survey Instrument

Our survey instrument begins with collecting respondents' general characteristics, including sex, age, profession, relationship status, and whether they live with children younger than 16 years old or adults older than 70 years old.

We then queried respondents' work details during COVID-19. Specifically, we asked whether they worked in Hubei province (where the city of Wuhan is located, the site of the most significant COVID-19 outbreak in mainland China during the study period). During the pandemic, many medical staff across the country left their long-term work locations and went to Hubei to participate in fighting against the COVID-19 pandemic work, so we divided people working in Hubei into two groups: those who were living in Hubei for at least 2 years before the outbreak and those who went to Hubei to participate in anti-pandemic work. We also queried whether respondents worked in COVID-19 isolation wards, whether they were directly in contact with any confirmed COVID-19 patients (regardless of any protective measures being taken), whether they underwent compulsory isolation in their hospital due to workplace exposure to COVID-19 (i.e., they were being quarantined in the hospital facilities not due to being sick themselves), and the duration of such isolation time. We additionally clarified this issue in our research, by dividing the medical staff into "compulsory isolation in the hospital (i.e., they still needed to stay in the hospital when they are not at work)" and "non-compulsory isolation in the hospital (they could go home after work)."

We then asked respondents about the time spent working during the COVID-19 outbreak: what their working hours were before and after the outbreak of COVID-19 (including the average working hours of each rotation and weekly working hours). We collected the working hours of medical staff between November 2019 to March 2020 (the official “winter” months in China) and selected January 15, 2020, as date of the outbreak of China’s COVID-19 pandemic. January 15, 2020, was the infection point for COVID-19 cases in Wuhan (the average number of daily hospital admissions for fever jumped from 300 to 600 that day).

### Patient Health Questionnaire-9 (PHQ-9)

After the collection of respondent characteristics and work details, the Patient Health Questionnaire-9 (PHQ-9) standardized questionnaire was used to ascertain the psychological state of surveyed ED staff. The Patient Health Questionnaire depression module is a self-rated version of the Primary Care Evaluation of Mental Disorders Patient Questionnaire (PRIME-MD PQ) for depression (10, 11). PHQ-9 has been validated in two large studies involving 3,000 patients in seven obstetrics and gynecology clinics and another study with 3,000 patients in eight primary care clinics (12). This scale scores each of the nine diagnostic criteria for depression in the DSM-IV on a scale from “0” (not at all) to “3” (nearly every day) (12). The PHQ-9 is scored 0–27, with the interpretation based on the following intervals: 0–4, 5–9, 10–14, 15–19, and 20–27. The cutoff score for major depression symptoms in prior studies was set at 10, with subjects scoring higher than 10 being defined as having depressive symptoms. Using the Mental Health Professional (MHP) Validation Interviews as the criterion standard, a PHQ-9 score  $\geq 10$  had a sensitivity of 88% and a specificity of 88% for major depression (13), while a PHQ-9 score  $< 10$  yielded a negative predictive value of 0.99 (14). PHQ-9 has been widely applied in clinical institutions and scientific research to assist in making the diagnosis of depression, quantify depressive symptoms, and monitor their severity. We utilized the standard score of  $\geq 10$  as the critical value to divide those with or without a depressed state in this study. We hypothesized that most respondents would have a score  $> 10$ .

### Survey Process

In this study, we combined PHQ-9 with our own queries for respondent characteristics and work details as noted above. We then used an online questionnaire system (Gold Data, Jingshuo Technology Corporation, Beijing, China) as the platform for distributing our survey tool. We pushed out the survey instrument in an online “snowball” method of sampling by sending the survey out through friendship circles and promotion through emergency medicine groups on the WeChat messaging platform (Tencent Corporation, Shenzhen, China). The Gold Data system was then able to collect the survey data electronically.

### Statistical Analysis

Continuous variables were described with mean and standard deviation, while categorical variables were described by

frequency and percentages. When the distribution of a continuous variable was skewed, the median and interquartile ranges were presented. Student’s *T*-tests or one-way analysis of variance was employed for two groups or multiple-group continuous-measure comparisons, as appropriate. Chi-square tests were used for comparing categorical measures. Multiple logistic regression models were used to estimate the odds ratio (OR) and 95% confidence interval (CI) for the association between associated factors and depressive symptoms, with the risk factors selected by a forward stepwise method. All analyses were conducted using SAS version 9.2 (SAS Institute, Inc., Cary, NC, USA). A  $p < 0.05$  was considered statistically significant.

## RESULTS

We received 7,000 completed questionnaires through the online survey system, of which 6,588 (94.00%) were valid. Respondents came from 1,060 hospital EDs in 27 (out of a surveyed 31) provinces, autonomous regions, or independent municipalities in China. The average PHQ-9 score for all medical staff was  $10.94 \pm 5.1$ , and 3,795 out of 6,588 participants (57.60%) had a PHQ-9 score  $\geq 10$ . The prevalence of depressive symptoms was high with a PHQ-9 score distribution of 10–14 (34.44%), 15–19 (16.27%), and 20–27 (6.89%).

### Participant Characteristics

Participant characteristics are shown in **Tables 1, 2**. Among these samples, 33.58% were male and 66.42% were female. Most respondents (87.56%) were  $\leq 45$  years old. Among the medical staff surveyed, nurses and doctors accounted for 59.01 and 38.29%, respectively. Almost all (95.1%) participants were from outside of Hubei province during the COVID-19 outbreak. In addition, 56.70% of participants had children  $\leq 16$  years old at home who needed care, while 31.21% of participants lived with elderly family members  $\geq 70$  years old.

Almost half (45.86%) of the ED staff who participated in this study worked in their hospital’s COVID-19 isolation area(s), and 15.62% of them had direct contact with patients known to be infected with COVID-19. Almost all (92.93%) ED staff were forced to quarantine in their hospital while on service.

### Factors Associated With Major Depressive Symptoms Among ED Staff

Results of univariate analysis are shown in **Table 2**. Severe depressive symptoms divided by prevalence according to age group, occupation, and marital status were all statistically significant. In addition, the prevalence of PHQ-9 scores  $\geq 10$  was higher in males compared to females ( $p = 0.040$ ). Similar results were found in participants who lived with children  $\leq 16$  and adults  $\geq 70$ , those who worked in the COVID-19 isolation unit, and those who had direct contact with COVID-19 patients ( $p < 0.05$ ). There was no significant difference in the PHQ-9 scores between people who were or were not working in Hubei province during the outbreak.

## Duty Time and Quarantine of the ED Staff

Among all respondents, the average time per duty rotation was 10 h, and the average time at work per week was nearly 50 h. There was no difference in the number of hours worked in Hubei

compared to other provinces (working hours per week,  $50.38 \pm 22.0$  vs.  $48.34 \pm 18.6$ ,  $p = 0.101$ ; working hours per rotation,  $11.78 \pm 8.0$  vs.  $11.89 \pm 7.6$ ,  $p = 0.799$ ). There was no difference in the average daily work hours per shift before or during the pandemic among respondents ( $11.88 \pm 7.4$  vs.  $11.89 \pm 7.6$ ,  $p = 0.850$ ). However, the average weekly work hours before COVID-19 were more than the average hours during COVID-19 ( $49.49 \pm 18.5$  vs.  $48.44 \pm 18.8$ ,  $p < 0.001$ ).

In our survey, the ED staff who were forced to quarantine in their hospital had a higher PHQ-9 score than those who were not forced into hospital isolation ( $11.4 \pm 4.9$  vs.  $10.9 \pm 5.1$ ,  $p = 0.0129$ ; **Table 2**). In addition, there was no statistically significant difference in scores between groups that had more or <14 quarantine days (PHQ score,  $11.63 \pm 5.1$  vs.  $11.359 \pm 4.8$ ,  $p = 0.970$ ).

## Factors Associated With Depressive Symptoms by Multivariate Analysis

As shown previously, univariate analysis (**Table 2**) revealed several variables associated with a PHQ-9 score  $\geq 10$ . Subsequent multiple logistic regression analysis showed that a score  $\geq 10$  during the COVID-19 pandemic was significantly associated with direct contact with confirmed COVID-19 patients (OR = 1.153, 95% CI: 0.994–1.338), working in the COVID-19 isolation unit (OR = 1.366, 95% CI: 1.23–1.517), respondents between 31 and 45 years of age (OR = 1.139, 95% CI: 1.004–1.293), and those staff living with children  $\leq 16$  years old (OR = 1.126, 95% CI: 1.001–1.267) or adults  $\geq 70$  years old (OR = 1.325, 95% CI: 1.177–1.492). Results of the multivariate logistic regression analysis are shown in **Table 3**.

## DISCUSSION

This was a large-scale, multicenter, cross-sectional study of the prevalence and risk factors for depression among medical staff during the COVID-19 pandemic. Because the population surveyed in this study covered most provinces and cities in China, we can draw a relatively complete picture of the prevalence of depressive symptoms among Chinese ED staff during the fight against the COVID-19 pandemic. The results of this study show that more than half of all staff surveyed experienced PHQ-9 scores  $\geq 10$ , and such elevated scores were associated with age, family factors, and exposure to COVID-19 patients and were independent of work time or location. These results offer a comprehensive national assessment of potential depressive state in ED staff that may be used to guide future mental health improvement efforts.

Many recent psychological investigations on health professionals during COVID-19 have shown that health professionals fighting COVID-19 are suffering from more psychiatric disorders than other occupational groups (8, 15, 16). Wang et al. (17) performed a survey of Chinese physicians in Liaoning province and found that the prevalence of depressive symptoms among doctors was 65.3%. Lai et al. (8) performed a multicenter cross-sectional survey which collected demographic data and mental health measures of 1,257 health professionals

that treat patients exposed to COVID-19 in China, and they reported that 50.4% showed symptoms of depression. The rate of depressive state (PHQ-9 score ≥ 10) was 57.60% in our study. The proportion of people with depressive symptoms is slightly higher than the results of previous studies. One possible reason for this is that our study included only ED staff, whereas participants in other studies were from a variety of other specialties (e.g., respiratory medicine, critical care medicine, other internal

medicine specialties, or anesthesia). In China, medical staff in the ED have often already experienced high levels of stress even before COVID-19 began due to heavy workloads under uncertain conditions.

In most previous studies on the psychological impact of the COVID-19 pandemic on frontline healthcare workers, female nurses with close contact with COVID-19 patients appeared to have the highest mental health risks (18–21). It is important

to note that most previous studies included predominantly female participants, particularly nurses. Like the population composition of most previous studies, female participants also accounted for most of the population in our survey, but male respondents on average had higher PHQ-9 scores than female respondents. While the reasons behind this result are still unclear, this does help illustrate that female respondents do not have a monopoly on depression. Among other factors related to depressive symptoms among the ED staff surveyed, our correlation analysis indicated that a younger age and a married marital status were associated with depression. These predictors were mostly consistent with previous research (22, 23). The 31–45-year-old age group accounted for the largest proportion of subjects as well as the subgroup with the highest PHQ-9 scores. Compared with younger doctors, senior medical staff with more work experience may have more experience dealing with complex situations, which could explain their lower perceived stress and better resilience (24).

Isolation for ED staff during the COVID-19 outbreak was an additional stressor for frontline medical staff. During the COVID-19 period, the Chinese government strongly recommended that everyone reduce travel and self-quarantine as much as possible in their current place of residence, so it can be difficult to clearly define any additional “compulsory” element of isolation. In this study, we further divided any isolating ED staff into those who reported “compulsory isolation” in their hospital (they needed to remain on hospital property even when they are not on duty) and “non-compulsory isolation” outside of their hospital (they could go home after work). Isolation and confinement during the epidemic could cause a loss of daily habits, reduce socialization with other people, and directly lead to boredom and depression (25). ED staff who were not isolated in the hospital could still live at home, communicate with family and friends, and continue to receive their family’s emotional support and encouragement. In addition, ED staff who were forced to be isolated at their hospital may be in close contact with infected patients, thereby aggravating social stigma. In our study, the average PHQ-9 score and the proportion of PHQ-9 scores  $\geq 10$  were indeed higher in those ED staff who had to isolate in the hospital compared to those who could go home after work.

Surprisingly, compared with those inside Hubei province, those outside of Hubei province had no significant difference in PHQ-9 scores, this is different from the results of other cross-sectional studies during the same period, which showed that medical staff deployed to Hubei province had a higher prevalence of depressive symptoms than physicians and nurses working in fever clinics and infectious disease wards outside of Hubei province (8, 22, 26–28). During the outbreak of COVID-19, physicians and nurses deployed to Hubei province had to face confirmed COVID-19 patients. They had to work in unfamiliar environments, the patients they saw every day were more critical, and many of them needed immediate care (26, 27). In our study, ED medical personnel working in Hubei made up a relatively small portion (4.93%) of the overall study population, and this may prevent a meaningful analysis of their risk profile, being a limitation to the present study. Working in Wuhan was associated with more stress, but statistical significance was not met, possibly due to an insufficient sample size.

Looking at duty hours, we found that, regardless of the pandemic, the average working hours of all Chinese ED staff are relatively long. The average shift is 12 h long, and the average work hours per week are close to 50 h. High-intensity and time-consuming work may cause medical staff to become fatigued, resulting in higher overall PHQ-9 scores.

During the COVID-19 outbreak, there was no difference in both the number of duty hours per day and the number of duty hours per week in different regions (including Hubei province). This indicates that even though Hubei was the epicenter in China’s fight against the pandemic and there were more COVID-19 patients there than in other provinces, there seems to have been no serious imbalance in work hours compared to elsewhere in China. In addition, the duty hours for staff in other provinces did not decrease either. The number of medical staff in other provinces may have declined due to transfers to Hubei, but, due to fewer ED cases throughout the country, the remaining workers seemed to be on duty about the same amount of time. The workload of first-line medical staff in provinces other than Hubei should therefore not be minimized.

In a related point, the total number of work hours per week for ED staff was less after the COVID-19 outbreak than before.

There are many reasons for this, including additional medical staffing support from other departments, thereby reducing the average work hours for emergency medicine staff. National policy required medical staff who worked in the COVID-19 isolation ward(s) to have 14 days of compulsory isolation, which may also have reduced the average number of hours worked. During the COVID-19 period, the number of patients with fever increased significantly compared to previous years, and the number of patients who went to the hospital for other diseases was much smaller than usual. Similar situations have been reported in other regions. For example, from February 1 to April 30, 2020, the number of ED patients in Hong Kong decreased by 37% (28).

Our study had several limitations. First, like other screening questionnaires, the PHQ-9 scale is not sufficiently accurate to establish a definitive diagnosis of major depression. Scores exceeding the threshold are, in effect, a positive screen which should prompt a careful mental health assessment. Even though a score  $\geq 10$  does not equal major depression, high score may lead to other diagnoses that share symptoms with major depression, such as anxiety disorder, alcohol use disorder, or subsyndromal depression. Second, although we have obtained correlations for many single-factor analyses, many variables related to depression have not yet been explored. The correlation between different variables requires the creation of a comprehensive variable, which can be directly linked to the PHQ-9 score. Finally, this was a cross-sectional study and cannot directly establish the relationship between depression and related factors.

In conclusion, our study showed that most Chinese ED staff who worked clinically during the response to COVID-19 had elevated PHQ-9 scores which put them at a very high risk for major depression. This is the first comprehensive study to explore

the prevalence and associated factors of depression among emergency medicine workers in Chinese EDs. Policymakers should implement appropriate proactive interventions for ED staff in times of extreme distress, either during COVID-19 outbreaks or during future pandemics.

**Objective:** The purpose of this meta-analysis was to summarize the prevalence and risk factors of mental health problems among healthcare workers during the COVID-19 pandemic.

**Methods:** We applied an optimized search strategy across the PubMed, EMBASE, Scopus, PsycINFO, and four Chinese databases, with hand searching supplemented to identify relevant surveys. Studies were eligible for inclusion if they were published in peer-reviewed literature and used a validated method to assess the prevalence and risk factors of mental health problems among healthcare workers during the COVID-19 pandemic. Heterogeneity was quantified using  $Q$  statistics and the  $I^2$  statistics. The potential causes of heterogeneity were investigated using subgroup analysis and meta-regression analysis. Sensitivity analysis was performed to examine the robustness of the results.

**Results:** We pooled and analyzed data from 20 studies comprising 10,886 healthcare workers. The prevalence of depression, anxiety, insomnia, post-traumatic stress symptoms, phobia, obsessive-compulsive symptoms, and somatization symptoms was 24.1, 28.6, 44.1, 25.6, 35.0, 16.2, and 10.7%, respectively. Female and nurses had a high prevalence of depression and anxiety. Frontline healthcare workers had a higher prevalence of anxiety and a lower prevalence of depression than the those in the second-line. Furthermore, the proportion of moderate-severe depression and anxiety is higher in the frontline. Additionally, four studies reported on risk factors of mental health problems.

**Conclusions:** In this systematic review, healthcare workers have a relatively high prevalence of depression, anxiety, insomnia, post-traumatic stress symptoms, phobia, obsessive-compulsive symptoms, and somatization symptoms during the COVID-19 pandemic, and focus should be on the healthcare workers at high risk of mental problems. Mental health problems in healthcare workers should be taken

seriously, and timely screening and appropriate intervention for the high-risk group are highly recommended.

## INTRODUCTION

At the end of 2019, an emerging infectious disease named coronavirus disease 2019 (COVID-19) caused by severe acute

respiratory syndrome coronavirus 2 (SARS-CoV-2) broke out and caused a global pandemic that put healthcare workers (HCWs) across the world under unprecedented challenges and huge psychological impact (1, 2). In the fight against COVID-19,

HCWs, healthcare workers; PHQ-9, nine-item Patient Health Questionnaire; DASS-21, 21-item Depression, Anxiety, and Stress Scale; SDS, Zung Self-Rating Depression Scale; HAMD, Hamilton Depression Scale; GAD-7, seven-item Generalized Anxiety Disorder; SAS, Zung Self-Rating Anxiety Scale; HAMA, Hamilton Anxiety Scale; ISI-7, seven-item Insomnia Severity Index; PSQI, Pittsburgh Sleep Quality Index; SQR-20, Self-Reporting Questionnaires; IES-R, Impact of Event Scale—Revised; PCL-C, PTSD Checklist—Civilian Version; PTSD-SS, Post-traumatic Stress Disorder Self-Rating Scale; SCL-90, Symptom Checklist 90; SCL-90-R, Symptom Checklist 90—Revised; AHRQ Checklist, The Agency for Healthcare Research and Quality Methodology Checklist.

HCWs played a leading role. The HCWs were in the vanguard of the battle to combat COVID-19, providing medical services to the most affected areas (3). The mental health of HCWs was greatly challenged during the Middle East respiratory syndrome (MERS) and severe acute respiratory syndrome (SARS) (4–7). As generally known, COVID-19 is more contagious than SARS and MERS (8, 9) and can bring HCWs on the frontline mental health problems (10–14). Similarly, during the COVID-19 pandemic, HCWs encountered a huge psychological burden, with a high prevalence of depression, anxiety, insomnia, and distress (15, 16). Moreover, frontline HCWs, in fighting COVID-19, have more severe degrees of mental health symptoms than other HCWs (15, 17). Beyond the effects of mental health problems on individuals, the mental health problems of HCWs may link to poor-quality patient care and increased medical errors (18, 19). A reliable estimate of the prevalence of mental health problems among HCWs during the COVID-19 pandemic is of vital importance to its prevention, identification, and treatment. To the best of our knowledge, there has not been a meta-analysis of the prevalence of mental health problems and risk factors among HCWs during the COVID-19 pandemic published in the literature. We conducted a systematic review and meta-analysis of the prevalence of mental health problems and risk factors among HCWs during the COVID-19 pandemic to identify at-risk HCWs and provide timely assistance and intervention.

## METHODS

### Protocol

The protocol of our study has been registered on the International Prospective Register of Systematic Reviews (PROSPERO, CRD42020179189). The review methods are described in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-analyses guidelines (20) and the Meta-analysis of Observational Studies in Epidemiology criteria (21).

### Search Strategy and Study Eligibility

The search was performed in all fields in the PubMed, EMBASE, Scopus, PsycINFO, and four Chinese databases, including Chinese Biomedical Literature Database, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Wanfang database, with no language restrictions, from January 1, 2020 (subsequent to the emergence of COVID-19 in China) to April 14, 2020. The detailed search terms and full strategies are available in **Supplementary Material 1**. Additionally, a manual search was performed by reviewing the reference lists of the related articles by two investigators. Where necessary, we contacted the authors for any additional data.

Population-based or hospital-based studies fulfilling the following criteria were included in the present analysis: (1) the HCWs including doctors, nurses, and other medical personnel who were directly or indirectly involved in the diagnosis, treatment, or care of patients with confirmed or suspected cases of COVID-19, (2) studies reported the prevalence or risk factors of mental health problems (depression, anxiety, insomnia, etc.)

among HCWs which were assessed by structured interviews or validated questionnaires, (3) cross-sectional or cohort studies, and (4) published in a peer-reviewed journal.

Studies without original data and studies in which the data could not be reliably extracted after corresponding with the authors were excluded. If the same sample was reported in more than one study, the larger sample size with the longest follow-up duration will be included.

### Data Extraction and Quality Assessment

Two authors independently extracted the data, reported by the selected articles, and documented the following details in a standardized table: general information of publication (first author, year and location of the study, study period, and language), study design (cohort or cross-sectional), survey method, sampling method, study sample origin (population-based or hospital-based), sample size, number of HCWs, number of female HCWs, number of mental health problems among HCWs, instrument used to assess mental health problems, risk factors of each mental health problem, and the effects of each risk factor. The methodological quality of the included cross-sectional studies was assessed using an 11-item checklist which was recommended by the Agency for Healthcare Research and Quality (AHRQ). The answer to each item is “no,” “unclear,” and “yes,” respectively. Study quality was defined as follows: low quality (0–3 yes), moderate quality (4–7 yes), and high quality (8–11 yes). Any discrepancies will be resolved by consensus, and if necessary, a third reviewer will be consulted to arbitrate.

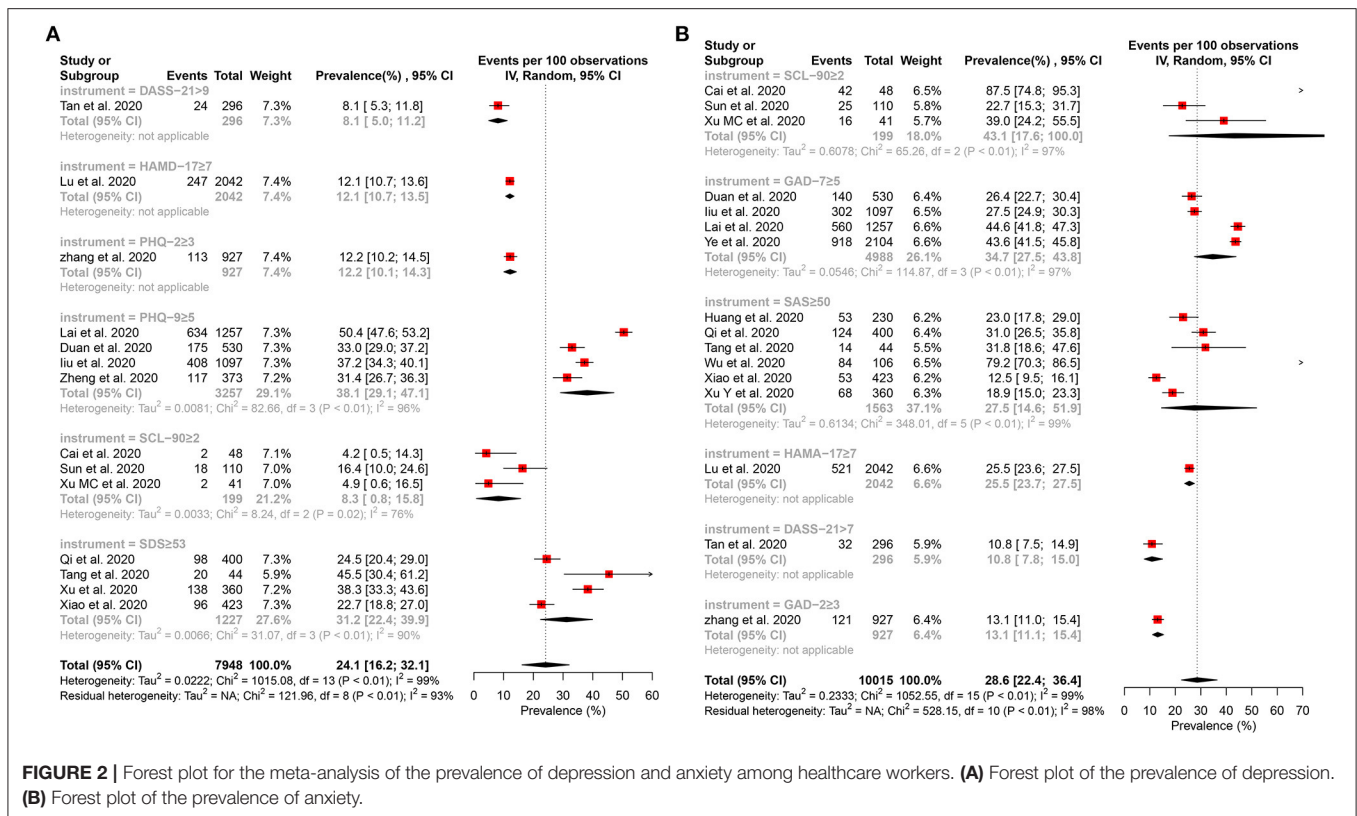

### Data Synthesis and Analysis

The pooled prevalence of each mental health problem and its 95% confidence intervals (CI) were calculated using random-effects meta-analysis that accounted for the heterogeneity of studies (22). The heterogeneity of studies was assessed by  $Q$ -test and  $I^2$ .  $I^2 > 50\%$  and  $p < 0.05$  in the  $Q$ -test were interpreted as the presence of significant heterogeneity (23, 24). When significant heterogeneity was identified, the source of heterogeneity was explored by subgroup analysis and meta-regression. Subgroup analyses were conducted with stratification by sample size, staff type, position, and gender. Sensitivity analysis using the leave-one-out method was performed to examine the robustness of the results. The potential publication bias was evaluated by funnel plot and the Egger linear regression test (25, 26). The statistical tests were two-sided and used a significance threshold of  $P < 0.05$ . We performed the statistical analysis in R (version 4.0.0; <https://www.r-project.org/>). A systematic narrative synthesis will be conducted if it is impossible to handle any meta-analysis.

## RESULTS

### Study Characteristics

According to the search strategy, a total of 1,898 records were retrieved, and 20 records were finally included (**Figure 1**). All studies were of a cross-sectional design, involving a total of 10,886 HCWs in 12,788 individuals for the quantitative synthesis; 70% of all participants were women, and 80% of the

**FIGURE 2 |** Forest plot for the meta-analysis of the prevalence of depression and anxiety among healthcare workers. **(A)** Forest plot of the prevalence of depression. **(B)** Forest plot of the prevalence of anxiety.

research were completed by February 2020. Nineteen studies took place in China, plus one in Singapore. Five studies were published in English, and the remaining 15 studies were published in Chinese. The median of participants per study was 639 (range, 37–2,299). Various instruments were utilized. For depression, the most commonly used tools were the Zung Self-Rating Depression Scale, the nine-item Patient Health Questionnaire, the Symptom Checklist-90 (SCL-90), and the 21-item Depression, Anxiety, and Stress Scale (DASS-21). For anxiety, the Zung Self-Rating Anxiety Scale, the SCL-90, and the seven-item Generalized Anxiety Disorder were used. For insomnia, the seven-item Insomnia Severity Index and the Pittsburgh Sleep Quality Index were used. For post-traumatic stress symptoms (PTSS), the Post-traumatic Stress Disorder Self-Rating Scale (PTSD-SS), the Impact of Event Scale—Revised version (IES-R), and the PTSD Checklist—Civilian version (PCL-C) were used. Obsessive-compulsive symptoms, somatization symptoms, and phobia were assessed by the SCL-90 and the 90-item Symptom Checklist—Revised. Eleven studies included frontline HCWs only, six included both frontline and second-line HCWs, and three included second-line HCWs only. When evaluated by the AHRQ assessment criteria, one study received eight points, one received seven points, four received six points, four received five points, nine received four points, and one received three points. Most studies are of moderate quality, with methodological quality scores ranging from 4 to 7. The detailed characteristics of the included studies are shown in **Table 1**.

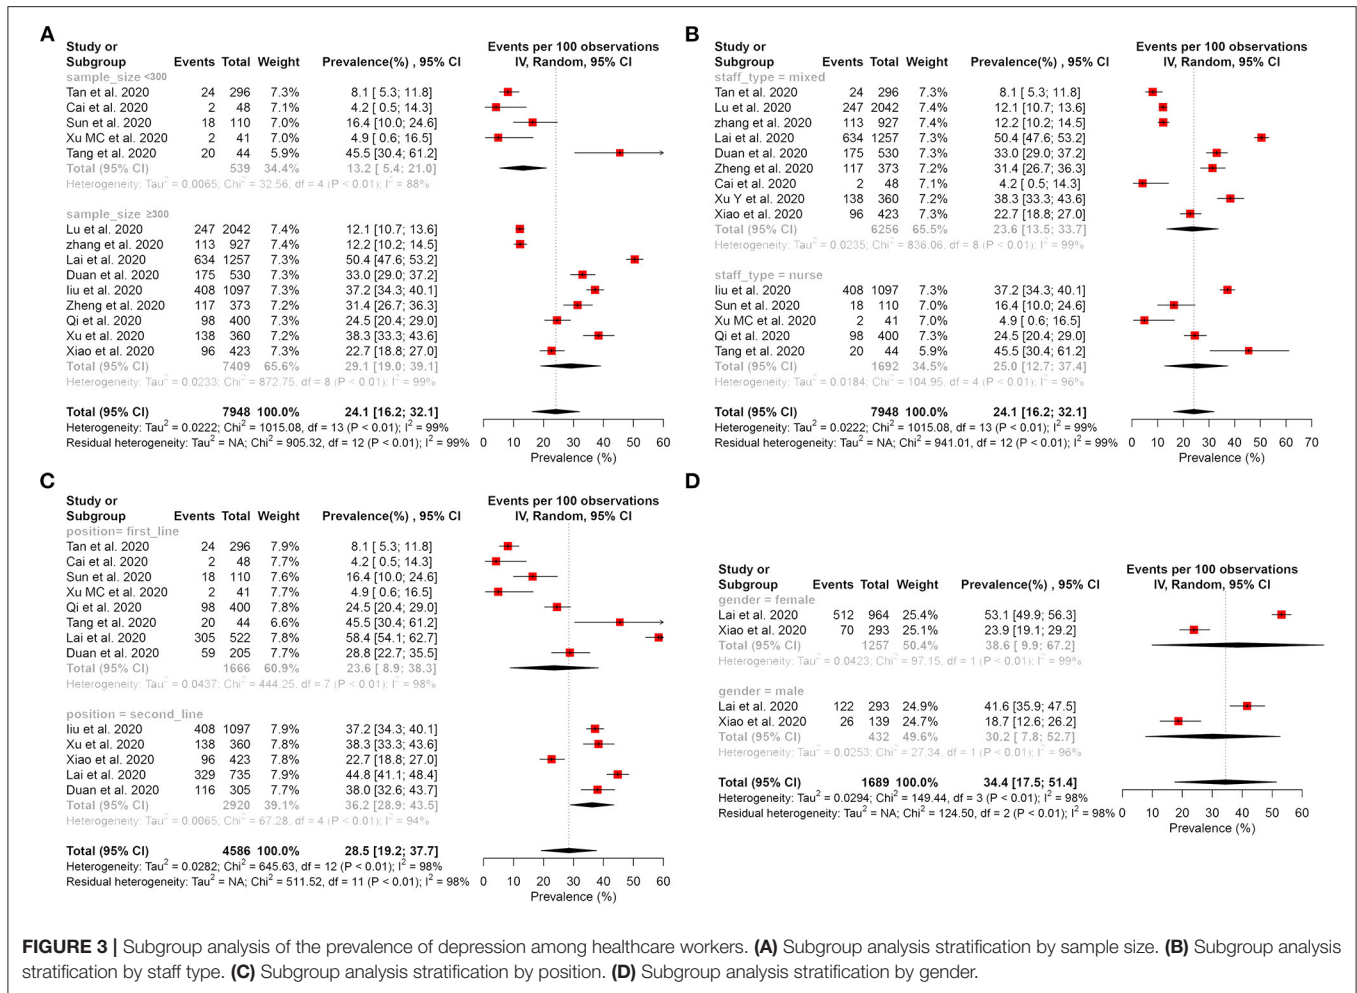

## Prevalence of Mental Health Problems in HCWs

### Prevalence of Depressive Symptom

Fourteen studies (15–17, 27–29, 32, 34–41) reported that the pooled prevalence of depressive symptom among HCWs was 24.1% (95% CI: 16.2–32.1%,  $I^2 = 99%$ ,  $P < 0.01$ ), with a range from 4.2 to 50.4% (**Figure 2A**). A subgroup analysis revealed that the second-line HCWs (36.2%, 95% CI: 28.9–43.5%,  $I^2 = 94%$ ,  $P < 0.01$ ) and female HCWs (38.6%, 95% CI: 9.9–67.2%,  $I^2 = 99%$ ,  $P < 0.01$ ) had a higher prevalence of depression symptom than frontline and male HCWs separately (**Figure 3**). About 9.6% of HCWs were identified by instruments as individuals with moderate to severe depression (**Figure 4A**). Among them, the prevalence of moderate to severe depression in frontline HCWs (14.6%, 95% CI: 6.3–23.0%,  $I^2 = 91%$ ,  $P < 0.01$ ) is higher than those in the second-line (8.7%, 95% CI: 3.9–13.4%,  $I^2 = 94%$ ,  $P < 0.01$ ; **Figure 4B**).

### Prevalence of Anxiety Symptom

Sixteen studies (15–17, 27, 29, 31, 32, 34–36, 38–43) reported that the pooled prevalence of anxiety among HCWs was 28.6% (95% CI: 22.4–36.4%,  $I^2 = 99%$ ,  $P < 0.01$ ), with a range from 10.8 to 87.5% (**Figure 2B**). In the subgroup analysis stratified by position, the frontline HCWs (33.5%, 95% CI: 23.5–47.7%,  $I^2 = 98%$ ,  $P < 0.01$ ) had a higher prevalence of anxiety than the second-line HCWs (**Figure 5C**). Of the 16 studies, seven studies reported that the prevalence of anxiety is higher in nurses (36.8%, 95% CI: 26.8–50.5,  $P < 0.001$ ) than that in the mixed staff

**FIGURE 3 |** Subgroup analysis of the prevalence of depression among healthcare workers. (A) Subgroup analysis stratification by sample size. (B) Subgroup analysis stratification by staff type. (C) Subgroup analysis stratification by position. (D) Subgroup analysis stratification by gender.

type including nurses and doctors (Figure 5B). In the subgroup stratified by gender, female HCWs (26.6%, 95% CI: 13.1–53.9%,  $I^2 = 98\%$ ,  $P < 0.01$ ) had a higher prevalence of anxiety than male HCWs (Figure 5D). About 7.2% of HCWs were identified by instruments as individuals with moderate to severe anxiety (Figure 6A). Similar to the symptoms of depression, the anxiety symptoms of frontline HCWs are more severe than that of the second-line HCWs (Figure 6B).

### Prevalence of Insomnia

Five studies (15, 30, 32, 38, 42) reported that the pooled prevalence of insomnia among HCWs was 44.1% (95% CI: 31.3–57.0%,  $I^2 = 98\%$ ,  $P < 0.01$ ), with a range from 21.3 to 65.2% (Figure 7A). About 11.8% of the HCWs were identified by instruments to be with moderate to severe anxiety (Figure 7B).

### Prevalence of PTSS

Five studies (15, 31–33, 36) reported that the pooled prevalence of PTSS among the HCWs was 25.6% (95% CI: 11.8–39.4%,  $I^2 = 99\%$ ,  $P < 0.01$ ), with a range from 5.7 to 50.7% (Figure 7C).

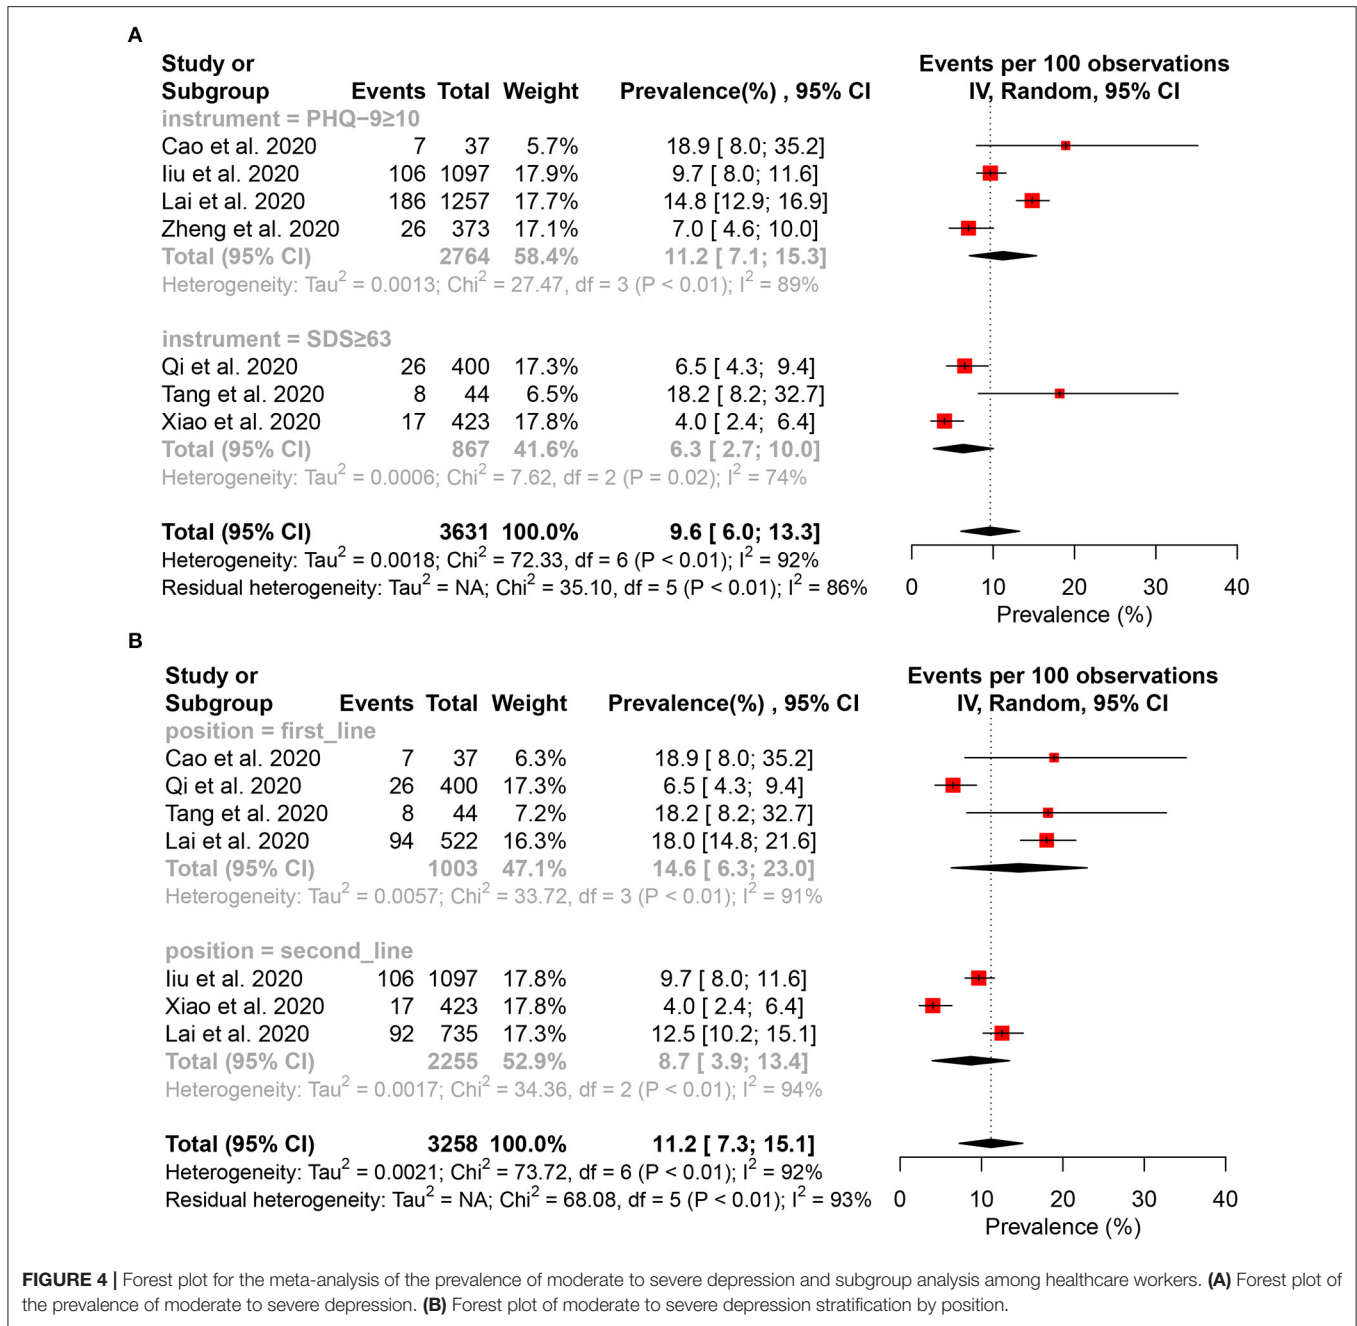

### Other Mental Health Problems

Four studies (27, 35, 38, 40) evaluated obsessive–compulsive symptoms (Figure 7D), somatization symptoms (Figure 7E), and phobia (Figure 7F), and their prevalence were 16.2% (95% CI: 3.0–29.5%,  $I^2 = 93\%$ ,  $P < 0.01$ ), 10.7% (95% CI: 1.9–19.6%,  $I^2 = 88\%$ ,  $P < 0.01$ ), and 35.0% (95% CI: 8.6–61.4%,  $I^2 = 98\%$ ,  $P < 0.01$ ) separately.

### Risk Factors of Mental Health Problems

A total of four studies reported on the risk factors of mental health problems (15, 17, 29, 38). Due to a lack of consistency in methods, outcome metrics, and control groups, a narrative synthesis of risk factors was conducted, with the main findings tabulated (Table 2). Poor health status/organic diseases, female, working in a secondary hospital, intermediate technical title, and frontline/high-risk contact with COVID-19 were the risk factors for depression. Compared with non-medical staff working in hospitals, the occupational attributes of medical staff were a protective factor. For anxiety, the risk factors were as follows: fear of COVID-19 infection, poor health status/organic diseases, female, working in a

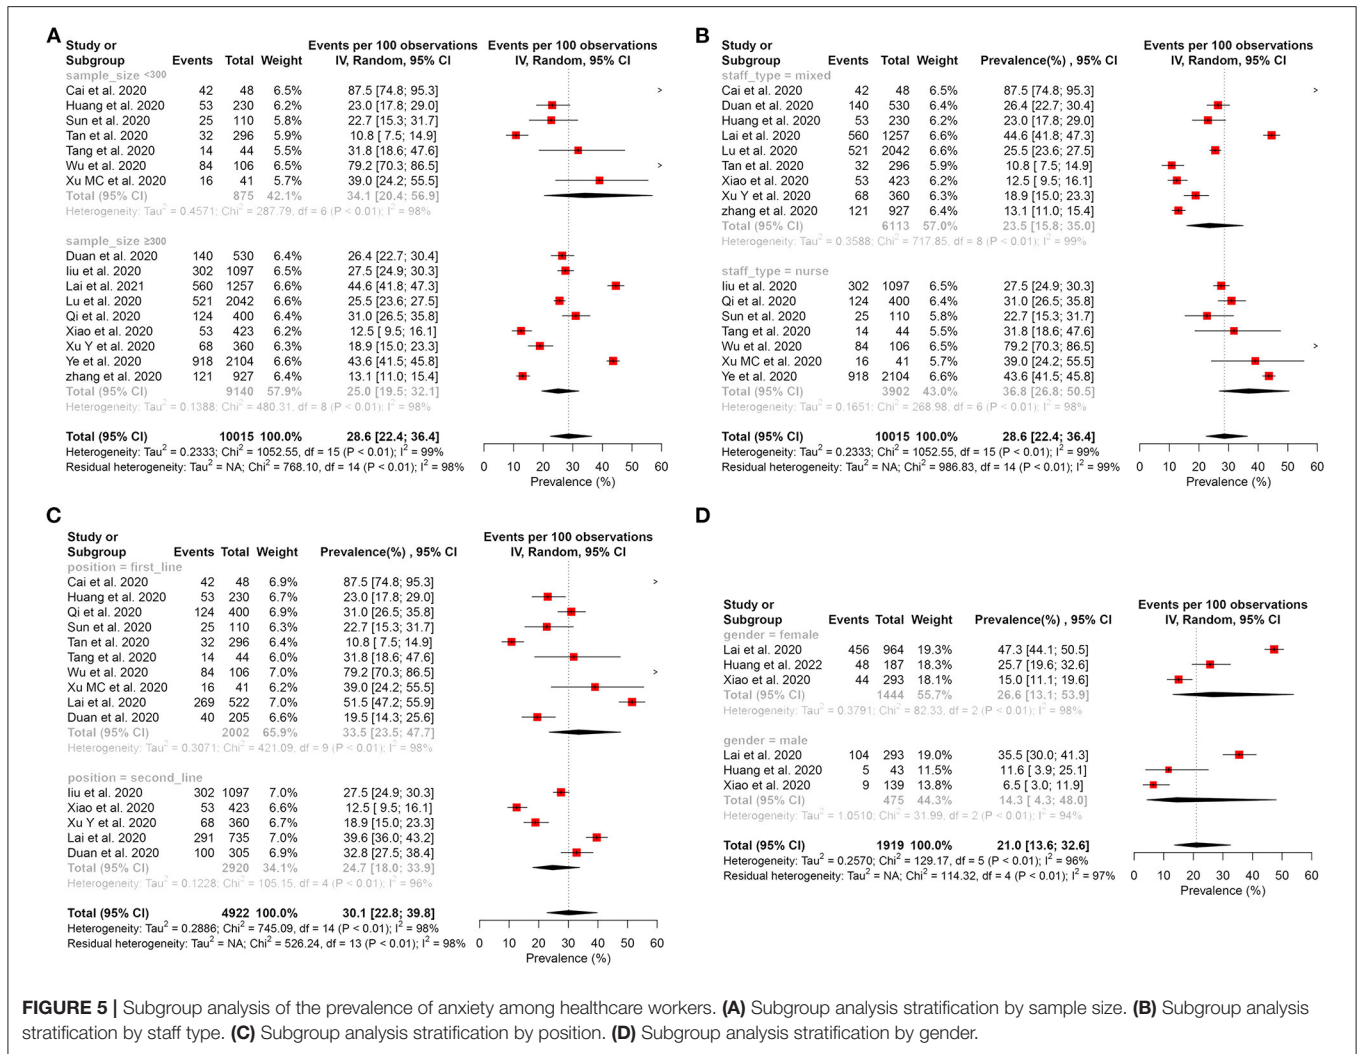

**FIGURE 4 |** Forest plot for the meta-analysis of the prevalence of moderate to severe depression and subgroup analysis among healthcare workers. **(A)** Forest plot of the prevalence of moderate to severe depression. **(B)** Forest plot of moderate to severe depression stratification by position.

secondary hospital, intermediate technical title, frontline/high-risk contact with COVID-19, and living in rural areas. Similar to the protective factor of depression, the professional attribute of medical staff was the protective factor relative to non-medical staff working in hospitals. Working in frontline, living in rural areas, contact with COVID-19 patients, and organic diseases were the risk factors of insomnia. Female, intermediate technical title, and frontline were the risk factors of PTSS, while working outside Hubei province was the protective factor. Living in rural areas, organic diseases, and contact with patients with COVID-19 were the risk

factors of obsessive-compulsive symptoms. The risk factors for somatization symptoms were living in rural areas and organic diseases.

### Heterogeneity Analysis

To identify potential sources of heterogeneity, a subgroup analysis was conducted. However, high heterogeneity was not significantly explained by sample size, staff type, position, and gender (Figures 3, 5). In the univariate meta-regression analyses of the prevalence of depression, a significant estimate was found for the covariate of instruments with R<sup>2</sup> (amount of heterogeneity

**FIGURE 5 |** Subgroup analysis of the prevalence of anxiety among healthcare workers. (A) Subgroup analysis stratification by sample size. (B) Subgroup analysis stratification by staff type. (C) Subgroup analysis stratification by position. (D) Subgroup analysis stratification by gender.

accounted for) = 67.75%,  $P < 0.0001$ . No significant estimates were found for the covariates of sample size (less or more than 300), hospital (survey in one or more hospital), country (China or another country), position (frontline or second-line), or staff type (nurses or mixed with nurses and doctors). The meta-regression showed that country was significantly associated with the prevalence of anxiety ( $R^2 = 4.63\%$ ,  $P < 0.0001$ ); however, it was not significantly correlated with instrument ( $R^2 = 18.11\%$ ,  $P = 0.0533$ ), sample size ( $R^2 = 19.56\%$ ,  $P = 0.1469$ ), hospital ( $R^2 = 0.00\%$ ,  $P = 0.7880$ ), position ( $R^2 = 11.11\%$ ,  $P = 0.1744$ ), and staff type ( $R^2 = 0.00\%$ ,  $P = 0.1030$ ). A sensitivity analysis was conducted by excluding, one by one, the included studies that demonstrated no substantial alteration (Supplementary Tables 1, 2; Supplementary Figures 1, 2).

### Publication Bias

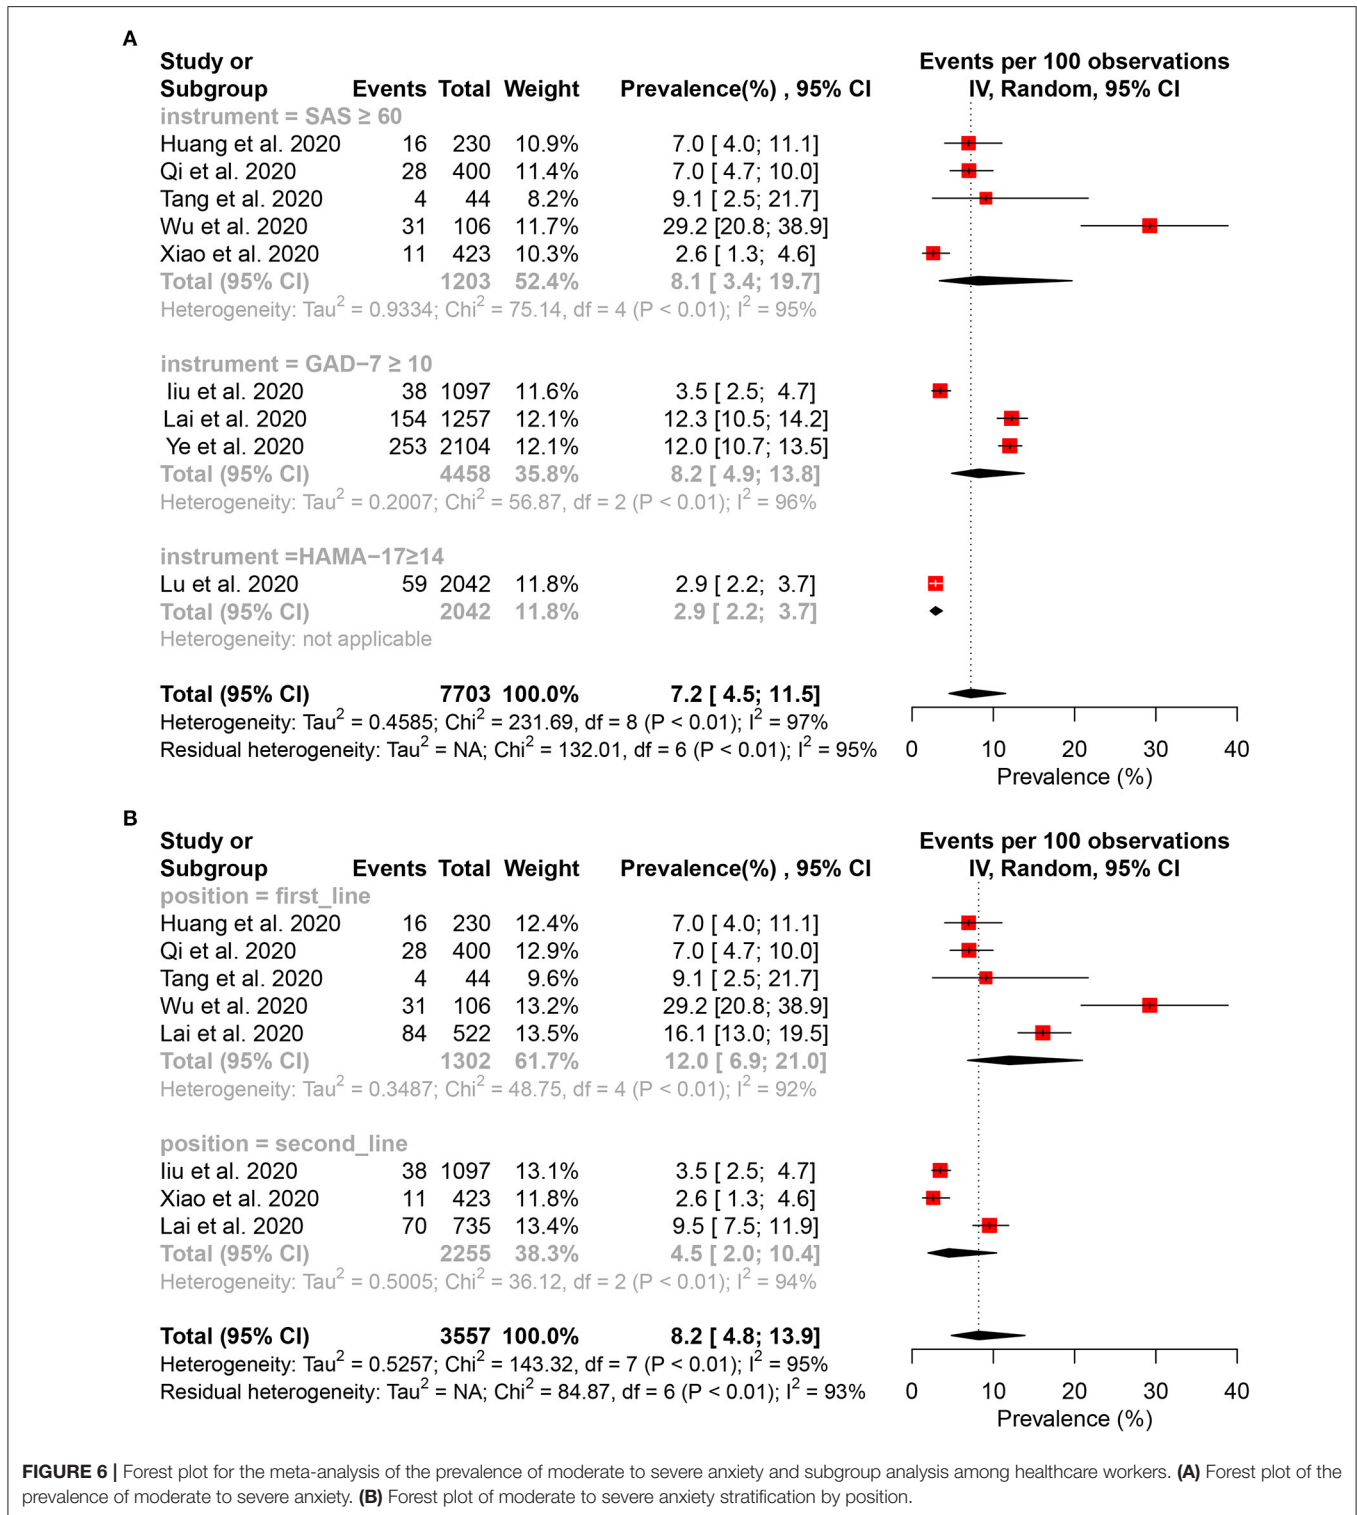

The funnel plot for the primary outcomes seems somewhat asymmetrical (Supplementary Figures 3, 4). However, the Egger's linear regression test of funnel plot asymmetry was

performed, and it indicated no significant asymmetry ( $P_{depression} = 0.3001$ ,  $P_{anxiety} = 0.1045$ ).

### DISCUSSION

The present study investigates the prevalence and risk factors of mental health problems among HCWs during the COVID-19 pandemic based on 10,886 HCWs summarized in 20 cross-sectional studies. According to our research, the prevalence of depression, anxiety, insomnia, PTSS, phobia, obsessive-compulsive symptoms, and somatization symptoms was 24.1, 28.6, 44.1, 25.6, 35.0, 16.2, and 10.7%, respectively. These findings highlight an important issue in HCWs during the COVID-19 pandemic.

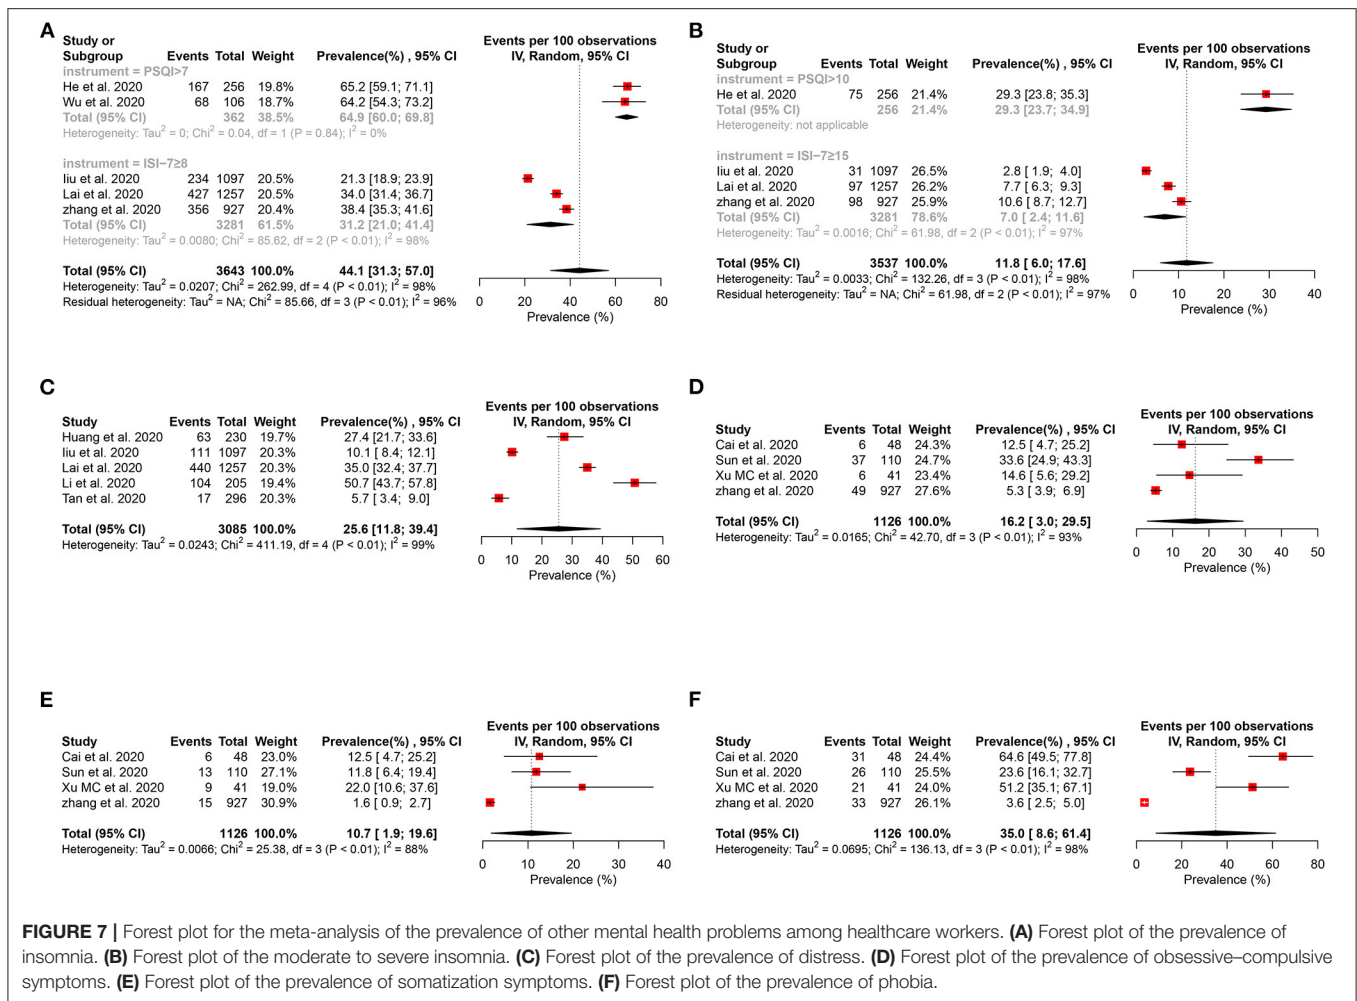

It is no surprise that HCWs have a much higher prevalence of mental health problems during the COVID-19 pandemic. There are many factors that can explain this. The ever-increasing number of confirmed and suspected cases, overwhelming workload, depletion of personal protection equipment, widespread media coverage, lack of specific drugs, and feelings

**FIGURE 6 |** Forest plot for the meta-analysis of the prevalence of moderate to severe anxiety and subgroup analysis among healthcare workers. **(A)** Forest plot of the prevalence of moderate to severe anxiety. **(B)** Forest plot of moderate to severe anxiety stratification by position.

of being inadequately supported may all contribute to the mental burden of these HCWs (44). Previous studies showed that HCWs feared contagion and infection of their family and experienced high levels of PTSS, anxiety, and depression symptoms during the outbreak of SARS in 2003 (45, 46). The

mental health problems faced by medical staff may be related to many difficulties in work safety, such as the insufficient understanding of the disease at the initial stage, the lack of knowledge concerning prevention and control, the long-term heavy workload, the high risk of exposure to confirmed or

suspected cases, the shortage of medical protective equipment, the lack of rest, and the exposure to critical life events during the COVID-19 pandemic (38, 47).

It is worth noting that 25.6% of HCWs suffer from PTSS. Post-traumatic stress disorder (PTSD) is a common consequence of major disasters. During the COVID-19 pandemic, HCWs have endured huge threats and unprecedented challenges, which may cause them to develop acute stress disorder that will potentially degenerate into chronic PTSD over time. A survey conducted 2 months after the outbreak of SARS in Singapore revealed that ~20% of HCWs were suffering from PTSD (48). What is more, a cohort study that lasted 30 months post-SARS among SARS survivors found that HCWs have a much higher percentage of chronic PTSD than non-HCWs (40.7 vs. 19%;  $P = 0.031$ ) (49). Additionally, female, working in frontline, and intermediate technical title were the risk factors of PTSS during the COVID-19 pandemic; however, working outside Hubei province was the protective factor (15).

We found that 70% of all participants were female (most of whom were nurses). Moreover, a subgroup analysis revealed that females and nurses had a high prevalence of depression and

anxiety. During the SARS outbreak, a study conducted among HCWs in emergency departments also showed that nurses were more likely to develop distress than physicians (50). During the COVID-19 pandemic, frontline nurses may be at risk of infection due to the close and frequent contact with patients and the longer-than-usual working hours during the COVID-19 pandemic. This also reminds us that the society should be more concerned on the mental health of women and nurses during the major epidemic.

Another important finding in the subgroup analysis revealed that the frontline HCWs had a higher prevalence of anxiety and a lower prevalence of depression than the second-line HCWs. A high level of anxiety in the early stage of the emerging infectious disease may be an adaptive defense mechanism response to potentially threatening events (51). However, when it is chronic or disproportionate, it becomes harmful and can be a key component in the development of various psychiatric disorders (51, 52). What deserves our attention is that, compared with the second-line HCWs, the proportions of moderate-to-severe anxiety and depression are higher among the frontline staff. Working in the center of a pandemic area such as Wuhan or

high-risk contact with COVID-19 patients in frontline positions, such as the emergency department, respiratory department, fever clinic, etc., is a risk factor for mental health problems (15, 17, 38). For this reason, we should pay more attention to the frontline medical staff. Timely screening and appropriate intervention are important to reduce the severity and chronicity of mental health problems.

In addition, the physical condition of medical staff was an important risk factor for mental health problems. The prevalence of depression, anxiety, insomnia, obsessive-compulsive symptoms, and somatization symptoms of medical staff with poor health conditions or comorbidities of organic diseases is higher than that of the healthy ones (29, 38). Surprisingly, living in rural areas is a risk factor for anxiety, insomnia, obsessive-compulsive symptoms, and somatization symptoms (38). Differences in the working environment, medical technology, and the knowledge of COVID-19 may partially explain this phenomenon.

Limitations should be considered when interpreting the findings of this study. First, it was limited in scope. Of the 20 studies, 19 are from China, 15 of which are published in Chinese and thus limiting the generalization of other countries. Second, it is important to note that the vast majority of participants were assessed by a self-rating scale rather than by gold-standard diagnostic clinical interviews for mental health disorders, and the duration of symptoms of most participants did not meet the diagnostic criteria. The sensitivity and the specificity of these instruments for diagnosing mental health problems vary substantially. Third, all studies are cross-sectional studies, and there is no longitudinal study. Moreover, most of them were completed in February 2020 or earlier. With the increasingly arduous situation, the mental health symptoms of HCWs could become more severe. Fourth, many other factors that could predispose medical staff to anxiety, for example, family history and emotional trauma, could not be assessed due to the wide variability of factors examined in the studies. Finally, only a few studies have explored the risk factors of mental health problems, which are not sufficient to fully understand the problem.

Moreover, all studies on risk factors were of a cross-sectional design, without baseline control and follow-up data, so it is impossible to determine the causal relationship between them. Some risk factor studies have not controlled for confounding factors and cannot exclude the influence of factors such as working position, COVID-19 exposure intensity, and some sociodemographic factors.

## CONCLUSIONS

In this systematic review, HCWs have a relatively high prevalence of depression, anxiety, insomnia, PTSS, phobia, obsessive-compulsive symptoms, and somatization symptoms during the COVID-19 pandemic, and focus should be on the HCWs at high risk of mental health problems. Further research is needed to identify effective strategies for preventing and treating mental health problems among HCWs during the COVID-19 pandemic.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## AUTHOR CONTRIBUTIONS

QH, DW, HW, and QW contributed to research conception and study design and contributed to data analysis/interpretation. QH, DW, MX, YT, YD, LZ, MD, and YW contributed to search and data acquisition. QH and DW contributed to statistical analysis and manuscript writing. QW and HW took responsibility that this study has been reported honestly, accurately, transparently, and contributed very important intellectual content during manuscript drafting or revision and accepts accountability for the work. All authors read and approved the final manuscript.

To date, April 19, 2021, the coronavirus disease 2019 (COVID-19) caused about 140,886,773 confirmed cases and more than 3,000,000 deaths worldwide since the beginning of the pandemic. Oncology patients are usually frail due to the fear of prognosis, recurrence, and outcomes of treatments. Thus, coping with cancer is a complicated process that is necessary to overcome oncological challenge, even more in case of Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) disease. This is a brief case report on a middle-aged man affected by advanced oral tongue cancer and COVID-19, describing his experience of cancer diagnosis, surgical treatment, and rehabilitation during the hospital quarantine for COVID-19. Besides the traumatic experience due to the functional alteration in breathing, eating, and speaking caused by major surgery and the concurrent facial disfigurement, our patient had to face a COVID-19 diagnosis, which implied hospital and social isolation. The aim of this perspective work is to focus on the role of the psychological support in the management of hospital distress related to COVID-19 psychophysical loneliness or alienation. In our experience, such support should anticipate patients' oncological surgery or treatment and should be implemented through telemedicine in case of isolation or after hospital discharge.

**Keywords:** oral tongue cancer, psychological distress, Coronavirus SARS-CoV-2, loneliness, coping, telemedicine

## INTRODUCTION

To date, April 19, 2021, the coronavirus disease 2019 (COVID-19) has caused 140,886,773 confirmed cases and 3,000,000 deaths worldwide, since the beginning of the pandemic (1). In the current international health emergency caused by Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2), the whole healthcare system has been facing an unprecedented crisis: both medical and psychological aspects are continuously evolving.

During the current pandemic, in some hospitals oncological treatments have continued despite the lack of places in intensive care units and surgical theaters due to the high number of severe COVID-19 cases (2–8).

Oral tongue carcinoma is a rare tumor but the most common cancer of the oral cavity, and surgery remains the gold standard of treatment (9). Among head and neck cancers, tongue neoplasm is surely the most psychologically traumatic cancer (10) due to the distressing alteration of essential functions. These include eating, swallowing, breathing, speech, loss of taste and smell, impaired sensitivity, xerostomia, residual pain, swelling, and facial disfigurement (11, 12). Moreover, disease and treatment cause heavy disabilities and patients often have to face extensive rehabilitative programs, consisting of speech therapy, swallowing, and dental/maxillofacial restoration, as well as physical and occupational therapies (13).

The diagnosis of oral cancer is one of the most psychologically traumatic events to experience (14). Among other disturbing (or afflicting) aspects, social isolation, and altered perception of the future perspectives are of utmost importance.

Although recently, most attention has been on the current pandemic, the incidence of all other diseases has not decreased, and COVID-19 has in part exacerbated medical and psychological conditions which were already in a precarious balance.

## ARTICLE TYPES

This study is a perspective, case report presentation. The study was reviewed by the European Institute of Oncology (IEO) Ethic Committee (IEO code 2432), and an informed consent for confidentiality, privacy, and data protection was obtained by the patient.

### Medical Case Presentation

On March 9, 2020, the day after Italy was placed in a national strict “lockdown” due to exponential increase of COVID-19 cases, a 50-year-old male patient was admitted to the Division of Otolaryngology and Head and Neck Surgery Division at the European Institute of Oncology in Milan for advanced oral tongue cancer treatment (15). He had no history of smoking and alcohol habits and no psychiatric records. According to the international guidelines for his disease stage, he underwent major surgery: right glossectomy type IIIA plus en-block ipsilateral neck dissection, temporary tracheotomy, and reconstruction of the oral defect with a radial forearm free flap. Surgery lasted for 12 h (16). On the second postoperative day, a nasopharyngeal swab and a bedside chest X-ray were performed for persistent fever and episodes of mild hypoxemia, revealing SARS-CoV-2 pulmonary infection. Thus, the patient was placed in droplet isolation and the hospitalization time was doubled. During his quarantine, the patient also requested psycho-oncological support. The patient’s social isolation continued for 6 weeks after hospital discharge, due to persistent viral positivity of nasopharyngeal swabs, further worsening his psychological frailty.

### Psychological Consequences of COVID-19 After Head and Neck Major Surgery

The usual postoperative course for patients undergoing major surgery for tongue cancer is very complicated: speaking is

not allowed, head mobilization is generally impaired, and face edema and scars represent difficult steps to overcome. Oral feeding is usually avoided until the 7th postoperative day, if no complication occurs, and swallowing and speech rehabilitation are very challenging.

For these reasons, even during the “non-pandemic era” patients affected by oral cancer could easily enter into a depressive status. In oral cancer patients, depressive symptoms are closely associated with treatment adherence, self-care behaviors, re-socialization, and aspects of resilience (13). Depression and fear of cancer recurrence and future life conditions are psychological aspects which commonly characterize the postoperative phase (14, 17, 18).

Consequently, patients have to face their conditions through coping strategies. Coping is “a cognitive and behavioral effort to manage specific external and/or internal demands that are appraised as taxing or exceeding the resources of the person” (19, 20).

Clearly, COVID-19 can only worsen the physical and psychological challenges which usually arise in an oral cancer patient.

During the COVID-19 pandemic, our Hospital applied several measures (8). Above all, patients’ family members and friends were not allowed to visit because of the risk of virus infection during postsurgery rehabilitation (8). Unfortunately, several studies confirm that isolation affects patients’ adherence to self-care and rehabilitation schedules, decreasing their motivation (21–25). This clinical and social scenario exposes patients to a higher risk of psychological burden, as recently published (23, 26).

## DISCUSSION

All discussed health-related conditions affected the normal coping strategies of our patient and increased his vulnerability (27).

During the postoperative rehabilitation, the patient was troubled by the fear of his oncologic disease and concurrent COVID-19. He openly discussed his concerns and anxiety of cancer recurrence, his future, and his problems of going back home, alone and isolated. He repeatedly mentioned the uncertainty of his cancer prognosis and the fear of dealing with the surgical outcomes, mainly the impaired ability to eat and speak. Furthermore, his consideration of the future was worsened by the consciousness of being infected by SARS-CoV-2, deteriorating his mood with consequent psychological consequences, thus prompting a mandatory psycho-oncological support. During the first psycho-oncological session, we assessed his need of support, since recent evidences show that well-being requires a comprehensive health-related quality of life assessment (28).

As the patient expressed anxiety and fears on the consequences of COVID-19 test positivity, we decided to offer two psychological sessions per week. The aim was to provide support for the hospitalization distress, exacerbated by loneliness and the viral infection.

He reported his anxiety due to confinement, loss of usual routine, and reduced social and physical contact with others. This condition caused boredom, frustration, and sense of isolation from the rest of the world. His feelings were exacerbated by his inability to speak well, which also limited the use of devices for remote communication, such as video calls on phone or tablet, used for worldwide connection with friends and family in the pandemic time (29).

The patient's awareness of his vulnerability was the starting point for the psychological support. The psychologist together with the patient planned a daily schedule of activities, in order to decrease boredom, loss of routine, and helplessness. With time, the patient showed increased locus of control and self-regulation by organizing activities and managing well his time (self-care, video call with football team, friends). Unfortunately, 3 weeks after surgery he tested positive for COVID-19 again.

The patient was discharged on the 23rd postoperative day and was asked to maintain self-isolation as required by national health dispositions.

Upon discharge after such complex procedures such as head and neck surgery, patients are usually happy and eager to return home. On the contrary, in this case, the idea of discharge increased the patient's concerns. He emphasized the fear of infecting his family members and to be alone and was worried that this infection could affect his postoperative course (29).

Because of his condition, the psychological support proceeded even after discharge, with interviews scheduled regularly twice a week. The counseling sessions were arranged by video calls. As described, the home quarantine strongly affected the patient's psychological distress, more than the cancer itself (30). This profound anxiety and depression disturbed the patient during his convalescence, until the long-expected negative swab, when the patient was finally allowed to embrace his family.

These events led us to reflect on the importance of a psychological support for all surgical patients during the pandemic era.

At the referral Hospital, as reported by international guidelines, psychological support is routinely provided to patients affected by head and neck cancer, especially to patients who have undergone complex and demolitive surgical treatment (31), such as the one herein presented.

Previously, in the non-COVID era, during hospital stay, psychological support generally consisted in two or three meetings, when requested by the patient. These meetings are focused on the impact of demolitive surgery on the patient's future and quality of life. In case of a COVID-positive patient, all issues related to the impact of the oncological disease on life are amplified because of COVID-19 diagnosis. Indeed, these patients are faced with two diagnosis: cancer and the SARS-CoV-2 infection. Moreover, we are planning to compare the psychological status of patients with oral tongue cancer who developed COVID-19 to others without COVID-19 in a future study.

The major limitation of this prospective work is that it is a simple case report, with results that cannot be neither generalized nor easily applicable in a wider patient cohort.

However, we underline that case reports on oncological matters also have a role in medical education, inspiring profound scientific research questions for clinicians and scientists. This is especially relevant in this scenario, where tongue tumors are a rare oncological pathology and, as such, even a single case can be very instructive for clinicians. Furthermore, this case report highlights the importance of psychological support and should be tailored to the new needs of each patient in this current pandemic era.

Most likely, the psychological support should be anticipated in order to prepare oncological patients in managing their life postsurgery and treatment, by focusing not only on their cancer disease but also on a possible SARS-CoV-2-related condition. From now on, the preoperative patient's interview should be implemented by explaining how the new health conditions might affect their treatments and recovery on the top of the oncological disease.

The use of telemedicine may be a valid support to keep in contact with our fragile patients both during COVID-induced isolation and after discharge. A remote-controlled technologic device is an essential tool today to be able to focus on patients' mental health and well-being in this COVID-19 time. In fact, this first case occurring at the onset of the Italian pandemic era prompted in our hospital the structuring of psychological tele-visits to provide methodical health support for all COVID-positive cancer patients.

In conclusion, the psycho-oncological support could play a crucial role in many aspects of head and neck cancer patients' care. It may need to be adapted and enhanced in this pandemic period. These reflections lead to interesting suggestions toward the elaboration of future preventing strategies in times of stress and crisis for the healthcare system.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. The patients/participants provided their written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

## AUTHOR CONTRIBUTIONS

MT conceptualized and designed the study. RD and PG drafted the initial manuscript and carried out and reviewed the literature review. FC and GPi revised the manuscript. SC, MA,

GPr, and FM critically reviewed the manuscript for important intellectual content. All authors approved the final manuscript as submitted and agreed to be accountable for all aspects of this work.

*Front. Public Health* 9:564706.  
doi: 10.3389/fpubh.2021.564706

**Objective:** To study the population-level mental health responses during the first wave of coronavirus disease 2019 (COVID-19) outbreak in Estonia and analyze its socio-demographic, behavioral, and health-related variations among general population.

**Methods:** This study used nationally representative data on 4,606 individuals, aged 18–79 years from a rapid-response cross-sectional survey conducted in April 2020. Point prevalence and mutually adjusted prevalence rate ratios for perceived stress from log-binomial regression analysis were presented for socio-demographic, behavioral, and health-related variables.

**Results:** This study found that 52.2% of population aged 18–79 reported elevated stress levels in relation to COVID-19 outbreak. Higher levels of perceived stress were found in women, in younger age groups, in Estonians, and in those with higher self-perceived infection risk, presence of respiratory symptoms, and less than optimal health, according to self-reports.

**Conclusion:** Although, the potential long-term health effects of the current crisis are yet unknown, the alarmingly high stress levels among people indicate that the COVID-19 pandemic might have had a widespread effect on people's mental health.

**Keywords:** COVID-19, SARS-CoV-2, pandemic, mental health, stress, Estonia

## INTRODUCTION

The ongoing outbreak of novel coronavirus SARS-CoV-2 started in December 2019 with the first documented cases of pneumonia of unknown origin registered in Hubei province, China (1). Despite the efforts to contain the virus locally, it spread rapidly across the world, and on March 11, 2020, the coronavirus disease 2019 (COVID-19) outbreak was labeled a pandemic by the World Health Organization. As of mid-March 2021, 120 million cases have been confirmed globally, and the estimated death toll exceeds 2.6 million (2).

While the acute health burden of COVID-19 is undoubtedly heavy, the wider health outcomes of the pandemic might be even more widespread. Evidence from earlier epidemics (e.g., SARS in 2003 or the H1N1 pandemic in 2009) suggests widespread mental health impacts (3–5). People who have been directly infected or those in direct contact with someone with the infection may experience increased stress and anxiety, depression, and also post-traumatic stress disorder (6, 7), but the perceived infection risk could also lead to higher anxiety among non-infected individuals (8). Given the short timeframe, only a limited number of studies have so far analyzed the mental health consequences of the current pandemic. However, the evidence from very recent systematic reviews (9, 10) confirms higher levels of mental health problems during the COVID-19 pandemic. Regardless of the study population, a higher psychological impact of COVID-19 is reported for females, for those having lower socioeconomic status, and for those at higher risk of contracting COVID-19 due to poor health or contact with COVID-19 patients (10).

This paper contributes to the field by covering the immediate mental health responses to the COVID-19 outbreak using a nationally representative dataset. More specifically, we will focus on the prevalence of perceived stress during the first wave of the pandemic in Estonia, where the first COVID-19 case was confirmed on February 25, 2020 (11). With 58 cases diagnosed, a state of emergency was declared by the government on March 12, 2020, to enforce appropriate measures to control the spread of infection. During the first wave, the 14-day incidence peaked on April 6 at 56.6 cases per 100,000 and after gradual decline in newly diagnosed cases, the state of emergency was ended on 17th May 2020 with 14-day incidence being 6.0 per 100,000 (Figure 1). By end of May 2020, ~5% of the population had been tested and fewer than 2,000 COVID-19 cases had been confirmed in total (11). However, Figure 1 also illustrates the situation 10 months later when the ongoing second wave resulted in almost 2,000 new cases daily and the 14-day incidence rate was close to 1,500 per 100,000 as of mid-March 2021.

Although, the current epidemiological situation is in a stark contrast with the first wave of the COVID-19 pandemic in Estonia, several aspects suggest that first wave may have had considerable impact on mental health despite the relatively modest incidence. First, the evolving pandemic saw extensive attention in all media platforms that, coupled with the overall novelty of the situation, may have resulted in increased perception of fear and anxiety (12). Second, the emergency situation itself and the measures taken to contain the spread of infection (13) were unprecedented and affected the daily lives of all inhabitants. In view of this, the aim of the study was to analyze the prevalence of perceived stress and its patterning across sociodemographic, behavioral, and health-related covariates during the first wave of the COVID-19 outbreak in Estonia.

## METHODS AND MATERIALS

### Data

This study uses data from a nationwide rapid-assessment survey conducted during the peak of the first wave of the pandemic in Estonia when the hospitalization rates were at their highest and

most restrictions had been enforced. A nationally representative stratified random sample of 12,000 individuals aged 18–79 years with a valid email address was obtained from Population Registry for the survey. The survey questionnaire was based on locally adapted version of WHO tool for behavioral insights on COVID-19 (14) with additional items on the presence of symptoms of upper respiratory infections, previous COVID-19 testing, self-rated health (SRH), and perceived stress. In total 4,606 responses were submitted during the 10-day study period between April 10 to April 20, 2020. After accounting for 558 cases who were unable to respond due to invalid email addresses, the adjusted response rate was 40.3%. Population weights based on age and gender distribution of the Estonian population were used to adjust for oversampling of youngest and oldest age groups and to compensate for the non-response. The study protocol was approved (no. 271, from April 8, 2020) by the Research Ethics Committee of the National Institute for Health Development.

### Variables

The dependent variable was self-reported perceived stress that was assessed with the question “Are you currently experiencing stress or anxiety?” The response options were dichotomized as (i) excessive stress (“yes, much more than previously” and “yes, somewhat more than previously”), and (ii) not stressed (“yes, but not more than previously” and “no, not at all”). The same instrument has been used in several national health surveys previously and thus provides a valid comparison.

Respondents’ demographic backgrounds were described by variables of gender, age, education, ethnicity, and place of residence. Age effects were analyzed in age groups of (i) 18–34, (ii) 35–49, (iii) 50–64, and (iv) 65–79. Educational level was measured by the highest level of education obtained and dichotomized into categories of (i) up to secondary or vocational and (ii) tertiary education. Self-reported ethnicity was grouped as (i) Estonians and (ii) non-Estonians, referring to other, mostly Russian-speaking ethnic groups. Respondents’ places of residence were dichotomized as (i) rural and (ii) urban areas.

Additional behavioral and health-related items included self-perceived infection risk, conforming to isolation measures, presence of respiratory symptoms, and SRH. Subjective infection risk was assessed with a binary (yes/no) question: “Do you think you are likely to become infected with the novel coronavirus?” Responses to questions “Are you currently in isolation (do you avoid social contact)?” and “Have you experienced symptoms typical of upper respiratory infections since the beginning of March 2020?” were used to assess conformity to isolation measures and presence of respiratory symptoms, respectively. SRH was covered with a single-item question, “How would you assess your present state of health?” with response options dichotomized into the categories (i) average or poor and (ii) good health.

### Analysis

The prevalence of stress was calculated as the proportion of cases reporting excess stress divided by the total number of cases by sociodemographic variables, with 95% confidence intervals (95% CI). To study the variations between stress

**FIGURE 1** | The 14-day incidence rate for COVID-19 cases per 100,000 over a 1-year period in Estonia.

and independent variables, log-binomial regression with robust variance estimates was used for the analysis. This approach avoids the overestimation of the association that is often found for logistic regression when the outcome is frequent (15, 16). The results are presented as exponentiated coefficients from a mutually adjusted model that are interpreted as prevalence ratios (PR) with 95% confidence intervals. All statistical analyses were conducted using SPSS Statistics for Windows, version 25.0 (IBM Corp. 2017). A  $p$ -value  $<0.05$  was regarded as statistically significant.

## RESULTS

In total, 52.2% of the respondents felt excessive stress e.g., were currently more anxious or stressed than previously (**Table 1**). The prevalence of stress was higher among women, in younger age groups, Estonians and among respondents with higher self-perceived infection risk, presence of respiratory symptoms, and less-than-good SRH.

In the mutually adjusted regression model, excess stress was significantly higher among women compared to men (PR 1.09; 95% CI 1.07–1.11), in younger age groups compared with 65- to 79-year-olds, and among Estonians compared to non-Estonians (PR 1.05; 95% CI 1.03–1.09). As with crude prevalence, the respondents' education or place of residence did not differentiate stress levels. However, those with higher self-perceived infection

risk, presence of respiratory symptoms, and less-than-good SRH had higher stress levels.

## DISCUSSION

### Main Findings

This study found that over half of the population experienced excess stress with higher stress prevalence found among women compared with men, in age groups below 65 years compared with 65- to 79-year-olds, and among Estonians compared with non-Estonians. In addition to these sociodemographic factors, higher stress was reported by those with higher self-perceived infection risk, presence of respiratory symptoms, and less-than-good SRH. With slight variations, these findings are generally in accordance with previous evidence (10) on the sociodemographic patterning of mental health outcomes during COVID-19 pandemic.

The alarmingly high stress levels found in current data are in stark contrast with earlier data from 2018 (17), where similar stress indicators were reported by 18.7% of men and 20.7% of women (19.9% in total). Also, the current stress prevalence is more than 2-fold compared with data from the previous economic recession in 2010 (17). As economic recessions lead to rises in unemployment levels and reductions in staff and wages are correlated with an increase in mood disorders, anxiety, depression, and suicide (18), it is very likely that both the direct epidemiological emergency and its wider social and economic consequences have already translated into an increase in mental

**TABLE 1** | Prevalence rates and adjusted prevalence ratios with 95% confidence intervals for excessive stress.

		Total sample (n = 4,606)		Prevalence	Prevalence ratio <sup>a</sup>

health problems as suggested by a few recently published studies (19, 20).

The demographic patterning of stress indicates that some sociodemographic groups were more affected than others. Similarly to a recent study (21), a distinct age gradient was found, with the highest stress being reported in the youngest age group, despite the evidence that COVID-19 presents a higher health risk for those aged 65 and older (22). This also contradicts earlier evidence on the mental health effects of the economic crisis from Estonia in the late 2000's (23), when perceived depression had increased most in ages 35 and up. However, the causes and the consequences of both crises are very different. As the older generations have experienced stressful life events (e.g., the post war period, Soviet repression, the struggle for independence, and extreme economic difficulties during the 1990's) (24), it is plausible that the current state of emergency with its unprecedented social distancing measures (25) could affect younger age groups the most. Such a negative psychological impact has also recently been demonstrated among undergraduates in the context of the COVID-19 pandemic (26). The gender differences in perceived stress found in our data are supported by earlier evidence that women are generally more vulnerable to stress- and fear-based disorders (27). However, a range of other potential explanations could be relevant in the current context as well. Women more often work in healthcare, the service sector,

and other high-risk occupations in the context of COVID-19. Several studies have shown higher levels of mental health problems in health care workers and in customer service during the current pandemic (28, 29). Moreover, the school closures and social distancing measures could put additional strain on women due to increase in tasks related to childcare, housework and caring for the sick (30). The higher stress prevalence seen in Estonians compared with other, mostly Russian-speaking ethnic groups is consistent with observed long-term trends in perceived stress and depression (17). This could also suggest that the health communication during the current pandemic has not preferred the majority ethnic group over minorities.

In addition to demographic indicators, several behavioral and health-related variables differentiated stress levels in our data. As the COVID-19 pandemic coincides with the period of seasonal influenza and other upper respiratory infections, self-perceived infection risk and presence of symptoms were both expectedly associated with higher stress. As the most common symptoms of COVID-19 are fever, cough, fatigue, and shortness of breath (31), having similar symptoms could lead to higher anxiety and stress levels. Similarly, those with average or poor SRH had 12% higher prevalence of excessive stress compared with respondents with good SRH. SRH is a valid estimate for overall health status that has strong predictive power for future health outcomes (32). SRH follows the age gradient, and poor health is often associated with

chronic conditions and comorbidities (33) that constitute higher health risk also in the context of COVID-19 (22).

The main strength of the study is the timing of the nationally representative survey that was purposely designed to assess the knowledge and public perception during the first wave of the COVID-19 pandemic. However, some potential limitations of the study need to be addressed. First, the survey relied on a self-assessed, single-item measure of stress and anxiety. Although, it is not sufficient for a clinical diagnosis, it reflects the subjective presence of anxiety and stress-related complaints and allows comparisons with previous health surveys in Estonia. Second, due to the state of emergency, the survey was conducted using a web questionnaire only. Therefore, the representative sample of adults had to include only individuals with valid email addresses in the population registry database. Although, earlier studies (17) have shown that ~90% of individuals have valid email addresses in the population registry database, a potential selection bias cannot be fully excluded in our data. Third, the cross-sectional data do not allow us to establish causality *per se*. Despite this, the time anchoring of the dependent variable provides relevant estimates with respect to the time frame of the current the study. Moreover, the study protocol has been amended to allow additional data collection from the same sample, thus providing an opportunity for a longitudinal design in further studies. Fourth, due to the short data collection period, the response rate was modest (40.3%). Finally, despite the inclusion of different demographic, health-related, and behavioral variables, it is unlikely that the set of variables accounts for the total variance of the dependent variable. Thus, potential residual bias should be considered when interpreting the results. However, the large sample size and the use of population weights to reduce the potential non-response bias assure the representativeness of the data.

## Conclusions

With over half of the 18- to 79-year-olds experiencing excess stress or anxiety during the first wave of COVID-19 pandemic in Estonia, the potential mental health impacts of the pandemic cannot be ignored. Although, direct causality cannot be established, the underlying uncertainty regarding the social, political, and economic aftermath of the pandemic is potentially said to have widespread negative effects on a population's mental health. Moreover, the long-term effects of current crisis are yet unknown. Further longitudinal studies are therefore needed to assess whether the high stress levels translate into acute or chronic (mental) health problems that could place additional strain on the health sector and affect public health outcomes in general. Close monitoring of the mental health outcomes is therefore warranted to ensure timely access to mental healthcare.

The COVID-19 outbreak and the restrictions that have been enforced by the health authorities are having a profound psychological impact on the population. Many people, including the students, faced forced modifications to their daily lives and this prompted the need for scalable strategies to promote resilience. We designed an online community intervention for psychology students and recent alumni aimed to promote functional coping strategies through openness and cognitive flexibility. This psycho-educational intervention was delivered through a private group on social media (Facebook) during the acute phase of the lockdown period and it involved the publication of exercises and quick lectures. Contents were posted regularly and members of the community were invited to share their comments. The posts included stimuli that promote open and flexible reflections on the current situation. The overall aim of this group was a cognitive reframing on the epidemic effects, promoting creative and flexible thinking. We ran a thematic analysis of the interactions and we collected qualitative feedback at the end of the intervention. The participants' comments dealt with changes in their perspectives, sharing discomfort, encouragement and support, and building a sense of community. Post-intervention comments were highly satisfied and confirmed the helpfulness of the intervention to promote flexibility and openness, eventually helping to manage the negative emotions related to the COVID-19 outbreak. This study provides preliminary evidence that an online psycho-educational community stimulating flexibility and openness can help to reframe the negative psychological impact of the outbreak, improving their management.

## INTRODUCTION

The COVID-19 pandemic has spread around the world since December 2019, infecting millions of people and causing hundreds of thousands of deaths (World Health Organization., 2020a). In response to the outbreak, several countries have implemented lockdown and other movement restriction strategies to prevent the virus from spreading. Countries have taken unprecedented measures, which varied across nations. Italy, which has been one of the worst-hit countries by the pandemic (at least in the first phase outside China), imposed a strict lockdown for several weeks. Together with the medical, social, and economical implications of the epidemic, there are multiple psychological consequences (Pfefferbaum and North, 2020; World Health Organization., 2020b). Stress, anxiety, depressive symptoms, sleep problems, and fear have globally increased (Torales et al., 2020). For example, an analysis of social media contents after the outbreak showed an increase in anxiety and depression symptoms and a reduction of life satisfaction and positive emotions (Li et al., 2020).

The lockdown that was implemented by many health authorities in the world restricted personal and work activities, limiting movements, and social contacts. This often resulted in a sense of uncertainty and loss of perceived control, with a negative impact on the psychological well-being (Mertens et al., 2020).

A large survey conducted in Italy at the beginning of the outbreak suggested that cognitive flexibility may be a protective factor against the negative psychological consequences of the COVID-19 situation (Pagnini et al., 2020). This is in line with previous studies reporting that psychological flexibility is a fundamental aspect of well-being (Kashdan and Rottenberg, 2010). A flexible mindset allows an improved adaptation and it helps to cope with challenging situations. Another psychological characteristic that resulted associated with improved well-being and functional coping during the epidemic is openness (Bogg and Milad, 2020; Pagnini et al., 2020), which refers to receptivity to new experiences and ideas. Openness and flexibility are also core components of creativity, which requires to widen the perspectives, connect the dots, and re-organize the relationships (Colombo et al., 2018). The importance of these constructs for well-being has been reported multiple times in the literature. In particular, the Langerian approach to mindfulness defined as the process of making novel distinctions, which includes openness, flexibility, curiosity, and creativity. According to this model, a mindful reappraisal can be provided when one realizes that there are different perspectives on the same aspect (Pagnini and Langer, 2015). This is the essence of Langerian mindfulness and has been repeatedly associated with quality of life (Langer, 1989; Pagnini and Phillips, 2015). Therefore, an improvement of these psychological characteristics generally results in improved well-being and coping skills (Pagnini et al., 2016). Following this theoretical idea, we developed a specific intervention aimed to reframe some negative perspectives about the pandemic and the social restrictions that were imposed during the first lockdown in Italy.

Social media played a particular role in disseminating the information about the outbreak, which sometimes included pitfalls such as fake news and panic transmission (Depoux et al., 2020; Salvi et al., 2021). Despite these risks, these forums can provide a learning space where self-efficacy and coping strategies can be built (Tower et al., 2015), which could represent a scalable and easily implementable strategy to promote adaptive coping against the COVID-19 situation (Van Bavel et al., 2020). During the first period of the pandemic, in Italy, social media were mainly used to exchange information and to share the common sentiment (Bhat et al., 2020), but they rarely provided structured interventions. A rapid review of the available literature on stress interventions for health care providers dealing with coronavirus (Callus et al., 2020) only identified one study protocol (Azam et al., 2019) using a digital intervention. More in general, the worldwide outbreak introduced new social and psychological challenges, which have been faced with both traditional psychological strategies with context-adjusted solutions, such as online consultations (Swartz, 2020), and innovative approaches, such as using VR or other technologies (Riva et al., 2020). Other studies explored the impact of online psychotherapy as a way to reduce coronavirus-related worries (Wahlund et al., 2021) or other forms of anxiety (Chen, 2020).

The project aimed to deliver, through a dedicated Facebook group, a group intervention that lead to a mindful reframing of the current situation. In other words, the goal of this intervention was to boost psychological flexibility, openness, and creativity through an active psycho-educational intervention. Group members were invited, with different stimuli, to embrace an open perspective about the challenges faced during the lockdown. The goal of the group was not only to ease the negative impact, but also to see the potential for growth and development. In this pilot study, we invited psychology students and recent alumni to join the group and its active discussion. The interactions and the subjectively reported effects were qualitatively assessed.

## METHODS

### Design

We conducted a pilot study to explore the interactions and the subjectively reported effects of a Facebook group, designed to stimulate cognitive flexibility, openness, and creativity, through stimuli and discussions. This research is an “active analysis” on Facebook (Eysenbach and Till, 2001), as there was an active interaction between research members and the participants (Franz et al., 2019). After the end of the intervention, the group members were invited to express their views on the program (see **Figure 1**).

### Intervention

On March 20, 2020, we created a private group on Facebook, titled “Coronavirus and quarantine... Shall we grow together?.” About every day or any other day, a stimulus was posted on the discussion wall. These stimuli were either reflections to boost flexible thinking, which included sentences aimed to reframe the

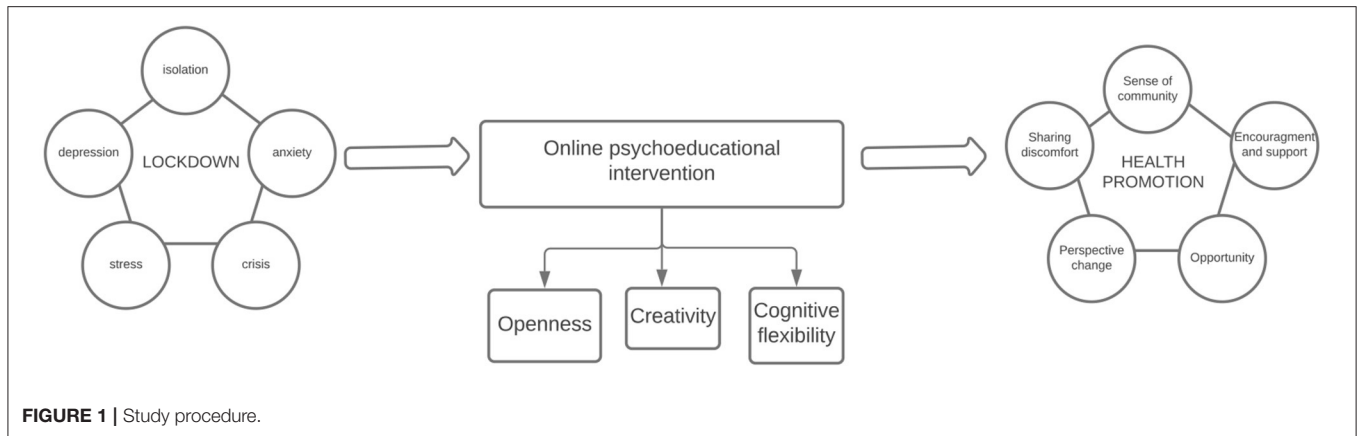

FIGURE 1 | Study procedure.

perspective on the current situation (e.g., “What will you miss of the lockdown, when it will be over?”) or exercises, which suggested activities that prompted a different perspective, such as brushing teeth with the non-dominant hand or to search for unexpected details in a movie. One of these exercises consisted of the voluntary sharing of a personal problem, with the invite to the other group members to help reframing or coping. Contents were all accompanied by an image to facilitate their visibility and improve the engagement. The group was moderated by a member of the research team (EB) and participants were able to reply to the existing posts, but not to create new posts on their own. All the contents were posted in Italian.

## Participants

We invited undergraduates, master’s students, and recent alumni (>3 years) from the Faculty of Psychology at Università Cattolica del Sacro Cuore (UCSC) in Milan, Italy, to join the group. A direct invitation was sent to their university-provided email address and announcements advertising the group were posted in UCSC students’ dedicated groups and pages. A total of 436 people joined the group, out of about 2,500 students and alumni contacted. When they joined the group, they accepted the posting instructions, which also included the consent for analyzing group data. The study was approved by the Ethics Commission of the Department of Psychology at UCSC.

## Data Collection and Analysis

All comments and reactions that were produced by the participants were collected over the 5-week period in which the intervention was conducted and put in a textual database through a careful copy-and-paste process. We recorded all the comments, the de-identified person who made them, and the number of “likes” and “reactions” (i.e., emotional reactions: Love, Fun, Wow, Sad, and Angry). Comments were examined with a thematic analysis (Braun and Clarke, 2006). This approach offers a robust and sophisticated toolkit for the analysis of qualitative data, is mostly appropriate when there is no deep theoretical commitments, and allows to explore the patterns across data (Braun and Clarke, 2014). Two researchers (EM and ET) independently immersed themselves in the materials, assigning the preliminary codes and extrapolating the categories. Once

independently created the categories, the researchers reviewed them with a third researcher (FP) and reached a consensus on the identified themes.

After about a month since the last post, a request for feedback was posted. In this message, there was an invitation to complete a short survey on the program satisfaction, implemented with the Qualtrics suite (Qualtrics, Provo, UT). The survey included a general evaluation on the group helpfulness on a Likert scale (1 = very helpful; 2 = helpful; 3 = quite helpful; 4 = not very helpful; and 5 = not helpful at all) and some open-ended questions on the use of the stimuli and the discussion, including pros and cons. Specifically, the open-ended questions were: “How did exercises and reflections impact your life?”; “How was this group helpful, if that was the case?”; “What were the aspects of the group that you mostly appreciated?”; “What were the aspects that you did not appreciate?”; and “What would you recommend we change, should we repeat this experience?.” The answers were assessed with another thematic analysis, following the same procedure previously described.

## RESULTS

### Group Activities and Participants

In the 5-week period of the intervention, there were a total of 28 posts, plus those dedicated to welcome the participants and asking to complete the final comments. Overall, there were 100 comments to the contents, made by 42 different participants, and 697 reactions. Of the 436 participants, 384 (88%) were female, with 266 (61%) ranging between 18 and 24 years, with 133 (30.5%) with an age between 25 and 34 years, and 37 people (8.5%) aged 35 or older.

### Analysis of the Interactions

The thematic analysis of the comments to the posts provided four key categories: “perspective changes to face the limitations,” “sharing discomfort,” “encouragement and support,” and “building a sense of community” (see **Table 1**). Participants’ IDs are reported in brackets.

**TABLE 1** | Categories from the analysis of the interactions.

Category	Definition	Example
<b>Perspective changes to face the limitations</b>	Reframing the meaning of the lockdown: from crisis to opportunity	<i>"I played board games with my family"</i> (#13)
<b>Sharing discomfort</b>	Expression of difficulties and negative emotions	<i>"I miss physical contacts with my loved ones..."</i> (#22)
<b>Encouragement and support</b>	Empathy and emotional support towards others' comments	<i>"I feel very close to you"</i> (#4)
<b>Building a sense of community</b>	Feeling of belonging and social recognition	<i>"We are all in the same boat"</i> (#13)

*Italics represent verbatim from the participants.*

### Perspective Changes to Face the Limitations

Comments included in this category referred to the shared strategies and to the attempts to change the perspective on the negative aspects of the lockdown. These contents explained how the students managed the restrictions of Covid-19 and their personal ways to adapt to change. The focus on the positive side of the condition emerged because they cognitively reframed the bad valence of isolation at home. In detail, the focus of attention switched from complaining about what it was not permitted to appreciating what they could do from home: *"I learned to do yoga"* (#2); *"I learned how to cook"* (#5); *"I spent time sunbathing on my balcony"* (#8). Many participants became aware of the importance to take a break from their previous busy life and enjoy more quality time with themselves and their family members (e.g., *"I played board games with my family,"* #13). Furthermore, several students stated that they often had video calls with friends and relatives whom they have been distant for long, as they would not generally meet in person.

### Sharing Discomfort

This category includes comments concerning difficulties and negative emotions experienced by the students during the quarantine. Many comments from this theme refer to nostalgic feelings for social proximity and emotional closeness: *"I miss physical contacts with my loved ones, which is a language itself"* (#22) and *"I miss hugging my grandparents"* (#36). Moreover, some members expressed a feeling of confusion and uncertainty, as *"I feel very sad and empty. The worst feeling is the constant perception of disorientation about my future. I get up every morning with no goals"* (#34) or *"In particular, all this uncertainty upsets me"* (#38).

### Encouragement and Support

The most common reactions in response to the shared discomfort were encouragement and support. Sometimes participants showed empathy and emotional support: *"I feel your difficulty"* (#33), *"I totally understand you, I feel very close to you"* (#4), *"You are not alone"* (#2), or *"My friends and I are facing similar problems"* (#21). Sometimes people gave practical advices: *"I created a game with my nephews that consists of sharing nice words*

**FIGURE 2** | Overall satisfaction with the group.

*to communicate how much we miss each other!"* (#29), or *"I write a thought on my diary every night. It is a good way not to forget what the present is teaching us"* (#20).

### Building a Sense of Community

The final category is populated by comments referring to the idea that students were building a sense of community and a form of social recognition: *"The first reason why we should feel closer is our common destiny: we are all in this together, we are facing the same restrictions, feeling the same fears and wishes"* (#24) or *"We are all in the same boat"* (#13). It is noteworthy to highlight that a great number of comments included both encouragement and a sense of community: *"It is in difficult times that we bring out the best in us!"* (#18), *"Most of us are struggling with this new situation because we are used to exerting control over events. However, the most important thing is adapting to a new routine, not to be pessimistic and appreciate simple things"* (#10), or *"Our mind is struggling because of anxiety and worry, but we shouldn't let this thing dividing us. What unites us is a sense of responsibility toward each other. For the first time, most of us are called to act not only for one's own sake, but especially for other's"* (#5). Another student said that *"The goal is not to sow panic by pointing out to each other, but to provide ideas and resources. One day I need you and the day after you need me, and I do anything possible to give you a starting point. This is beautiful"* (#32). It was also reported that feeling part of a large community while dealing with such a heavy catastrophe plays a significant role to fight loneliness.

### Post-intervention Survey

The post-intervention survey was completed by 25 participants. This self-selected sample was composed of 21 females (84%) and 4 males (6%), with an average age of 24.87 years. Of these, 6 (24%) declared to have commented at least one post, 12 (48%) reported that they interacted with "likes" or other reactions, and 7 (28%) only read the stimuli. Overall, 9 (35%) considered the program very helpful, 11 (42%) helpful, 4 (15%) quite helpful, and 2 (8%) not very helpful (see **Figure 2**).

Both exercises and stimuli were particularly appreciated, as they prompted an open perspective on the lockdown: *"They made me see a new point of view on the coronavirus-related limitations"*

(#9) or “*The group helped me to open up my mind*” (#18). Some students reported that the contents allowed them to manage their emotions: “*They toned down the perceived magnitude of certain events that seems hard to manage*” (#14) or “*It was helpful to see new opportunities and it allowed me to improve the management of my feelings*” (#17). Sometimes, participants shared the exercises and the reflections with other people outside of the group: “*I shared them with my relatives*” (#12), “*I used the exercises alone, but sometimes I discussed them with others, which made them more fun*” (#25). Together with the contents (e.g., “*Reflections and exercises have been very stimulating*,” #20), the group and the interactions have been particularly appreciated: “*I liked some original replies from the other group members*” (#9) or “*I appreciated the opportunity of supporting each other*” (#14). The limits that have been reported by the group members were focused on the limited ways of interaction (“*Sometimes, the discussion was limited*,” #6) and the fact that some contents were perceived as slightly repetitive (“*After a little while, contents got a little repetitive*,” #23). Finally, some suggested that the frequency of post publication was too intense (“*Maybe the contents were too frequent*,” #3).

## DISCUSSION

As a response to the psychological threat represented by the COVID-19 outbreak and its social implications, we developed a structured psycho-educational program, delivered through a private Facebook group for psychology students, to enhance cognitive flexibility, creativity, and openness. Once analyzed the interactions and the post-intervention feedback, it seems that these qualities have been positively impacted, at least for those who actively joined the discussion and provided feedback. The largest theme identified, in fact, is plenty of sentences that suggest that flexible and open new strategies have been proposed and adopted. This is also confirmed by the answers to the post-intervention questions. New perspectives and flexible thinking, as well as openness and creativity, seem to be the most referred problem-solving strategies. In particular, most stimuli aimed to help to reframe the challenges of the COVID-19-related situation, trying to see positive aspects and growing opportunities out of the lockdown and social restriction norms. These strategies were reported as successful in managing negative emotions and in promoting well-being, in line with previous findings from the literature (Kashdan and Rottenberg, 2010). In comparison with existing online psychological interventions (e.g., Chen, 2020; Wahlund et al., 2021), participating in this social community requires a limited time engagement, which may increase its generalizability.

Thinking flexibly and positively about these challenges does not mean to deny the stressful and perhaps depressive aspects of the outbreak, as already identified by other studies (Saita et al., 2021). Participants expressed their need to share emotions, in the search for recognition and acceptance. The reactions to these disclosures were highly accepting and supportive. Together with some creative strategies to face adversities, the

community responded with encouragement and recognition. The sense of community theme exemplifies the effects of these interactions, but it also describes the feeling that the whole human community has been affected. In line with this, it is worth noticing that some participants decided to practice the exercises and to share reflections with relatives and friends. In a sense, the slogan “*We are all in this situation together*” summarizes the feelings of connectedness, which may have grown despite the need for social distance (Ahmad et al., 2020). This pilot study supports the idea that the promotion of a mindful attitude, despite the psychological challenges posed by the outbreak and its social implications, can foster psychological well-being. This is in line with previous studies about interventions aimed to promote flexibility, openness, and mindful reframing (Garland et al., 2015). To our knowledge, this is the first work promoting this approach through social media and the first using it to face the psychological challenges of the COVID-19 pandemic.

Despite the coherence of these results and the clear narrative that arises from their interpretation, the study includes several limits. First of all, a comparison between the participants’ level of wellbeing pre- to post-intervention was not possible, since we did not measure any related construct neither before nor after the study took place. We only have data from those who interacted and replied to our stimuli and questions. We know nothing about the impact of the intervention on those who did not interact. We suggest that at least some of those who did not comment may be positively impacted by the training, for two reasons: Among those who responded to the final survey, the ones that reported no interaction expressed a positive view on the utility of the program; secondly, we have anecdotal evidence that some students, who did not engage group discussions, have found it helpful. However, it is hard to quantify the actual impact from the available data. Thirdly, generalization is problematic: The study was conducted in Italy, with students and alumni from a private academic institution, and focused on online data. Moreover, the obtained results refer to a self-selected group of psychology students and the responders to the survey were few, preventing more extensive quantitative analyses. Finally, to keep short the post-intervention survey, we did not collect many details about demographics and individual characteristics of the responders. Further data on different populations are therefore warranted.

## CONCLUSIONS

The study provides some insights on the potential for an intervention that promotes flexible thinking, openness, and creativity, as a way to deal with the outbreak and the lockdown. The intervention, in this case, is delivered through a widely used social media, which makes it extremely scalable and cost-effective. It requires the creation of a community, by using a private group, allowing participants to reply to each other, easing recognition and encouragement. Future studies should explore, in the context of the lockdown or other challenging situations, the effects

of the intervention with a controlled study and with a quantitative approach.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The study was reviewed and approved by Ethics Commission of the Department of Psychology at UCSC. The participants provided their written informed consent to participate in this study.

# Fatalism in the Early Days of the COVID-19 Pandemic: Implications for Mitigation and Mental Health

Joseph Hayes\* and Laura Clerk

Department of Psychology, Acadia University, Wolfville, NS, Canada

This research assessed fatalism toward COVID-19 and its role in behavioral intentions to support mitigation efforts (e. g., social distancing) and mental well-being. A COVID-19 fatalism measure was developed, and a messaging manipulation (fatalistic vs. optimistic vs. no message) was created to examine causal links between fatalism scores. Support for mitigation efforts and negative affect (anxiety, fear, depression, and insecurity) were measured to examine the consequences of fatalism toward COVID-19. Results showed that the fatalistic messaging condition increased fatalism whereas the optimistic message reduced it. The effects of the messaging manipulation were also apparent in the downstream measures of support for mitigation and negative affect through the mediator of fatalism toward COVID-19. Specifically, fatalism negatively predicted intentions to support mitigation. Regarding mental health, fatalism was positively associated with depression but negatively associated with fear and insecurity. Implications for COVID-19 mitigation efforts and mental health in the face of the coronavirus pandemic are discussed.

## FATALISM IN THE FIGHT AGAINST COVID-19: IMPLICATIONS FOR MITIGATION AND MENTAL HEALTH

On March 11th, 2020, the World Health Organization declared the COVID-19 outbreak a global pandemic (World Health Organization, 2020). In the 12 months that followed, more than 100 million people were infected and nearly 3 million people died (Worldometer, 2020). In the early days of this pandemic, most governments attempted to stop the spread of the virus by instituting lock-down measures and other mitigation protocols. Schools and businesses were closed, and people were asked to stay home as much as possible, practice social distancing when in public, and avoid large gathering or crowded environments (Centers for disease control prevention, 2020). Despite these efforts, the global spread of COVID-19 could not be contained.

As the death-toll from the pandemic rose, so too did the mental toll associated with mitigation efforts. Many people lost their job and faced severe financial strain (Mutikani, 2020; United States Department of Labor., 2020). Many more shifted to working from home, often in cramped urban apartment spaces, while also struggling to manage childcare and homeschooling (Cooney, 2020). Incidents of domestic violence increased (Taub, 2020). And more generally, people were forced to forego many of the things that typically provide meaning and purpose to life (e.g., social contacts, freedom of movement, sports and entertainment). To make matters worse, it quickly became apparent that this would likely be the new normal until a vaccine could be developed, which was estimated to take a year or more (Boyle, 2020).

Although the hardships and devastation of the pandemic would increase substantially as it wore on, the initial shock and disruption already seemed nearly impossible to manage during the early days. Rather than continue to struggle with mitigation efforts, we reasoned that many people would be willing to give up and submit to the deadly pandemic rather than fight against it. Given that most cases of COVID-19 are relatively mild, the appeal of letting go, and allowing the virus to wash through the population may have seemed more attractive than maintaining efforts to mitigate its spread. Plus, given the invisible nature of the virus (i.e., you cannot directly observe it in the environment), uncertainty regarding how it is transmitted (Han et al., 2020), and the delayed effects of mitigation efforts, it can be easy to become fatalistic and feel that nothing can be done to stop the virus from spreading. The purpose of the current research was to assess fatalism toward COVID-19 at a pivotal point in America's efforts to fight the virus—the first few weeks into the pandemic. Moreover, we aimed to examine the effect of different media messages on feelings of fatalism, and sought to gauge the consequences of COVID-19 fatalism on support for continued mitigation efforts and mental well-being.

## Fatalism Toward COVID-19

Fatalism is the belief that one's actions have little or no significant impact on important outcomes (Zimbardo and Boyd, 1999). People who are high in fatalism tend not to engage future-oriented planning, expend little effort in trying to achieve desirable goals, and are generally resigned to fate. In other words, they are willing to let external forces take over. Although the tendency to display fatalism is an individual difference, there are also situational circumstances that will promote fatalistic thinking independently of differences in personality. Indeed, fatalism may be particularly likely during the COVID-19 pandemic. Virus particles are invisible and easily transmitted from person to person. Those who contract the virus often have no idea where they became infected. Indeed, in some cases, transmission of the virus can happen in the absence of symptoms. The pandemic represents a powerful external force that can easily lead people to conclude that there is nothing they can do to influence the situation. In other words, they may feel that how the pandemic turns out is largely up to fate.

## Mental Health

When fatalism is pervasive, it tends to be strongly associated with depression and hopelessness (Seligman, 1975; Zimbardo and Boyd, 1999). However, fatalistic beliefs can also function to reduce the fear and anxiety aroused by insurmountable threats (Hayes et al., 2016; Lifshin et al., 2020). Struggling to control outcomes that appear intractable triggers anxious motivational conflict (Carver and Scheier, 1998; Gray and McNaughton, 2000), while choosing to let go of them can reduce this anxiety by eliminating the tension produced by wanting to control something uncontrollable (Rothbaum et al., 1982; Hayes et al., 2017).

With respect to COVID-19, mitigation efforts are difficult, costly, and have no clear end-date. Thus, becoming fatalistic in the fight against COVID-19 can be an attractive way of reducing

concerns about the pandemic. Indeed, recent work by Lifshin and colleagues suggests that people can become motivated to feel helpless against the virus to justify inaction and reduce anxiety (Lifshin et al., 2020). Importantly, however, we maintain that this method of palliation can also have broader negative consequences for mental health. When fatalism is extensive, it can promote depression and generalized disengagement from life (Hayes et al., 2016, 2017).

## Commitment to Mitigation Efforts

Another trouble with fatalism is that it reduces motivation and planful self-regulation (Hayes et al., 2016), which may be especially problematic vis-à-vis COVID-19 because it may undermine the principal means of addressing the pandemic—namely, social distancing. Becoming fatalistic about COVID-19 may lead people to ignore public health recommendations (e.g., “*we're all going to get this virus anyway, so why stay at home and suffer?*”), which is dangerous for the general public as well as the fatalistic individual as it increases the risk that they will become infected and spread the virus by not taking proper precautions. Understanding factors that contribute to COVID-19 fatalism, and how we can reduce these factors, is therefore imperative if collective mitigation efforts are to be successful.

## Media Messaging

One factor that may be particularly important in creating fatalism toward COVID-19 is the way in which it is presented in the media. Indeed, nearly every news story now appears related to the pandemic in some manner or another, and the information is often dire or shocking. While many of these messages seek to affirm the importance of collective action and the ironic sense of community that can come from social distancing for the well-being of others (e.g., #AloneTogether; Harrop, 2020), other messages often directly promote fatalism by claiming that the spread of the disease is inevitable (Slaughter, 2020). These messages often voice concern about the long-term economic impact of staying at home and shuttering businesses, suggesting that the cost associated with continued mitigation efforts is far greater than the cost of the virus (Hilton, 2020; Singer and Plant, 2020). U.S. President Donald Trump appeared to share these concerns when tweeting on March 23rd “WE CANNOT LET THE CURE BE WORSE THAN THE PROBLEM ITSELF” (Trump, 2020). Although these messages are very clearly anti-mitigation, we suspect they may be most effective in reducing support for mitigation efforts when they instill a sense of fatalism toward COVID-19. Indeed, fatalism and inaction go hand-in-hand.

## Study Overview

The purpose of the current research was to assess levels of fatalism toward COVID-19, to understand what factors influence this construct, and to examine the consequences of fatalism for mental health and support for COVID-19 mitigation efforts. Accordingly, we developed a self-report measure of fatalism toward COVID-19 and collected an online survey. To assess how COVID-19 fatalism can be causally influenced, we designed a fatalistic message arguing that the pandemic is unstoppable and

that mitigation efforts may do more harm than good (cf., Hilton, 2020; Singer and Plant, 2020; Slaughter, 2020; Trump, 2020). The fatalistic message intended to mimic those presented in the media or shared by prominent figures that the general public has been exposed to throughout the pandemic. For comparison, we created an optimistic message that emphasized the effectiveness of mitigation efforts and the connectedness that can come from tackling the pandemic collectively. We expected the fatalistic message to increase fatalism and the optimistic message to reduce it.

To assess the consequences of COVID-19 fatalism, at the end of the study we assessed support for mitigation efforts and negative emotionality. Regarding support for mitigation, we expected fatalism to be associated with reduced support for these efforts. Moreover, we hypothesized that our fatalistic and optimistic messaging conditions would influence support for mitigation by virtue of affecting self-reported feelings of fatalism (i.e., mediation). Regarding negative emotion, we expected fatalism to be positively associated with depression (Zimbardo and Boyd, 1999), but negatively associated with anxiety given evidence that fatalism in the face of insurmountable threats can reduce anxiety (Hayes et al., 2016; Lifshin et al., 2020).

## METHOD

### Participants and Design

In keeping with open science practices, we report all measures and manipulations included in the study. Full study materials are available online at <https://osf.io/sx7g2/>. We also explain how sample size was determined and report all data exclusions.

To determine minimum sample size requirements to confidently test our hypotheses, we conducted an a priori power analysis using G\*Power (Faul et al., 2007), and sought at least 80% power (with an alpha of 0.05) to detect a small effect (i.e.,  $f = 0.10$ – $0.24$ ;  $d = 0.20$ – $0.49$ ). The number of participants required to detect the lowest end of this range ( $f = 0.10$ ;  $d = 0.20$ ) using these criteria in a one-way ANOVA with three conditions yielded the highest estimate ( $N = 969$ ), so we strove to obtain a sample size that approximated this number.

Participants were 1,025 people recruited online through Amazon's Mechanical Turk. They were randomly assigned to one of three conditions in a between-subjects design. The only requirement for participation was United States residence. Exclusions included 149 participants who failed an attention check item asking them to leave a question blank (i.e., *Please do not answer this question, it is here to see if you are paying attention.*), 19 who did not correctly answer at least two (of four) multiple-choice questions about the contents of the article that they read, and six others for failing to complete all dependent variables for our main analyses. The total number of participants after exclusions was 851 (fatalistic  $n = 274$ , optimistic  $n = 291$ , no message  $n = 286$ ), which fell short of our sample size goal. Nevertheless, a *post-hoc* sensitivity analysis revealed that we retained 80% power to detect small effects ( $f = 0.11$ ,  $d = 0.21$ ; and 95% power to detect  $f = 0.13$ ,  $d = 0.27$ ), so we were confident in proceeding with our analyses without collecting more data. The final sample ranged in age from 18 to 78 ( $M_{\text{age}} = 41.0$ ,  $SD_{\text{age}} =$

14.0), and gender balance was roughly equal (female = 443, male = 391, other = 5, prefer not to disclose = 6).

### Measures and Procedure

The study was conducted on March 27th, 2020, 11 days into the initial mitigation period aimed at providing 15-days to slow the spread of the novel coronavirus (WhiteHouse.gov, 2020). The study was reviewed by an institutional research ethics board and was deemed to pose no more than minimal risk. Participants were informed that the study was an investigation of personality, attitudes, and opinions. They were not told that the purpose of the study was related to COVID-19 until the debriefing. Upon consenting to participate, respondents began by complete a series of demographic questions, followed by three brief personality questionnaires.

### Demographic and Personality Variables

Demographic items included age, gender, household income, education, and political orientation (among others, see online supplement for complete list of demographic items). We measured three personality factors that seemed like plausible candidates for influencing fatalism. Specifically, we assessed self-esteem (Rosenberg, 1965) and trait sensitivity to rewards and punishments (BAS and BIS; Carver and White, 1994) given that these variables influence reactions to threat (see Pyszczynski et al., 2004; Jonas et al., 2014). Exploratory analyses controlling for demographic and personality factors and exploratory tests of moderation are presented in the Supplementary Online Material (SOM; see <https://osf.io/sx7g2/>).

### Messaging Condition

Participants were randomly assigned to one of three messaging conditions. In the control condition, participants read no message and simply proceeded to a series of questions related to their attitudes and opinions about the COVID-19 pandemic. By contrast, those in the fatalistic and optimistic messaging conditions read a brief opinion piece before proceeding to these questions. The essays began with a threatening paragraph outlining the severity of the COVID-19 pandemic:

*COVID-19 is a killer. It has already killed more than 25,000 people worldwide and will likely kill many hundreds of thousands more. Making things worse, it is an invisible killer. We cannot see it, and we cannot even know when we have it on our hands. The only way that we know to keep it at bay is to stay away from each other. Social (or physical) distancing measures have been in place across the Western World for nearly 2 weeks. But the spread of COVID-19 rages on.*

For participants in the *fatalistic condition*, the essay went on to describe how social distancing can only be a temporary fix, and that the virus will remain problematic until we develop a vaccine, which will not happen for 18–24 months. The article then struck a fatalistic chord by asking whether people are truly willing to engage social distancing for 2 years. The author indicates that the virus is unstoppable and that he would rather let it run its course so that we can get back to normal sooner than later.

**TABLE 1** | Descriptive statistics for scale items assessing fatalism toward fighting Covid-19.

Item	Mean	SD	Skewness	Item-total Correlation
Staying home can make all the difference in the fight against covid-19*.	5.70	1.28	-1.35	-0.74
I can help to stop the spread of covid-19*.	5.52	1.32	-1.24	-0.73

The spread of covid-19 is controlled by forces that I cannot influence.	4.06	1.73	-0.12	0.45

SD, Standard Deviation; Items followed with an asterisk (\*) are reverse-keyed.

Participants in the *optimistic condition* read an article that began with the same opening paragraph but then proceeded to argue that social distancing is effective. The author pointed toward China and South Korea as examples of its effectiveness. The message is optimistic but nevertheless realistic, suggesting that social distancing will not eradicate the virus but will buy time so that a vaccine can be developed within 18–24 months. The author concludes by indicating that he is willing to do his part to prevent the spread of the virus. Finally, he appeals to the togetherness that collective social distancing can offer (see SOM for the full text of both messaging conditions).

Participants in the fatalistic and optimistic conditions then proceeded to complete five simple reading comprehension questions that were included to ensure adequate processing of the message. Four of these questions were multiple-choice, whereas one was an open-ended item asking participants to indicate the overall theme of the article. Only participants who correctly answered at least two of the four multiple choice questions were retained for data analyses.

## Specific Worries

Next, participants completed a 7-item scale assessing their specific worries related to the COVID-19 crisis. These items were included for exploratory purposes. They assessed worries about death and finances for the self, close others, and strangers. The final item assessed concern for the economy (see SOM for exploratory analyses of these items).

## Fatalism Toward COVID-19

Participants then completed a 16-item scale assessing fatalism toward COVID-19 ( $\alpha = 0.94$ ; see **Table 1** for complete item-details; see SOM for factor analytic results and other exploratory

analyses). This was our main dependent variable, and consisted of seven positively keyed items ("Since whatever will be will be, it doesn't really matter what I do to try to stop COVID-19") and nine negatively keyed items (indicative of self-efficacy; e.g., "It is within my power to help reduce the spread of COVID-19"). Participants rated their agreement with each item using a 7-point Likert scale (1 = strongly disagree; 7 = strongly agree).

## Behavioral Intention to Support Mitigation Efforts

Immediately after the fatalism questionnaire, we included an 11-item scale assessing behavioral intentions to support mitigation efforts ( $\alpha = 0.86$ , see SOM for complete item-details). Participants again responded using the 7-point scale. The items were geared predominantly toward intentions to engage social distancing (e.g., *I plan to keep my distance from others*) and to remain isolated (e.g., *I plan to stay isolated for as long as it is required*), but also assessed support for mitigation efforts more broadly (e.g., *I support lockdown efforts aimed at reducing the spread of COVID-19*).

## Emotional Distress

Finally, after rating their support for mitigation efforts, participants completed a brief emotion measure to gauge their emotional well-being. The measure consisted of 20 items assessing four different emotions (5-items each): anxiety ( $\alpha = 0.84$ ), fear ( $\alpha = 0.95$ ), depression ( $\alpha = 0.93$ ), and insecurity ( $\alpha = 0.87$ ; see SOM for complete item-details). Although our hypotheses were specifically related to anxiety and depression, we included items assessing fear and insecurity for exploratory purposes. Participants rated the extent to which they were

currently experiencing these emotions using a 7-point scale (1 = not at all; 7 = very much). Upon completion, participants were thanked for their participation and fully debriefed.

## RESULTS

Deidentified data and analysis script for all analyses reported below are available online at <https://osf.io/sx7g2/>. A document containing supplemental exploratory analyses that accompany the main findings can be found by following the same link.

Prior to beginning our analyses, we reversed scored negatively keyed items and computed scale means for each of our dependent variables. Descriptive statistics for the global sample are displayed in **Table 2**.

### Fatalism Toward COVID-19

To test our hypothesis about the effect of messaging condition on fatalism toward COVID-19, we conducted a one-way between-subjects ANOVA on the fatalism scores. Results showed a significant effect of condition,  $F_{(2,848)} = 11.16$ ,  $p < 0.001$ ,  $\eta^2 = 0.03$  (see **Figure 1**). Consistent with hypotheses, pairwise comparisons revealed that the fatalistic message increased fatalism relative to the no message control condition,  $t(848) = 2.04$ ,  $p = 0.041$ ,  $d = 0.17$ , whereas the optimistic message reduced fatalism relative to no message,  $t(848) = -2.68$ ,  $p = 0.007$ ,  $d = -0.22$ .

Note. Error bars represent 95% confidence intervals.

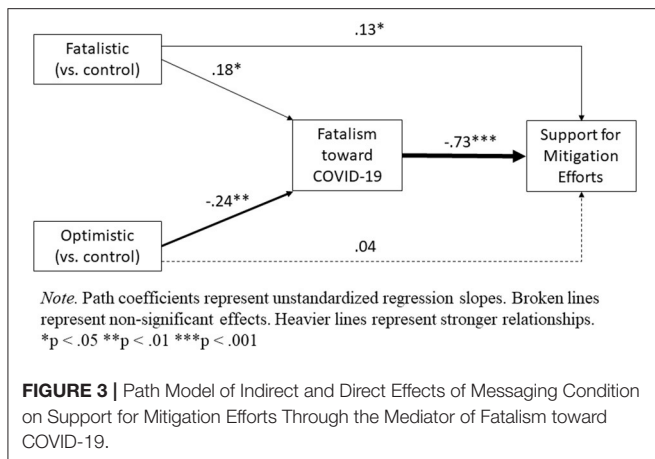

**FIGURE 2** | Effect of Messaging Condition on Support for COVID-19 Mitigation Efforts.

### Behavioral Intentions to Support Mitigation Efforts

Our next analysis examined the consequences of COVID-19 fatalism for behavioral intentions to support mitigation efforts. First, a bivariate correlation between these variables showed a highly significant association,  $r(851) = -0.78$ ,  $p < 0.001$ . Thus, higher levels of fatalism toward COVID-19 were associated with lower behavioral intentions to support mitigation efforts.

We also examined the effect of our messaging manipulation on support for mitigation efforts. A one-way ANOVA on support for mitigation with message condition as the independent variable revealed a significant effect,  $F_{(2, 848)} = 4.33$ ,  $p = 0.013$ ,  $\eta^2 = 0.01$  (see **Figure 2**). Pairwise comparisons revealed that whereas the optimistic message increased support for mitigation efforts relative to no message,  $t(848) = 2.57$ ,  $p = 0.010$ ,  $d = 0.21$ , the fatalistic message had no effect on support for mitigation,  $t(848) = -0.00$ ,  $p = 0.997$ ,  $d = -0.00$ .

Our main hypothesis regarding the effect of messaging condition on support for mitigation was that it would be mediated by fatalism toward COVID-19. Thus, we tested the indirect effect of our messaging manipulation on support for mitigation efforts through the hypothesized mediator of fatalism. Accordingly, we used Hayes' (2018) PROCESS macro to regress support for mitigation on messaging condition (dummy-coded to compare the fatalistic message with control in code 1 and the optimistic message with control in code 2) through the mediator of COVID-19 fatalism (Model 4, 5,000 bootstrap resamples). This analysis showed that the fatalistic message reduced support for mitigation indirectly by increasing fatalism toward COVID-19,  $b = -0.13$ , 95% confidence interval (CI) [-0.266, 0.003], whereas the optimistic message increased support for mitigation by reducing fatalism,  $b = 0.17$ , 95% CI [0.051, 0.299]. After accounting for these indirect effects, messaging condition still exerted a significant direct effect on support for mitigation efforts,  $F_{(2, 847)} = 3.31$ ,  $p = 0.037$ ,  $\eta_p^2 = 0.003$ . Interestingly, pairwise comparisons showed that whereas the direct effect of the optimistic message was not significant,  $t(847) = 0.77$ ,  $p = 0.443$ ,  $d = 0.04$ , the fatalistic message now revealed a significant direct effect,  $t(847) = 0.252$ ,  $p = 0.012$ ,  $d = 0.13$ , such that participants

**TABLE 3 |** Bivariate correlations among fatalism and negative emotions.

Variable	1	2	3	4
Anxiety (1)	–			
Fear (2)	0.80***	–		
Depression (3)	0.79***	0.81***	–	
Insecurity (4)	0.26***	0.27***	0.33***	–
Fatalism	0.07	0.02	0.09**	–0.05
Fatalism (partial correlations)	0.04	–0.10**	0.12***	–0.08*

Partial correlations with fatalism (bottom line) represent relationships between fatalism and each negative emotion while controlling for the other three. \* $p < 0.05$ , \*\* $p < 0.01$ , \*\*\* $p < 0.001$ .

increased their support for mitigation efforts after reading the fatalistic message relative to no message (see **Figure 3** for a full path model).

### Emotional Distress

Finally, we examined the emotional consequences of fatalism toward COVID-19. Bivariate correlations between fatalism and each of the negative emotions measured in the study are presented in **Table 3**. Given research showing divergent unique associations between fatalism and anxiety and depression when these highly correlated negative emotions are covaried for each other in statistical analyses (see Hayes et al., 2016; Hayes and Hubley, 2017), we also examined partial correlations between fatalism and each negative emotion controlling for the others in **Table 3**. In summary, although the overall correlations show only a significant positive association between fatalism and depression, the partial correlations also show significant *negative* associations between fatalism and fear and insecurity.

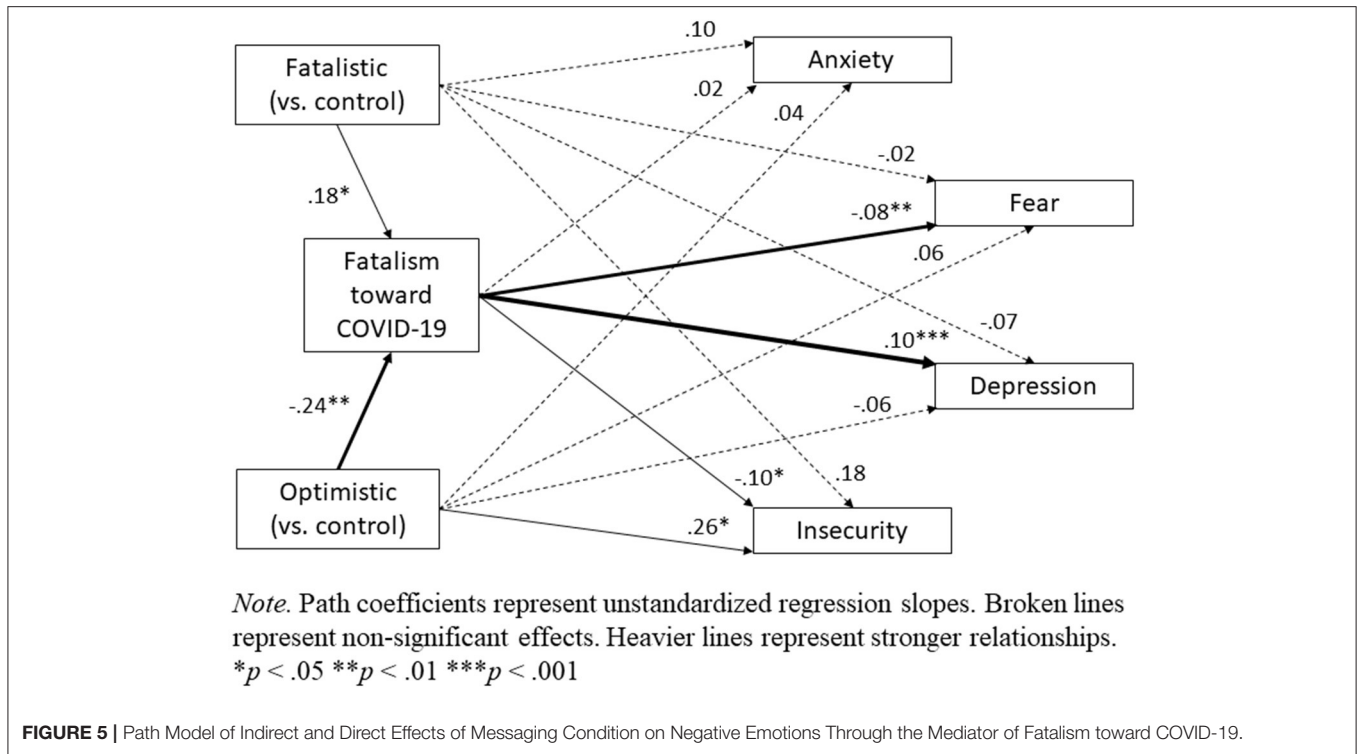

To examine the effect of messaging condition on negative emotionality, we first conducted four separate ANCOVAs on each emotion while controlling for the other three (removing the covariates did not affect these analyses, but see SOM for results without the covariates). These analyses revealed a significant effect of messaging condition on insecurity,  $F_{(2, 845)} = 3.21$ ,  $p = 0.041$ ,  $\eta_p^2 = 0.01$ , such that the optimistic message increased insecurity relative to no message,  $t(845) = 2.52$ ,  $p = 0.012$ ,  $d = 0.21$ , but the fatalistic message did not,  $t(845) = 1.43$ ,  $p = 0.155$ ,  $d = 0.12$ . There were no overall effects of condition for anxiety,

$F_{(2, 845)} = 1.33$ ,  $p = 0.266$ ,  $\eta_p^2 = 0.00$ , fear,  $F_{(2, 845)} = 1.14$ ,  $p = 0.320$ ,  $\eta_p^2 = 0.00$ , or depression,  $F_{(2, 845)} = 0.61$ ,  $p = 0.545$ ,  $\eta_p^2 = 0.00$  (see **Figure 4**). Nevertheless, given the significant effect of condition on fatalism and the significant partial correlations between fatalism and three of the four negative emotions, we tested for indirect effects of messaging condition on each emotion through the mediator of fatalism (as we did for support for mitigation) using Hayes’ (2018) PROCESS macro (Model 4, 5,000 bootstrap resamples). A full path model is displayed in **Figure 5**, and indirect effects are summarized in **Table 4** (see SOM for this analysis without the covariates). Overall, this analysis showed that by increasing fatalism toward COVID-19, the fatalistic message indirectly reduced fear and insecurity, but increased depression. The opposite pattern emerged for the optimistic message. By reducing fatalism toward COVID-19, the optimistic message indirectly increased fear and insecurity, but reduced depression.

### DISCUSSION

The results were generally consistent with our hypotheses. They offer insights into the role of fatalism in the early days of the COVID-19 pandemic and show how media messaging may have influenced support for virus mitigation efforts and overall mental health.

First, as anticipated, the fatalistic message increased fatalism toward COVID-19 while the optimistic message reduced it. Results for behavioral intentions to support mitigation efforts were partially consistent with hypotheses. As predicted, the optimistic message increased support for mitigation, and fatalism toward COVID-19 mediated this effect. However, the fatalistic message showed no overall effect on support for mitigation. Nevertheless, consistent with hypotheses, this message reduced support for mitigation indirectly by increasing fatalism toward COVID-19. Interestingly, after accounting for this indirect effect, we found that the fatalistic message increased support for mitigation directly (see **Figure 3**). This pattern explains why the fatalistic message had no overall effect on support for mitigation—suggesting that the message produced two opposing effects (a suppression effect). Whereas, some people became

**FIGURE 5 |** Path Model of Indirect and Direct Effects of Messaging Condition on Negative Emotions Through the Mediator of Fatalism toward COVID-19.

**TABLE 4 |** Indirect effects of messaging condition on negative emotions through COVID-19 Fatalism.

Message Condition	Outcome	Effect	Boot SE	Boot LLCI	Boot ULCI
Fatalistic (vs. control)	Anxiety	0.004	0.006	-0.004	0.022
	Fear	-0.015	0.009	-0.040	-0.002

Optimistic (vs. control)	Anxiety	-0.006	0.007	-0.024	0.006
	Fear	0.019	0.010	0.004	0.045
	Depression	-0.023	0.012	0.004	-0.006
	Insecurity	0.024	0.015	0.003	0.063

All indirect effects represent unstandardized regression coefficients. Boot, Bootstrapped; SE, Standard Error; LLCI, Lower Level Confidence Interval; ULCI, Upper Level Confidence Interval. Confidence intervals represent 95% CIs, thus intervals that do not contains zero are significant at the  $p < 0.05$  level.

fatalistic and thus less supportive of mitigation efforts, others reacted against the message by increasing their support for mitigation. This pattern may be indicative of reactance (Brehm, 1966), wherein people respond to external pressure by asserting their freedom and control. Although this interpretation would suggest that some identifiable moderator could predict who responded to fatalistic media messages with reactance (vs. fatalism), we found no significant moderators of this relationship in our data (see SOM for exploratory analyses). With that said, we included only a small number of personality scales in our study (self-esteem, BAS/BIS sensitivity). Future research could examine alternative personality factors (e.g., agreeableness), or other individual differences (e.g., personal experience or prior knowledge of viral epidemiology) that might moderate responses to fatalistic messages.

Fatalism toward COVID-19 also showed associations with emotional distress, and messaging condition evinced significant indirect effects on negative emotionality by influencing fatalism. First and foremost, fatalism was positively associated with depression. However, when controlling for the other negative emotions assessed in the study, fatalism was also negatively associated with fear and insecurity. These associations are only partially consistent with expectations. We hypothesized a positive association for depression given the withdrawal-oriented nature of fatalistically abandoning efforts to engage personal control (which was supported), but a negative association with anxiety given that fatalism can offer defense against intractable threats (Hayes et al., 2016). Results showed no associations between fatalism and anxiety (with or without the covariates). But the associations of fatalism with fear and insecurity may be consistent

with our hypothesis that fatalism is an attempt to cope with the intractable nature of the pandemic. In retrospect, anxiety should be most likely when examining distant or abstract threats where the possibility of negative outcomes is highly uncertain (McNaughton and Corr, 2004). While this may have applied to the early days of the pandemic, it is only conceivable that most people saw COVID-19 as a clear and present danger. If so, it would be reasonable to expect fear-related emotions (Greenberg et al., 1997; McNaughton and Corr, 2004). These results would need to be replicated to ensure that they are reliable, but the associations with fear and insecurity are at least partially consistent with our expectation that fatalism toward COVID-19 offers a means of reducing concerns about the pandemic.

One aspect of the results that was not anticipated was the effect of the optimistic message on feelings of insecurity (see **Figure 4**). Results from the mediational analysis suggest that part of this effect is attributable to reduced feelings of fatalism (which is consistent with our theorizing about the relationship between fatalism and pandemic concerns), but the direct effect shows that the optimistic message increased feelings of insecurity even after controlling for the influence of fatalism (see **Figure 5**). One possible interpretation for this effect is that people who read the optimistic message became more vigilant about their health-status. They may have become less confident that they were safe and healthy, for instance, and more guarded against contracting the virus and potentially transmitting it to others. From this perspective, feelings of insecurity may be somewhat adaptive during a pandemic. While feeling insecure is no doubt emotionally taxing and likely difficult to maintain for extended periods, a certain level of distress may be necessary to remain vigilant against infection. Future research could investigate this possibility more directly.

## Implications for COVID-19 Mitigation

The results of the current study have important implications for ongoing efforts to mitigate the spread of COVID-19 by suggesting a pivotal role for fatalism. Indeed, several studies now show that fatalistic thinking reduces behavioral intentions to follow public health advice aimed at mitigating the spread of COVID-19. More specifically, high belief in predetermination (Özdil et al., 2021), exaggerated estimates of the infectiousness of the virus (Akeşon et al., 2020), and the tendency to automatically associating the virus with death (Jimenez et al., 2020) have all been found to be associated with an unwillingness to follow mitigation protocols (see also Bogolyubova et al., 2021). In essence, people are unlikely to engage mitigation efforts unless they believe COVID-19 can be eradicated by such efforts and that their actions (e.g., social distancing, staying at home) are needed to stop the virus.

The current study suggests that media messaging plays an important role in affecting mitigation efforts by virtue of influencing fatalism toward COVID-19. Messages that paint a bleak picture of the pandemic, or suggest that it may take years to end (if it will end at all) may undermine support for mitigation efforts by promoting fatalism (cf., Briscese et al., 2020). Ironically, such messages may ultimately serve to prolong the pandemic and increase its severity by discouraging adherence to public

health guidelines. By the same token, our results also suggest that messaging about the virus can be an important means of reducing fatalism and thereby increasing support for mitigation. Pro-mitigation messages that are inherently anti-fatalistic by drawing clear connections between individual actions and the spread of the virus have been shown to increase intentions to practice social distancing (Lunn et al., 2020). Moreover, messages that promote a duty to care for others (Everett et al., 2020) have also been found to be effective in promoting adherence to mitigation protocols, and these too may function in part by reducing fatalism (see SOM for associations between concern for others, fatalism, and support for mitigation).

## Implications for Mental Health

The current research also has implications for understanding the mental health consequences of the pandemic. Numerous studies have found increased prevalence of psychological disfunction stemming from the pandemic (e.g., Bo et al., 2020; Choi et al., 2020; Forte et al., 2020; Gallagher et al., 2020; Hyland et al., 2020; Salari et al., 2020; Shevlin et al., 2020). These studies point toward elevated levels of anxiety, depression, and trauma. The pandemic not only poses a threat to our physical health, but also increases the burden of everyday life while sapping the financial and psychological resources needed to cope with this burden. Indeed, people with direct personal experience with the disease (e.g., Forte et al., 2020; Gallagher et al., 2020), low or reduced income (e.g., Hyland et al., 2020; Shevlin et al., 2020), and those who are alone or detached from loved ones (e.g., Horesh et al., 2020; Parlapani et al., 2020) are among those reporting higher levels of psychological distress during the pandemic.

Studies suggests that at least some of the mental distress triggered by the pandemic stems from feelings of fatalism toward COVID-19. Specifically, Ngien and Jiang (2021) found that COVID-19 fatalism was positively associated with stress among Chinese youth, and Bogolyubova et al. (2021) found that fatalism predicted post-traumatic stress symptoms in an international sample. In the current study, we found that fatalism toward COVID-19 was positively associated with depression. Moreover, we found that media messaging can influence depression by affecting fatalism. In fact, our fatalistic message was partly inspired by extent media messages, including Donald Trump's tweet about the cure being worse than the disease. At the time of data collection (March 27th), the possibility that President Trump would forgo restrictions and allow the virus to go unmitigated to save the economy appeared real. We reasoned that this anti-mitigation rhetoric may be effective in reducing support for mitigation, but suspected it would also promote depression and despair by causing many people to feel fatalistic about the pandemic. Our results support this reasoning. And moreover, the data also show that optimistic media messaging can reduce feelings of depression by reducing fatalism toward the COVID-19 pandemic. Ngien and Jiang (2021) observed similar results showing that social media use reduced pandemic stress by virtue of reducing feelings of fatalism. Thus, the mental well-being of people who consume media related to the pandemic may hinge in part upon the extent to which the message makes them feel fatalistic (vs. powerful and effective) toward the virus.

Our data also add complexity to the mental health picture by showing that fatalism toward the pandemic can offer protection against fear and insecurity. These results are consistent with research by Özdil et al. (2021) who found that fatalistic beliefs relating to predetermination and luck were negatively associated with fear of COVID-19. Similarly, Lifshin et al. (2020) found that extremely high levels of helplessness toward becoming infected were associated with lower levels of anxiety. Thus, believing that nothing can be done to stop the virus or to prevent oneself from being infected precludes the need to worry about it. Indeed, we maintain that this is the inherent appeal of fatalism in response to intractable threats such as the COVID-19 pandemic. However, fatalism should not be viewed as a healthy solution to the problem. Indeed, the evidence suggest that fatalism is associated with reduced intentions to follow public health advice—behavior that poses a risk to oneself and others. Moreover, even the evidence suggesting that fatalism is associated with lower fear and anxiety shows that this is not without caveats. For instance, Özdil et al. (2021) found that at least one facet of fatalistic (pessimism) was associated with *more* fear of COVID-19. This may help to explain why we only found a negative association between fatalism and fear after controlling for other negative emotions (such as depression, which is strongly associated with pessimism). Likewise, Lifshin et al. (2020) found that moderate (vs. low) levels of helplessness were associated with *increased* anxiety (i.e., the relationship between helplessness and anxiety was curvilinear). According to Lifshin et al. (2020), moderate levels of helplessness may be associated with feeling overwhelmed by difficult circumstances that exceed one's capacity for control whereas extremely high levels of helplessness can offer relief from anxiety because there is truly nothing that can be done.

In our view, fatalism toward a specific phenomenon that is truly impossible to control can be an adaptive response under the circumstances. The trouble occurs when people turn to fatalism too quickly or the fatalistic giving-up process is too extensive (see Hayes et al., 2017). Becoming fatalistic too quickly can lead people to miss the chance to control something that ultimately *can* be controlled. In the context of COVID-19, fatalism in the first few weeks of the pandemic may have led humanity to miss the opportunity to minimize the global impact of COVID-19. Moreover, given what may be lost by giving-in to a pandemic (the health and survival of oneself and those to which one is connected), fatalism in the context of COVID-19 may be quite extensive and could trigger generalized fatalism that leads to severe depression and other mental health issues. Whatever the case may be, it appears that the emotional correlates of fatalism toward COVID-19 are complex and multifaceted. Future research should continue to investigate the role of fatalism in mental health outcomes to the pandemic and beyond.

### Important Limitations

Although this research is largely supportive of our hypotheses, it also has several important limitations. First, the size of the effects of our manipulation on COVID-19 fatalism, support for mitigation efforts, and emotional well-being are quite small. Indeed, according to rules of thumb for gauging the size of a standardized effect (Cohen's *d*), nearly all effect sizes observed in

this study were small ( $< 0.49$ ) or very small ( $< 0.20$ ). These effects were detected as significant due to a relatively large sample size. Nevertheless, what may begin as a small effect at the beginning of a pandemic may snowball into much larger effects as time passes.

Second, the measures that we employed to test our hypotheses were not standardized instruments. It is therefore difficult to compare the scores observed in the current study with comparable scores in the existing literature. Did participants in our sample report particularly high levels of fatalism? Likewise, were the depression scores observed in our sample indicative of clinical depression or normal sadness? The reason that we did not use standardized measures of fatalism or support for mitigation efforts was that none existed at the time of data collection. Even now it is hard to know if the observed values are relatively high or low. Nevertheless, we can gain some perspective on the level of negative affect reported in the current study by comparing the current data to pre-pandemic studies in our lab that used similar methodology. For instance, Hayes and Hubley (2017) assessed anxiety and depression with the same items used in the current research (in addition to several others). Mean scores for anxiety were significantly higher in the current sample ( $M = 2.98$ ;  $SD = 1.44$ ;  $n = 851$ ) than they were on the same items prior to the pandemic ( $M = 2.03$ ;  $SD = 1.40$ ;  $n = 204$ ),  $t(1,053) = 8.45$ ,  $p < 0.001$ ,  $d = 0.66$ . Likewise, scores on the depression items were also significantly higher in the current sample ( $M = 2.69$ ;  $SD = 1.69$ ;  $n = 851$ ), than before the pandemic ( $M = 2.07$ ;  $SD = 1.67$ ;  $n = 204$ ),  $t(1,053) = 4.82$ ,  $p < 0.001$ ,  $d = 0.38$ . Thus, the levels of anxiety and depression reported in this study are significantly above what we have observed in our previous research. This is consistent with several studies that *did* use standardized measures and also found increased anxiety and depression in response to the pandemic (e.g., Hyland et al., 2020; Özdin and Özdin, 2020; Shevlin et al., 2020). To provide further contextualization to the depression scores in our sample, Hayes and Hubley (2017) also assessed depression using the CESD-10 (Andresen et al., 1994) together with the same 5-items used to assess depression in the current study. Scores on the 5-item state depression scale were highly correlated with scores on the CESD-10 in this previous study,  $r(204) = 0.76$ ,  $p < 0.001$ . As such, while we cannot offer firm conclusions about the severity of negative affect observed in this study, the available evidence suggests that participants were experiencing abnormally high levels of anxiety and depression.

### CONCLUSION

The COVID-19 pandemic has been a shock to nearly everyone on the planet. The early stages may have been among the most stressful and uncertain. The threat of potential infection and death coupled with seemingly irreparable disruptions to nearly every aspect of everyday life represents a burden of momentous proportions. The current research suggests that fatalistically giving up may have helped to quell some of the fear and insecurity aroused by the pandemic. Feeling that one cannot possibly change the situation may offer some relief from a situation that demands constant vigilance and control. But fatalism is also strongly associated with depression, so fatalistically withdrawing

from efforts to cope with the pandemic is not without emotional costs (cf., Hayes et al., 2016).

Critically, fatalism toward COVID-19 was also found to promote giving up on public health regulations that function to protect oneself and others. Fatalism in the face of COVID-19 is thus self-destructive and a public health liability. Unfortunately, media messages—some of which came directly from prominent authority figures—only served to promote fatalism in the early stages of the pandemic. The cost of early failures to mitigate the spread of a deadly virus cannot be overstated.

When faced with future pandemics, the current research suggests that early interventions aimed at preventing (rather than promoting) fatalistic thinking might be among the most important means of promoting adherence to mitigation protocols and reducing depression. Recognizing that people may be drawn toward fatalism to reduce fear and insecurity might be equally important. Offering alternative means of coping with these negative affective states—with public policy and/or consistent optimistic media messaging—may be an effective means of preventing fatalism from taking hold.

## DATA AVAILABILITY STATEMENT

The dataset presented in this study can be found in an online repository: Open Science Framework, <https://osf.io/sx7g2/>.

## INTRODUCTION

Recently, the need for a mental health technology revolution during COVID-19 was noted (1). These authors suggested that interventions should be targeted toward vulnerable groups and adapted to their individual needs (1), and we have expanded this concept here. One vulnerable group that will benefit from such a technology revolution and targeted interventions comprises individuals with Autism Spectrum Disorder (ASD). We discuss how technology can be leveraged to address the specific challenges experienced by these individuals and their families during the pandemic.

## USING TECHNOLOGY FOR FAMILIES WITH ASD DURING THE PANDEMIC

One way technology can be used during the pandemic for families with ASD is through telehealth, which refers to providing various remote services electronically, such as patient care, education, and monitoring (2). Relatedly, telemental health is the utilization of information and communication technologies to remotely provide mental health care, evaluations, and therapy (3). Telemental health is viewed as a valuable tool during COVID-19 as it can effectively respond to the mental health needs of individuals in isolation or with restricted mobility while minimizing infection risk and, therefore, can be an option to provide care without interruptions and with adherence to social distancing (3).

## Remote Intervention Administration to Parents and Children

Attempts at using technology for remote service delivery to families with ASD predate the pandemic. One study focusing on parent coaching instead of a direct intervention with children with ASD showed that parents, service providers, and ASD specialists perceived remote technologies to be helpful by improving the skills of the parents; reducing cost, time, and travel; providing flexible, ongoing, and regular support; and allowing families to access support from their home. At the same time, this remote coaching often resulted in frustration due to technical difficulties, and it was agreed that remote technology should not replace face-to-face contact but only augment it (4). Therefore, overcoming such frustrations to harness the provided advantages will be important in refining remote parent coaching for families with ASD.

Another study exploring this possibility before the pandemic focused on web-based training and telemedicine to train parents to implement the Applied Behavior Analysis (ABA) strategies with their children. This program was beneficial in increasing parents' knowledge of the ABA strategies and their implementation (5). These findings are corroborated by a systematic review of a remote parent-mediated intervention training yielding a preliminary evidence of improved parental knowledge and social behavior and communication skills of children with ASD (6). In terms of the remote interventions for children with ASD, one hopeful finding shows that children with ASD who received remote support and those who received face-to-face support did not significantly differ in terms of the gains they made in terms of social communication as measured by initiations of joint attention and requesting (7). Such protocols can be exploited during COVID-19 to remotely provide interventions to children with ASD and to provide training to their parents to implement validated intervention strategies at home.

A web-based parent training tutorial to enhance interactions was found by parents to be user-friendly and easy to understand. They reported that the tutorial increased their knowledge about how to communicate with their child and that they felt comfortable to apply these techniques to their communication with their child (8). Another program for parents included live distance coaching sessions, in addition to online activities and interactive tutorials, on how to use the ABA procedures to teach new skills, generalize them to other settings, and reduce challenging behavior (5). This program resulted in gains in the parents' knowledge and ABA implementation skills that were independent of their educational background.

One instance of telemental health administration for families of individuals with ASD was recently started in Italy by a group of professionals *via* online observations and discussions with families they had been consulting with since before the lockdown (9). They coached parents on structuring the entire day for their children with ASD and their siblings, selecting contextually appropriate activities, and setting up a positive reinforcement system at home. The researchers observed that many parents were able to implement these effectively, bring order to their homes, and help their children be happy, calm, productive, and engaged (10).

Using remote intervention techniques for families with ASD to supplement face-to-face interventions would be ideal, as would using both online tutorials and live distance coaching sessions. Yet, when the available resources do not allow for these ideal conditions, using web-based tutorials to disseminate knowledge to parents of children with ASD can provide them with resources to more successfully handle the difficulties of pandemic conditions for their families.

## Remote Psychological Counseling

In addition to providing interventions and parent training remotely, technology may enable remote psychological counseling for families with ASD. Because of various limitations that prevent these families from receiving full-time psychological

services, it has been suggested that remote counseling may emerge as the only available alternative support for some families of children with ASD (9). For a successful online counseling for these families, it has been recommended that the family environment of the child should be taken into account, the consultation provider should be a professional, interventions should have measurable characteristics, and face-to-face interactions with the child with ASD should be possible (9). Though these recommendations may better apply to non-pandemic conditions, they can nonetheless be established during COVID-19 as well by using videoconferencing for the face-to-face interactions and ensuring the other conditions for the counseling process. It has been noted that, although, ideally, teletherapy should not replace in-person services, it does become necessary when no other comparable service option is available (11), which may be the case during the pandemic for many families with ASD.

## Social Connectedness

Another way technology can be used during the lockdown is for social connectedness. There is evidence from a sample of adults with ASD that the majority of that sample of 108 adults used social networking sites, and the most commonly given reason for this was for social connection. However, decreased loneliness was not specifically associated with social media use but was associated with offline friendship's quality and quantity (12). In line with this, during the pandemic conditions, the ability and prevalence of social media utilization by individuals with ASD should not be assumed to be enough to alleviate their feelings of loneliness. Therefore, other programs geared toward fostering virtual interactions could be implemented by autism communities and foundations to assist with forming such connections.

## Mobile Applications

Embracing the suggestion that digital mental health tools should be affordable, accessible, and appropriate for all individuals (1), we discuss how technological applications can be used to address two fundamental adversities faced by individuals with ASD during COVID-19: understanding and following the measures necessitated by COVID-19 and continuing special education during the implemented lockdown and social distancing measures.

Firstly, using technology to help individuals with ASD comprehend and follow the COVID-19-related measures is important, as our study showed that 75% of the parents of children with ASD reported that their children did not understand properly, or understood only to a medium degree, the COVID-19-related measures and necessities, such as staying home or social distancing (13). When asked if they were using a resource with their children that explained what COVID-19 is and what needs to be done, 80% said no, and 85% said that they would want such a resource for children with ASD and if it existed, they would use it (13). For this purpose, our Crises and Disasters Management Game (CDMG) (14) can be adapted following the guidelines for developing computer games for

**FIGURE 1** | From hand modelling to graphical user interface (GUI) design of a potential application or module for teaching Covid-19 measures to children with autism, adapted from (3).

children with ASD (15). CDMG is a simulation game for man-made crises (e.g., fires) and natural disasters (e.g., earthquakes). In this game, the players lose points for engaging in behaviors that can cause or exacerbate crises. By experiencing different scenarios, such as that of an indoor fire, players learn how to safely navigate through crises and disasters. Being a simulation game, CDMG is a safe and cost-effective choice that presents no danger or risk to players. Given these properties, CDMG can be adapted to help children with ASD keep safe during the COVID-19 pandemic. For instance, the new addition of a COVID-19 safety precautions scenario can teach children with ASD how to take personal protection precautions such as staying home and washing their hands. Children with ASD may, in turn, gain points and receive reinforcers as they do so, which are the commonly used behavior modification methods in special education.

Another scenario can simulate safety measures outside, where children can select to use masks, gloves, and other hygienic products, such as alcohol-based disinfectants, and gain points as they abide by these measures (see **Figure 1**). The rules for designing softwares for children with ASD (15) can easily be implemented in the CDMG game. For instance, since

children with ASD prefer reliable routines and predictable environments, the game interface can be kept as simple as possible with a low differentiation between global and local cohesion. Such accommodations can make the new scenarios added to this game to be ASD-friendly and present a safe and fun environment for them to practice the COVID-19-related measures, which will reinforce these behaviors with rewards and points and increase their likelihood of being applied in real life.

Secondly, special education for individuals with ASD is halted due to the lockdown and social distancing measures necessitated by the pandemic. Although mainstream education can continue *via* distance education for typically developing individuals, this is not the case for the one-on-one, special education for individuals with ASD. Our findings revealed that 92% of the children with ASD are not continuing their special education during COVID-19 (13). Therefore, in addition to the telemental health opportunities it offers, technology enables individuals with ASD to continue their special education from home with applications created specifically for them using the ABA principles that are used in their special education centers.

In 2014, we designed an application that teaches children with ASD a skill that is part of the special education curriculum *via* tablets (16). The ABA-based hinting and scoring system we created was used as the basis for the autism education application Otsimo, which was selected as the best autism education application of 2019 by the University of Edinburgh. Otsimo now has a total of 339,989 users from 180 countries; of which, 208,176 use it for special education and the rest for speech therapy. Though this application initially targeted the ASD population, it is now being used by other developmental disability groups as well, serving as a technological platform to remotely address the educational and speech therapy needs of those with speech delay, developmental delay, ADHD, apraxia, premature birth, cerebral palsy, and Down syndrome. More recently, we created an ABA-based language teaching application for individuals with ASD using dynamic difficulty adjustment principles, which increased the engagement of children by adapting the content to their skill levels and the time spent with educational materials at home for these families<sup>1</sup>. Therefore, technology can also be used to bring special education to the homes of families with ASD (17).

## CONCLUSION

We believe that the recently recommended mental health technology revolution (1) should include components specifically designed for individuals with ASD who experience behavioral and social challenges even without the strains of the COVID-19 period. Therefore, we recommend that the authors' suggestion

of promptly investing in high-quality and accessible online and mobile mental health technologies during this pandemic (1) should include applications for disaster protocol training and distance education specifically geared toward individuals with ASD to help make this taxing period more manageable for the affected individuals and their families. Additionally, previous evidence and reports about using technology for remote parent training, for interventions for children with ASD, and for counseling for families with individuals with ASD can guide authorities to adapt such services to the pandemic conditions. We suggest that this could be done by formulating effective telemental health options that overcome the challenges reported for these remote endeavors in the past, and take into account the difficulties disclosed by the parents of children with ASD and sources for which they communicate a need in order to better cope with the changes associated with lockdowns and other measures necessitated by the pandemic.

Studies investigating the psychosomatic effects of social isolation in animals have shown that one of the physiologic system that gets disrupted by this environment-affective change is the Endocannabinoid System. As the levels of endocannabinoids change in limbic areas and prefrontal cortex during stressful times, so is the subject more prone to fearful and negative thoughts and aggressive behavior. The interplay of social isolation on the hypothalamic-pituitary-adrenal axis and cannabinoid tone triggers a vicious cycle which further impairs the natural body's homeostatic neuroendocrine levels and provokes a series of risk factors for developing health complications. In this paper, we explore the psychosomatic impact of prolonged quarantine in healthy individuals, and propose management and coping strategies that may improve endocannabinoid tone, such as integration of probiotics, cannabidiol, meditation, and physical exercise interventions with the aim of supporting interpersonal, individual, and professional adherence with COVID-19 emergency public measures whilst minimizing their psycho-physical impact.

**Keywords:** cannabinoid, stress, HPA, resilience, lockdown, CBD, COVID-19, meditation

## INTRODUCTION

### The Psycho-Social Impact of Social Restriction

The current emergency public measures applied to prevent COVID-19 spread have restricted fully or partially people in lockdown cities, with half of humanity directly affected by these changes. (1) Billions of lives have been significantly altered, and a global, multilevel, and demanding stress-coping-adjustment process is ongoing.

Historically, social isolation has been used extensively as a research model for psychosis, suicide, anxiety and depression: all conditions in which the endocannabinoid system is implicated through different pathways, including the modulation of hypothalamic-pituitary-adrenal axis (HPA) function (2–4). Social isolation has been directly linked to increased incidence of suicide (5) and is considered a crucial factor contributing to suicide in humans (6–8). It induces

abnormal forms of behavior including an increase in anxiety- and depressive-like activities—such as increase in immobility time, decrease in grooming activity (3), exacerbation of aggressive behavior, and impaired fear extinction (9–11)—effects which directly affect both glucocorticoid and endocannabinoid responses (12).

Although lockdowns are used for social distancing and not to “socially isolate” people, the psychopathologist Baek has introduced the concept of “socially withdrawn” to define those individuals who are isolated because of their extreme involvement in the cyber space and the lack of relationship in real life (13). One may reckon that “real life” and “cyber life” are separated by a fine line when all interpersonal and professional relationships are experienced remotely, as it is currently happening to billions of people worldwide.

Prolonged social distancing has inevitably decreased the physical expressions of affection and social bonding and altered the neuroendocrine balance of neuropeptides (e.g., oxytocin), endocannabinoids (e.g., anandamide), and corticosteroids (e.g., cortisol), key physiologic systems mutually involved not only in maintaining emotional wellbeing but also in the regulation of the immune response, making the implementation of homeostatic strategies targeting those neural pathways even more pivotal during a viral global pandemic (14).

## Lockdown: Endocannabinoid and HPA Tone Disruption

Although the endocannabinoid (eCB) system is expressed ubiquitously in the brain, the highest CB1 receptor density is distributed in key areas for the regulation of stress and emotions: prefrontal cortex (PFC), hippocampus, and amygdala (15).

Previous studies have shown that antagonism or genetic removal of CB1 induces anxiety (16, 17); on the other hand, stress, fear, and negative emotions—as many people are prone to experience since COVID-19 diffusion—may alter the expression of CB1R in the amygdala, nucleus accumbens (reward system), and PFC (18–20). As the PFC is linked to the negative modulation of aggression in animals (21, 22), social isolation may induce a PFC-specific neuronal loss, which is associated with increased levels of aggressive behavior (23).

Social isolation also impairs the hypothalamic eCB system, a brain area also involved in the onset and manifestation of aggressive and fear-related behavior in mammals (24). Studies have demonstrated that the changes in the eCB system may contribute to the display of the stress response, yielding HPA axis stimulation and increased anxiety behavior (25). Indeed, rats that are housed as isolates show an alteration of the basal HPA axis activity and impairments in glucocorticoid-mediated negative feedback (26). These neuroendocrine unbalances are paralleled in human social isolation, with studies showing that cortisol levels are higher in chronically isolated individuals (27–29).

## PSYCHOPATHOLOGY OF eCB UNBALANCE

The endocannabinoids anandamide (AEA) and 2-arachidonoylglycerol (2-AG) are partial and full agonists at CB1 and CB2 receptors, respectively (30); increasing their levels *via* deletion or pharmacological inhibition of their metabolic enzyme fatty acid amide hydrolase (FAAH) was shown to reduce anxiety-like behavior (31, 32). An innate decreased anxiety-like conduct and better stress-coping behavior is associated, both in animals and in humans, with a common polymorphism in the FAAH gene and enhanced fronto-amygdala connectivity (33). Conversely, eCB levels are altered following several stressors. AEA is usually decreased, whereas 2-AG is most often increased under stressful conditions (25, 32, 34, 35). Chronic stress engenders a reduction of AEA concentration in the amygdala–hippocampal–cortico-striatal circuit, a feature commonly found in depression and posttraumatic stress disorder (PTSD) (2, 36). In these conditions, low AEA levels are associated with low cortisol levels and an upregulation of CB1 in the brain, effects which seem to be more pronounced in females than in males (37, 38). Gender differences on eCBs support the knowledge that women have a higher risk for anxiety, depression, and PTSD than men (39, 40). In addition, as reports have been showing consistently, during global health crises like COVID-19, women have been reporting higher rates of anxiety and depression than men, which relate with external stressors prevalently targeting women (increase of workload in the healthcare sector, increase of domestic burden, impoverishment, and increase in domestic violence) (41–45).

In short, endogenous cannabinoid signaling is essential for stress adaptation, while chronic stress (e.g., repeated restraint) reduces AEA levels throughout the corticolimbic stress circuit (31, 32).

These data were confirmed by studies examining the effects of social isolation on genes linked with eCB signaling, showing that this stressful condition alters several brain regions implicated in the pathophysiology of schizophrenia and PTSD, both in animals and in humans. CB1 is involved in stress regulation and result altered in several psychiatric disorders—such as anxiety, depression, bipolar disorder, PTSD, schizophrenia, attention deficit hyperactivity disorder, and eating disorders (46, 47). While prefrontal CB2 decreases after repeated stress both in males and in females, social isolation may induce upregulation of CB1R mRNA transcripts in cortical regions and downregulation in the amygdala in a gender-specific pattern due to the interaction between eCBs and sex steroids (48, 49). Females (both adolescent and adults) show higher baseline of CB1 and CB2 mRNA expression levels than males do, which is consistent among animal and human studies, as well as heightened eCB tone disruption to both acute and chronic models of stress (50–52).

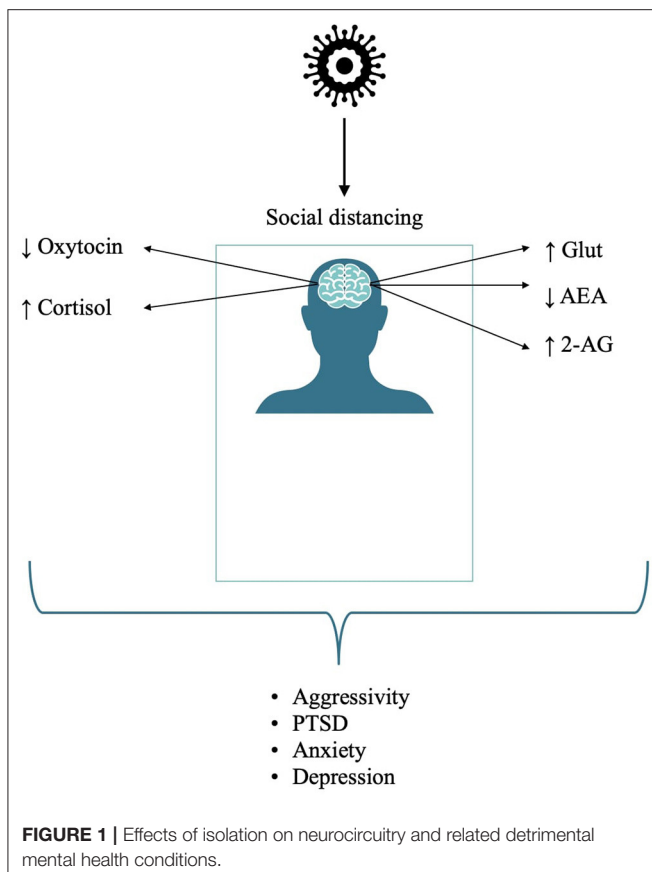

Changes also occur in the regulation of eCB mRNA expression in amygdaloid regions, especially AEA, a fact associated with increased anxiety in rats reared in isolation (48, 53, 54). The COVID-19 pandemic has led to a worldwide stressful time with a dual impact: lockdown and fear of disease and death; thus, resilience and appropriate coping strategies become factors

of crucial importance to reduce its impact and prevent stress switching into chronic ailments. Neurobiological observations have identified increased firing at the basolateral amygdala (BLA) and prelimbic PFC (plPFC) circuit as one of the key events in the “switch” from distress to psychiatric disorders (55). Recent findings have shown that the neuronal hyper-firing occurring in the BLA-plPFC circuit is due to the stress-induced downregulation of the eCB tone in this region; this induces an increased glutamate release, which, in turn, switches stress exposure into anxious behavior and burn-down (56).

Taken together, these data suggest the need for strategies aimed at not only decreasing stress *per se* but also helping to restore the eCB homeostasis, which is tightly bound to individual reactions in stressful environments and events (56). See **Figure 1** for a summary on the effects of isolation on neurocircuitry and related mental health conditions.

## Nutraceutical Interventions

It was shown that the microbiota is tightly connected to emotional behaviors and stress-induced changes (57) and that a perturbation in the microbiota causes functional changes in the eCB tone and behavioral alterations that correlate with depressive states. Therefore, the administration of probiotics may potentially help improve both depressive-like behaviors as well as stimulate the eCB tone, increasing AEA levels (58).

Another approved dietary supplement, N-palmitoylethanolamide (PEA), a fatty acid amide belonging to the eCB system (found increased under stressful conditions), has also shown promising potential antidepressant properties alone or in combination with other classes of antidepressants (59). Preclinical studies have shown its efficacy in depression and depression associated with neuropathic pain and traumatic brain injury models, which could serve the post-COVID symptoms (60). In a translational perspective, a randomized, double-blind study in depressed patients indicated a fast-antidepressant action of PEA when associated with citalopram (59). Several foods may also help modify gut microbial metabolism and glucocorticoid productions (61). One study demonstrated that a daily consumption of 40 g of dark chocolate during a 2-week period was sufficient to reduce the stress hormone cortisol and stress-related impairments (62). Moreover, it was shown that *Theobroma cacao* contains N-acylethanolamines (N-linoleoylethanolamide and N-oleoylethanolamide) which act as FAAH inhibitors (63–65).

Other food compounds that boost the eCB tone are found in black pepper, both *via* CB2 direct agonism by one of its sesquiterpenoids, b-caryophyllene, and *via* AEA uptake inhibition by the pepper’s alkaloid guineensine (66, 67). B-Caryophyllene is commonly found in spices and hence called “dietary cannabinoid” and was recently shown to also elicit antidepressant-like activity in isolated and stressed animals *via* CB2 interaction (68, 69).

Remaining in the “dark colored” food palette, *Tuber melanosporum* (black truffles) contain biosynthetic enzymes for AEA; the eCB concentration increases up to levels that have been found sufficient to activate CB1 and CB2 as the truffles’ pigmentation augments (70).

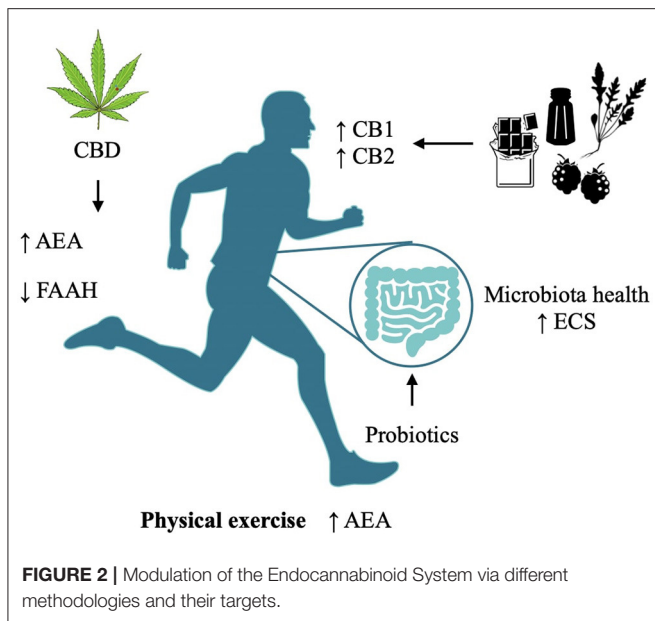

Fruit and vegetable containing the flavonoid kaempferol are also recommended to balance the eCB tone as it is possible that a high dietary intake of this substance could boost serum AEA levels *via* FAAH inhibition (71). Kaempferol is commonly found in capers, *Kaempferia galanga*, saffron, arugula, blackberries, and many other edible plants (72).

Finally, although it is still debated in literature whether a dietary intake would be sufficient to produce CBR-mediated effects, curcumin, the main constituent of turmeric, was nonetheless found to decrease immobility in animal depression models (73, 74).

## Phytoceutic Interventions

During lockdown in Canada and a few US States, cannabis was declared an essential service, allowing dispensaries to continue their activity and deliver cannabis products to customers (75). The authors agree that there is a rationale for the use of cannabis during these times. Studies have shown that the depressive-like behaviors induced by social distancing are mitigated by CB receptor activation (3). Moreover, isolation induces a reduction in PFC dendritic dopamine D2 receptors which can be rescued by CB1 stimulation (76). Where cannabis was more available, an increase of its use during lockdown measures was reported, perhaps highlighting an intuitive understanding by consumers for the need to increase the eCB tone (77–81). The increased

cannabis use was self-administered, yet not associated with an increase in DSM-5-CCSM total, depression, anxiety, and sleep problem scores in these Countries (78). However, as we recommend strategies that may be applied to the population at large, we would encourage the use of compounds other than tetrahydrocannabinol (THC)-containing cannabis, hence devoid of intoxicating effects. As lockdown poses an increased risk for isolation-induced aggression, the use of cannabidiol (CBD), a cannabis compound with anxiolytic, antidepressant, and antipsychotic properties, could prove useful (82). CBD has been tested in isolated animals, confirming its beneficial effects in attenuating aggressive behavior through a mechanism associated with an increase in AEA levels (via FAAH inhibition) and activation of 5-HT<sub>1A</sub> and CB<sub>1</sub> receptors (83).

Another non-psychotropic plant, *Echinacea*, can interact with cannabinoid receptors, both directly *via* alkamide interaction at CB<sub>2</sub> and indirectly *via* AEA reuptake inhibition (84, 85). *Echinacea* preparations, often used as a home remedy for colds, have been showing to induce an anxiolytic effect in animal models (86).

## Physical Activity

Physical activity has shown to play an important role in maintaining mental health, decreasing anxiety and alleviating depressive symptoms, and has been hence already recommended as a regular practice during the pandemic to prevent metabolic and immunological dysfunctions (87–89). Interestingly, it also modulates the eCB system balance, a fact suggesting its relevance from both a neurobiological and psychosomatic perspective (90). Indeed, increased eCB concentrations were found following a simple jog, bike ride, hike, and other moderate intensity aerobic exercises, while the differences of FAAH hydrolytic activity in active and sedentary individuals result in different AEA plasma levels (91–94).

## Hypnosis and Meditation

Meditation and hypnosis, despite their seemingly different history and conceptualization, may be regarded as two faces of the same coin, sharing several historical, procedural, and neuropsychological aspects (95, 96) as well as their link to the placebo effect (97). Placebo effect involves both endogenous opioids and the eCB system (98). As a whole, the available data on neuropsychological aspects of hypnosis and meditation highlight the relevance of a holistic approach encompassing the inseparable mind–brain–body–environment unit. A wealth of data has shown how hypnosis and meditation may enhance metacognitive control and engender intentional changes of activation/deactivation of unconscious brain areas and circuits leading to outstanding results, one for all hypnotic analgesia (99–102). Both hypnosis and meditation may help develop awareness, mindfulness, and metacognition, restructuring the patient's problem, enhance one's control over mind and body, and manage functional and psychosomatic disorders (95, 103). Therefore, one must establish a bidirectional mind–brain relationship, where brain changes yield mind ones and vice versa. As a result, both pharmacological and nutraceutical interventions may improve brain functions and help decrease symptoms, while behavioral techniques directly modulate the same brain function through cognition, a top-down mind–brain rearrangement.

A broad range of neurological and psychiatric disorders as well as deficits in self-referential processing, such as depersonalization, seem to be related to an altered balance between the default mode network, the salience network, and the central executive network (104). Their complex interplay and connection with other circuits as a dynamic whole is able to update according to demands (105), while their alterations may engender psychiatric disorders. Likewise, traumatic experiences may lead to increased activity of amygdala paralleled by a decreased capacity of anterior cingulate cortex to inhibit it (106).

On a neuropsychological standpoint, both hypnosis and meditation strongly affect the default mode network, a circuit involved in self-referential processing, and the anterior cingulate cortex, which, as mentioned above, may play a central role in dissociative identity disorders and PTSD (107). In doing so, they can help modulate the interrelationship of the abovementioned networks, which are the neuropsychological components of several psychological and psychiatric disorders and favor resilience.

## CONCLUSIONS

When life adversities and distress are concerned, like those related to COVID-19, resilience plays a key role. Resilience is a complex construct endowed with profound philosophical implications extending to Eastern culture (103); initially coined in physics and engineering, later on it has extended to both biology and psychology. Resilience is the capacity to withstand adversities by keeping the homeostasis, by recovering the initial

balance following perturbation or achieve a new balance through allostasis.

At a physiological level, maintenance of homeostasis is the primary function of the eCB system. During stressful times, the eCB tone changes in limbic areas and prefrontal cortex, which makes subjects more prone to a fearful state, negative thoughts, and aggressive behavior.

On a psychological standpoint, resilience is the capacity to withstand or quickly recover from difficult conditions, such as those related to family and social relationships, financial stressors, and workplace and health problems; it is a dynamic process of both biological and psychological adaptation, including emotional and intellectual aspects and their management in the sociocultural and environmental interaction that allows a better adaptation and coping by cognitive improvement and self-transformation, features reflected in the brain through their interplay with neurotransmitter regulation. This is the rationale for presenting different lifestyle interventions and holistic approaches that integrate phytotherapy and nutraceutical agents together with behavioral techniques—like hypnosis and meditation—which are presented with the aim of spreading preventive awareness on maintaining a healthy eCB system, especially during stressful situations like COVID-19. See **Figure 2** for a summary of the interventions. A detailed analysis of each of the therapies is far beyond the limit of this article; instead, we discuss first the knowledge drawn from the neurocorrelates of psychological and psychiatric disorders, and then we outline a few essential aspects of their implication in relation to the

current state of emergency. We aim to support governments worldwide in using evidence-based suggestions and indications to manage the socioeconomic problems generated by poor mental health.

## DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/supplementary material, further inquiries can be directed to the corresponding author/s.

## AUTHOR CONTRIBUTIONS

VB conceived and designed the study, and wrote the first draft of the manuscript. VB and EF wrote sections of the manuscript. All authors contributed to manuscript revision, read, and approved the submitted version.

## FUNDING

This study was supported by Dipartimento Neuroscienze, UNIPD VB grant number was 1973.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the contribution of Andrea Cristofolletto for the image, courtesy of Cannabiscienza Srl.

The COVID-19 emergency has affected us all, but not equally. Families where parents have mental illness (PMI) are potentially at increased risk, but little is known about how they or their support services managed under lockdown/restrictions. We harnessed our existing partnerships with adult and child mental health services in the Republic of Ireland (RoI) and Northern Ireland (NI) to investigate the qualitative experiences of service users and families in coping during the first COVID-19 lockdown (March–May 2020), and how services were supporting them. Semi-structured phone/online interviews were conducted with 22 clinicians/managers (12 from RoI; 10 from NI) who provided information from their caseloads (~155 families with PMI). Sixteen family members (10 from RoI, 6 from NI) were also interviewed. Data were analysed using standard thematic analysis. Sixty percent of families reported improved mental health, primarily due to respite from daily stresses and the “normalisation” of mental distress in the general population. Approximately 30%, typically with more severe/enduring mental illness, reported additional challenges, and mental distress including: unmanageable child behaviours; fear of relapse/hospitalisation; financial difficulties; absence of child care; and a lack of routines. Service provision varied considerably across regions. The experiences within this case study highlight unique opportunities to address the multiple stresses of pre-emergency daily living. We also highlight how mental health services and governments might become more “pandemic ready” to more effectively support vulnerable families, including addressing service overload issues, optimising the use of digital technologies, and providing in-person contact and social supports where required.

## INTRODUCTION

On the 11th March 2020, the World Health Organisation declared the novel coronavirus (COVID-19) a pandemic, with immediate, global impact on our daily lives (1). As infections escalated during the first wave of the virus, the impact of lockdown/public health restrictions on mental health in the general population was increasingly recognised, as well as the need to support parents and children (2, 3). A UK population-based survey conducted in April 2020 highlighted greater concerns about the psychosocial effects of the emergency (e.g., stress, anxiety) than the risk of infection (4). Other similar surveys in the UK, US, and China found that 62% (5), 56% (6), and 54% (7) of

respondents reported moderate to severe levels of pandemic-related emotional distress during this time, including anxiety, stress, increased substance misuse, sleep difficulties and emotional regulation difficulties. Key triggers included: disrupted social networks/isolation; pressurised home environments (e.g., from overcrowding, home working, and lack of childcare); income loss/insecurity; and fear of infection.

Despite international calls to investigate the impact of COVID-19 on vulnerable groups (2), far less research has examined the experiences of those with pre-existing mental illness, socially disadvantaged families, or the services that support them. During the first, and subsequent lockdowns, there was increased alcohol consumption in 27% of family households (8, 9), and EU states (including Ireland and the UK) experienced a 60% increase in domestic violence-related calls (10). Furthermore, child protection referrals decreased by 35–50% during the first lockdown (March to June 2020), suggesting that cases were not being identified due to the closure/restrictions in usual referral sources (e.g., schools, General Practitioners and allied health professionals) (11, 12).

A UK study conducted during the first lockdown showed that levels of anxiety, depression, loneliness, and thoughts of self-harm were higher among people with pre-existing mental illness than in the general population (13). However, it is not known how many survey respondents were parents with dependent children. Internationally, a “hidden population” of one in four children have a parent with mental illness (PMI) and Northern Ireland (NI) currently has the highest levels of maternal mental illness within the UK (14), experienced by 30% of children aged 0–16 years. Despite substantial evidence indicating the intergenerational transmission of mental illness (15), the complex needs of these children and families typically go un-recognised and untreated (16).

Currently, most mental health services do not recognise the parenting status of service users due to individualised approaches to assessment and treatment, segregation of adult and child, and adolescent mental health services (AMHS/CAMHS) and professional competencies around child welfare concerns (17). Therefore, family-focused mental health initiatives, such as COPMI<sup>1</sup> in Australia and the UK Think Family Initiative (including NI) (18), were established to promote public/service awareness of the need to identify and support these “hidden” families (19, 20). However, other countries, including the RoI, lack basic policy guidance on how to identify and support families with PMI (21, 22).

In 2017, the Health Services Executive in the RoI funded the “PRIMERA”<sup>2</sup> research programme (2017–2021) to help implement and evaluate family-focused practise for families with PMI (randomised controlled trial (RCT) involving 92

families [152 parents, 249 children]) in 15 sites across the RoI and involving adult, child, and primary care mental health services (23, 24). Eighty percent of the PRIMERA parent sample attend AMHS for various mental health disorders; 20% receive antidepressant medication or primary care psychological support (24). This research provided the impetus for this paper.

Given the sudden and dramatic changes related to COVID-19, we were keen to ascertain how services and families with PMI in two different jurisdictions (the RoI and NI) were responding to stringent emergency-related restrictions. The objectives of this article were to explore: (1) the experiences of service users and families with PMI during the first COVID-19 lockdown; and (2) the views/experiences of mental health service providers who were supporting these families.

## METHOD

### Participants

We utilised (and sought permission from) our existing adult and child mental health service partners from the PRIMERA research and the Think Family initiative in NI (TFNI) to investigate clinician experiences on how services were supporting families with PMI during the first COVID-19 lockdown (March to end of May 2020), and to explore with a sample of such families how they were coping during this time.

In the RoI, service-provider participants included 12 clinicians/managers, linked to 8 PRIMERA sites, and working across AMHS, CAMHS, and primary care outpatient mental health services. They provided information on how families with PMI on their caseloads (~70 families) were coping during the first lockdown and on their own experiences of supporting these families (45 of the families were also participants in the PRIMERA RCT). Clinicians were predominantly from the disciplines of social work and social care ( $n = 7$ ), with reports also from three psychologists, one clinical nurse, and one family therapist. Family participants included 10 parents (6 PMI, 4 partners of PMI) and were purposively selected from the PRIMERA RCT sample ( $n = 92$ ). All families (including the 70 reported upon by clinicians and the 10 who provided direct report) had a similar profile to our larger RCT sample in terms of age and gender (88% female, aged 26–50 years), mental health disorder, site/location and (mainly socially deprived) socioeconomic status. Within the PRIMERA RCT sample, anxiety and/or depression are the most common mental health challenges (64%), followed by bipolar disorder (18%), emotional regulation disorder (10%), psychosis (6%), and Post Traumatic Stress Disorder (PTSD; 2%). At baseline, on average, families reported clinically significant emotional, interpersonal and family distress.

In NI, 10 Assistant Directors/psychiatrists, representing the views of acute adult mental health services across NI, provided feedback to the TFNI Coordinator (MD) on clinician and service user experiences ( $n = 85$ ) during the first lockdown (Donaghy, personal communication 27.05.2020). Data on the prevalence and severity of mental illness presentations are not yet routinely collected in acute adult mental health services

**Abbreviations:** AMHS, adult mental health services; CAMHS, child and adolescent mental health services; COPMI, children of parents with mental illness; NI, Northern Ireland; PMI, parental mental illness; PRIMERA, Promoting Research and Innovation in Mental hEalth seRvices for fAmilies and children; RoI, Republic of Ireland; TFNI, Think Family initiative in Northern Ireland.

<sup>1</sup>COPMI - Children of Parents with Mental Illness.

<sup>2</sup>PRIMERA - Promoting Research and Innovation in Mental hEalth seRvices for fAmilies and children.

in NI (25). Assistant Directors/psychiatrists estimated that the most common diagnoses are anxiety and depression, substance misuse disorders, bipolar disorder, PTSD and psychoses, which is consistent with research on prevalence of psychopathology in NI (26). We do not have accurate age or gender data for this sample but it estimated that service users with PMI are mainly female and aged 25–55 years old. Family participants in NI ( $n = 6$ ) were service users from one health care Trust in NI, female ( $n = 5$ ), aged 30–50 years old. Their diagnoses included anxiety and depression ( $n = 4$ ), bipolar disorder ( $n = 1$ ) and emotional regulation disorder ( $n = 1$ ). Their experiences were seen as typical of service-user experiences in NI more generally (Donaghy, personal communication 27.05.2020).

## Data Collection and Analysis

Semi-structured one-to-one phone interviews—lasting 15–30 min—were conducted with families ( $n = 16$ ) in the RoI and NI to explore their perceptions of how the COVID-19 emergency had impacted parent and family mental health and well-being. Likewise, service providers ( $n = 22$ ) in the RoI and NI provided feedback (via phone, email, and online platforms) on how ~155 families with PMI on their caseloads, were coping during the lockdown, as well as on their own experience of supporting these families. Detailed notes were taken from interviewees and due to time constraints, were subjected to selected verbatim transcription. Data were analysed using Braun and Clarke's thematic analysis to identify key themes across both jurisdictions, involving the process of familiarisation, coding, and generating, reviewing and naming themes (27). This process was framed and contextualised using The Family Model (28) (Figure 1), which highlights the interconnections among parent, child and family mental health, service responses, cultural influences, and protective and stressor factors within a transgenerational approach to mental health recovery.

The study was approved by Maynooth University Social Research Ethics Committee.

## RESULTS

Sample quotes for identified themes can be seen in the Supplementary Table 1.

### Improved Family Mental Health or No Change During Lockdown

Unexpectedly, both clinicians and families indicated that most families (~60%) reported substantially improved mental health and family relationships during this first lockdown, despite having a mental health diagnosis.

#### Respite From Stresses of Daily Life and Time to Connect With Family

A key factor was the respite from the stresses of daily life. The slower pace of life, with less pressure to be up and out early in the morning for work, school, and childcare, as well as minimal service appointments and extracurricular activities,

meant that about 60% of parents and children felt more rested and relaxed during the lockdown, and according to clinician and family reports, experienced less stress, anxiety and depression. Several parents ( $n = 7$ ) indicated that they now had time to “*just be themselves.*” Other parents ( $n = 5$ ) recounted benefitting from more emotional and childcare support from partners due to home-based remote working. Ten parents also reported that they had more time to connect with their children (e.g., through cooking, walking, and gardening) and that this, combined with less school and exam pressures, had led, for the first time, to more open and honest communication from their children:

*“He has opened up so much about how he feels about us separating and that is definitely due to the time we’re spending together now.”*

*“I didn’t realise how much stress commuting was doing to us until it stopped.”*

Both clinicians ( $n = 13$ ) and parents ( $n = 6$ ) indicated that family conflicts were more easily resolved, and had led to subsequent feelings of parental empowerment. A number of clinicians noted ( $n = 9$ ) that positive experiences of lockdown were more common in two-parent families and with less severe PMI, although several service users with psychosis and bipolar disorder also reported improved mental health.

*“Taking away the daily pressures of school, exams and work means that families are able to connect better with each other. There are less triggers for conflict, and when there is conflict, they seem more able to reach a positive resolution. For some parents they have become more confident in themselves, more empowered. This seems to be good for everyone’s mental health.”* (Clinician, RoI).

### A Chance to Feel Normal

Confinement in lockdown and fears of infection meant that anxiety and other mental health concerns became normalised and, consequently, many parents ( $n = 10$ ) reported that they felt less alone and more “*normal*” in expressing anxiety “*as the whole world is in crisis.*” Several clinicians ( $n = 8$ ) indicated that many parents were now feeling less stigmatised and were more openly discussing their mental health issues. This, in turn, was seen as beneficial for their own coping and parent-child relationships. Several parents ( $n = 7$ ) also reported that they enjoyed the respite from attending multiple service appointments and felt less monitored and judged as a result.

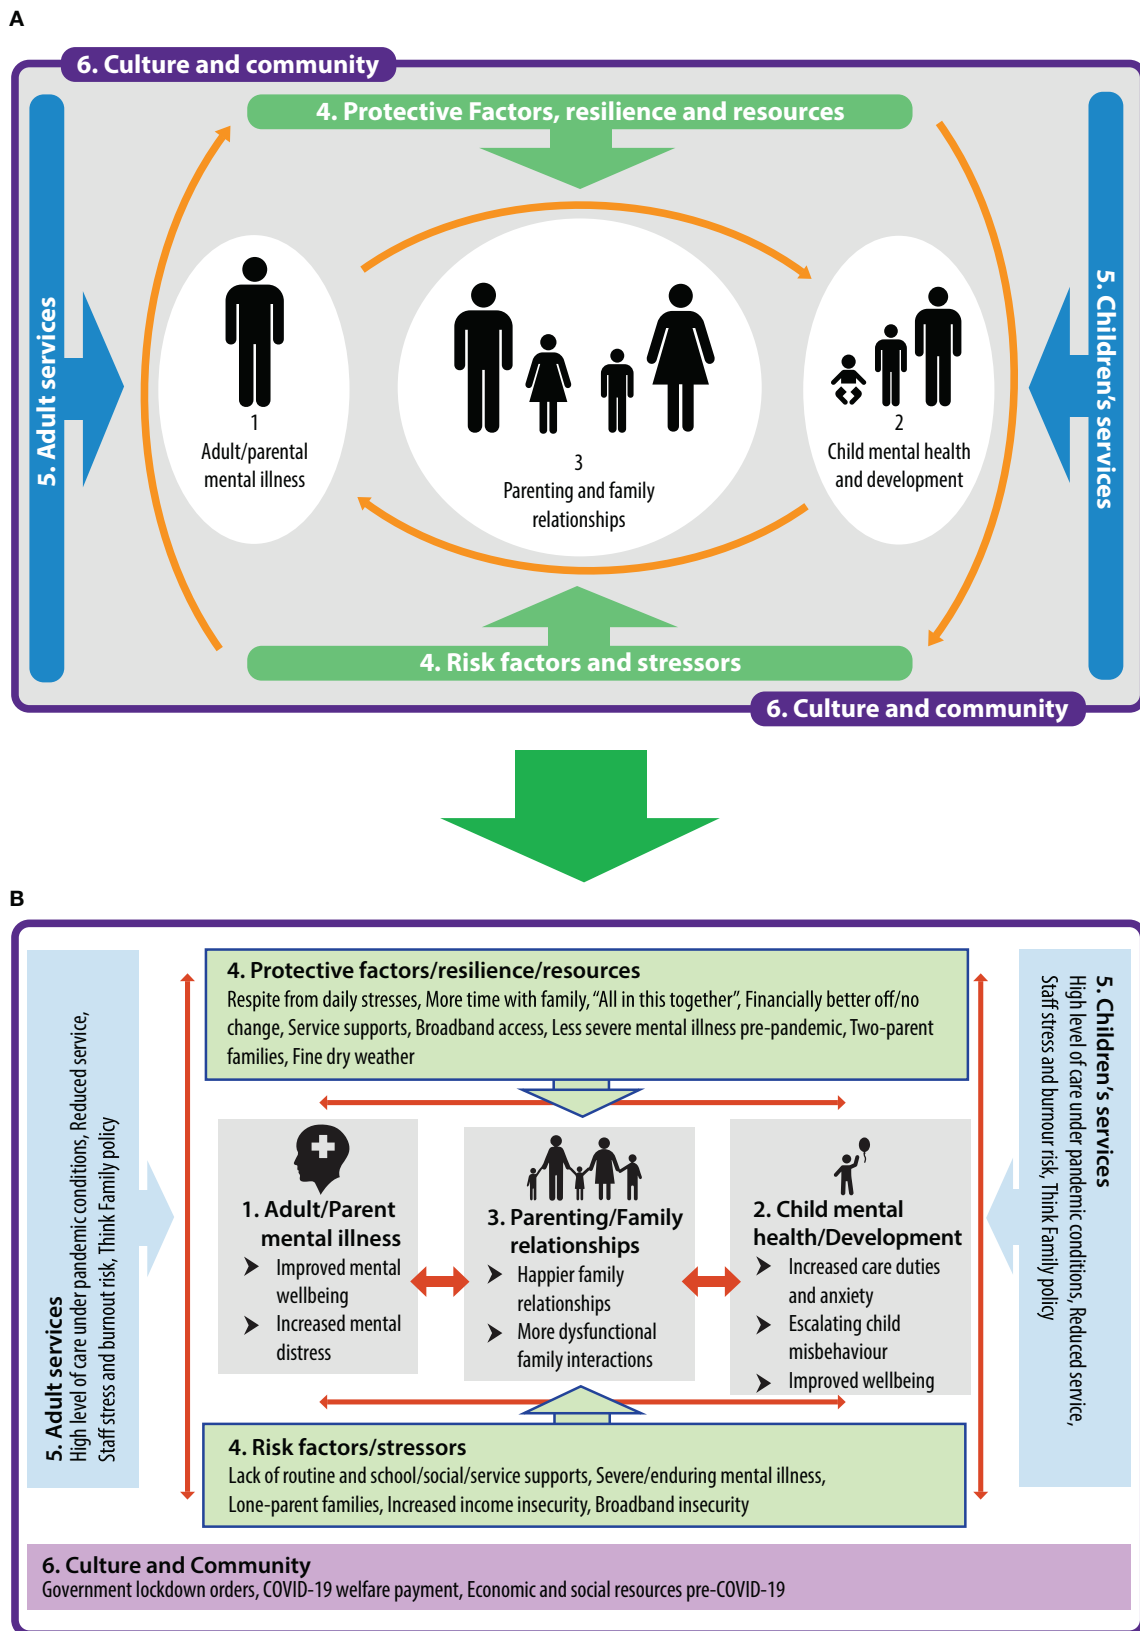

*“I’m surprised by how well I’m doing and even better than some people I know who don’t attend [mental health] services. I can just be myself, take time to look after myself... I feel less judged. The phone calls with my addiction counsellor are helping.”* (Parent).

*“The recognition that the crisis is having a psychological impact on the general population has given some parents permission to discuss their own mental health needs more openly, with Covid as the protagonist.”* (Clinician, RoI).

### No Change

A small number of parents ( $n = 2$ ) indicated that lockdown had not affected their mental health. Current family routines were largely similar to pre-emergency conditions in terms of one

**FIGURE 1 | (A)** The family model (16). **(B)** Qualitative themes contextualised within framework of the family model.

parent going to work whilst the service-user parent stayed at home with the children. However, the experience of lockdown may change over time. For instance, three parents reported that the initial stages were more difficult, but were coping better now. Conversely, others ( $n = 3$ ) were finding the restrictions increasingly challenging over time.

## Families Struggling During Lockdown Increased Family Distress Due to Worsening Parental Mental Illness

Clinician and family reports indicated that ~30% of families were experiencing substantial additional challenges due to lockdown restrictions, notably in cases involving more severe/enduring PMI. Mental distress was exacerbated in instances where a parent was at risk of relapse and hospitalisation. For example, a clinician reported that within one lone-parent family, extended family members would usually step in to provide childcare, but instead, the children were undertaking inappropriate levels of care/work to help prevent their mother's relapse. The mother expressed concerns about where her children could stay if she were hospitalised as well as the potentially increased risk of infection from hospital admission.

*"Families with one parent are finding this period very difficult especially if they feel they're relapsing. They have the added worry of who is going to look after the children."* (Clinician, NI).

More than half of clinicians ( $n = 12$ ) reported that lockdown increased anxiety and irritability for some parents, which they projected onto their children or partners. Correspondingly, two partners of service-user parents reported struggling with the increased tension and hostility in the home, lack of social outlets and reduced mental health service supports. A number of clinicians ( $n = 6$ ) and families ( $n = 4$ ) indicated increased alcohol use as a coping measure. Five clinicians observed that parents who have emotional regulation difficulties were particularly struggling. These parents missed their usual routines and having time away from their children, thereby leading to more strained relationships with their children and partners. In both the RoI and NI, clinicians ( $n = 8$ ) advised that there appeared to be a deterioration in client mental health as lockdown continued, with increased case complexity and a rise in referrals as time went on.

*"Where a parent has emotional dysregulation, they are struggling with not being able to get respite from children and home life."* (Clinician, RoI).

## Escalating Child Misbehaviour

Four parents reported that child externalising misbehaviour (e.g., disobedience, conflict) had escalated during lockdown which, in turn, contributed to parental mental distress. The lack of routine and socialising activities for children was very challenging for some parents in managing misbehaviour. Two parents indicated that the child welfare and protection service in the RoI (Tusla) was involved. One parent compared the home atmosphere to "a volcano" while another said: "We're literally breaking apart." Similarly, five clinicians described volatile home situations where Tusla involvement was required.

*"I didn't think it was going to be this hard. With the schools closed, I can't manage the [five] children. We're literally breaking apart...Tusla are involved."* (Parent).

## Protecting Others From Increased Stress

A number of parents ( $n = 3$ ) and clinicians ( $n = 9$ ) reported that the lack of childcare support, and expectations of working from home while home schooling, had exacerbated parental stress, but that parents were working with services to mitigate negative effects on their families. Five parents indicated they were experiencing financial difficulties and feared job losses. While parents were trying to protect their children from their financial (and other) worries, one clinician noted that children were also trying to manage their own mental health concerns so as not to overburden their parents. This is commonly seen in families with PMI, where communication of anxieties may be perceived as compounding family burden (29).

*"We are finding it very hard financially with me not allowed to work and schools closed. The kids are not doing too bad but we [parents] are struggling."* (Parent).

## Coercive Controlling Behaviour

There were also some examples of abusive relationships from clinician and family reports. For example, one parent with pre-existing depression indicated that her partner regularly flouted the physical distancing rules and left her alone while pregnant to look after their 7-month-old baby while he went drinking. She was in tele-contact with a psychologist to help her manage the coercive controlling dynamics of the relationship.

## Service Responses and Staff Well-Being

There was considerable variation across regions in NI and the RoI in terms of mental health service capacity to respond to families. Clinicians in some adult and primary care mental health services in both NI and the RoI were partially redeployed to frontline COVID-19 duties (e.g., covid testing), and several ( $n = 6$ ) reported high levels of stress and burnout risk due to a lack of childcare support, being redeployed and on call for frontline COVID-19 duties, and a belief that phone support alone was insufficient to meet the needs of many of their clients:

*"We are providing 'essential' services which is extremely important for public health safety due to COVID-19, but does feel inadequate from a mental health perspective."* (Clinician, RoI).

Four clinicians in the RoI questioned the strategy of redeploying short-staffed mental health teams to frontline swabbing duties. In other areas—both in NI and the RoI—crisis child protection services were reduced, and were not intervening in volatile situations where children were at risk of entering care.

*"Foster placements are breaking down with no crisis intervention, and young people are being transferred to residential care. Social workers are overwhelmed."* (Clinician, RoI).

Clinicians ( $n = 10$ ) in both jurisdictions also reported more positive experiences. One CAMHS area in the RoI, covering four counties, reported that phone support was well-received by families. Two AMHS areas (straddling three counties) provided high levels of tele-psychiatry support to families due to fewer new referrals than usual. Phone support reportedly

worked best in a context of pre-existing relationships with families, although most clinicians ( $n = 14$ ) believed that, in the longer term, face-to-face support would be required and that risk assessments were more difficult to conduct remotely. Commendably, within the two AMHS areas noted above, clinicians continued to undertake home visits and outpatient clinics for more vulnerable patients during the first lockdown, using COVID-19 guidelines. In addition, clinicians in these areas liaised with community organisations to help with service users' food and medication needs. While AMHS and CAMHS in NI were reportedly utilising online technologies during the emergency (Department of Health, 2020), very few of the PRIMERA AMHS and CAMHS sites were using virtual supports by June 2020. However, considerable progress has been made since then: during subsequent lockdowns, online and video platforms for individual and group interventions were commonly provided as part of service delivery in most PRIMERA sites, along with in-person support when required.

*“Telephone support has been received well by most service users. We have been able to provide more intensive telephone support as the rate of new referrals to adult mental health services has more than halved since the Covid restrictions. We have also been able to arrange home visits and out-patient clinics where required, using Covid guidelines.”* (Clinician, RoI).

## DISCUSSION

This paper provides an important snapshot in time of families with PMI during the first lockdown (March–May 2020) in two neighbouring jurisdictions. The observation that most families experienced improvements, or no change in their mental health, was unexpected, especially in view of the generally negative effect of COVID-19 on adult mental health in the general population (5).

For most (including some with severe/enduring mental illness), the lockdown provided a welcome respite from the stressors of “normal” daily life including school runs, service appointments, extracurricular activities and long commutes to work, all of which led to parents feeling more rested/relaxed, with considerable benefits for the entire family. Likewise, the results of a small study in one CAMHS area in the RoI, indicated that clients reported improved mental health during the first lockdown (30). Other research has also found that confinement benefitted those with schizophrenia and eating disorders (31–33), although others have reported adverse effects (34). Within the context of the current study, most of our feedback concerned families of lower socioeconomic status, and consequently, some furloughed workers (especially those in the RoI) were possibly benefitting from the COVID-19 unemployment payment; in addition, families more dependent on welfare benefits may be less affected by the immediate economic implications of the emergency (e.g., potential job loss). Further contextual factors, such as the unusually fine weather in Ireland and the UK during the first lockdown, also contributed to a “semi-holiday” experience for some families. Several families also reported feeling more “normal” due to a perception that mental distress was being experienced more widely in the population.

Disaster research suggests that crises may prompt responses of psychological resilience (35), and certainly a spirit of “battening down” to conquer the virus was evident among our family participants. However, it is less clear as to whether or not resilience efforts can be sustained indefinitely across a series of lockdowns. It is likely that many families in our study experienced a temporary “cocooning” effect from the “normal” hassles of daily life in the first lockdown and were not yet experiencing the probable longer-term negative economic and educational implications of the emergency. Life may become more stressful for families as countries emerge from lockdown and daily responsibilities return. Many commentators anticipate severe unemployment, especially with regard to low-income jobs less amenable to remote working (e.g., tourism, retail), and increased risk of mental illness and suicide, with services unable to meet expected demand (5, 36). More recent research supports this view, indicating a decline in referrals to mental health services during the first lockdown, but increased numbers and case complexity several months later (37, 38). In addition, the results of a survey of adult mental health service users in the RoI undertaken from May to August 2020, showed increased anxiety and isolation, and less engagement with services (39). Notably, the sample in the current study differed in that they were engaged with family-support services during lockdown due to their involvement in the PRIMERA research in the RoI and being part of the “Think Family” initiative in NI.

While the health, economic, and psychosocial impact of the COVID-19 emergency constitutes a major crisis, the positive experiences of many families during lockdown (all with pre-existing mental health challenges) nevertheless provide a unique opportunity to rethink how we can better structure our “normal” lives to minimise the stresses of early starts, long commutes, and work/family imbalances. Many sectors/governments (e.g., New Zealand) are considering the feasibility and benefits of remote digital working, 4-day weeks, and staggered commuting to reduce the risk of contracting and spreading COVID-19 (40, 41). Microsoft Japan have asked companies to join them in repeating their 2019 4-day-week experiment where they reported a 40% increase in productivity, with fewer sick days, happier, more motivated staff and a 23% reduction in electricity usage (42). Such measures could help mitigate COVID-19 infection, whilst also creating better work/family balance.

We were struck by the observation that service overload may contribute, at least in part, to family distress. Several families reported a sense of relief due to less surveillance (and implicit judgement) from services (although all were receiving some level of phone (and other) support by family-focused clinicians during the lockdown). Indeed, an ongoing NI case-file audit has found an average of 9.2 services (ranging from 1 to 23) working with these families (43). This suggests a need for services to avoid duplication and to consider more carefully the optimal number of appointments for families in a given week/month. However, while families enjoyed a temporary respite from attending services, a UK Department of Health (2019) report indicated that child health/development is likely to be significantly impaired without such supports in the longer term (44). In the RoI—and as confinement continued—service users reported increased

**TABLE 1** | Recommendations for mental health services in current pandemic and future non-pandemic contexts.

- Enable mental health services to become “pandemic ready”: that is, continue service provision during lockdowns and as we slowly emerge from them, use a blend of phone, online and in-person formats (using pandemic guidelines where appropriate)
- Develop/adapt/scale-up online interventions (e.g., psycho-educational videos) for use in both a pandemic and non-pandemic service context
- Incorporate more peer-based and community/voluntary sector provision of supports to provide for the medication needs of service users
- Minimise the redeployment of short-staffed mental health professionals to frontline pandemic duties. Instead, recruit dedicated testing/swabbing teams, as happened in Ireland 6 months into the COVID-19 pandemic
- Recognise the drawbacks of service overload and duplication
- Implement a “think family” approach to mental health service provision

anxiety and isolation due to less face-to-face engagement with mental health services (39).

Notwithstanding the mental health benefits of lockdown for many families in the current study, a substantial proportion of families, typically with more severe/enduring mental illness or emotional regulation difficulties, experienced additional challenges and mental distress due to confinement/isolation, lack of routines, anxiety, substance misuse, and child externalising issues. This is similar to reports highlighting an increased risk of additional mental distress and financial difficulties for the more socially disadvantaged, as well as increased alcohol misuse and domestic violence during lockdown (5, 10). Furthermore, we found substantial variation in the support provided to families across service areas, including management decisions on allowing safe in-person contact and redeploying clinicians to frontline COVID-19 duties, which had implications both for family mental health and staff well-being (45). As countries around the world begin vaccination programmes on an unprecedented scale, it is nevertheless likely that future pandemics will occur (46) and, in this context, lessons can be learned from those service areas that were able to more effectively support vulnerable families during the COVID-19 pandemic.

We also note that it took far longer for mental health services to implement remote digital technologies during the first lockdown when compared to the education and business sectors (this happened, in part, due to the redeployment of mental health clinicians to frontline COVID-19 duties). While there was commendable outreach by phone, the opportunities provided by digital technologies were not exploited in either NI or the RoI at the time. Encouragingly, considerable progress has been made in mental health remote provision during subsequent lockdowns, and research indicates that online mental health supports can be effective, particularly when blended with face-to-face contact, although not all clients may be able to access these due to unreliable broadband connectivity or a lack of confidence in using virtual platforms (47). A range of high quality online resources exist that could be more widely disseminated/promoted to clinicians and families with PMI, including COPMI and the Emerging

Minds websites<sup>3</sup>, although more evidence on their effectiveness is required. Recommendations for optimal online delivery include: addressing issues of client engagement, identifying core components of evidence-based interventions when adapting to virtual delivery, and monitoring outcomes and effectiveness (47).

This study was limited by time/resource constraints which meant that we were unable to directly interview more family members, conduct full verbatim transcription, and administer a mental health questionnaire to enable comparison with population mental health during the first lockdown. Nevertheless, this study has important implications for policy and practise in eliciting important insights into how a key underserved population—families with parental mental illness—coped during COVID-19 restrictions, as well as highlighting the experiences of service providers in supporting these families. The findings also provide some useful pointers as to how services and governments might more effectively support vulnerable families in both the context of the current pandemic but also as we emerge from it, and into the future (see **Table 1**). Lastly, the experiences outlined here suggest that we have a unique opportunity to re-imagine how we structure our daily work and family lives to improve work-life balance in a post-pandemic world.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Maynooth University Social Research Ethics Committee. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

SMcGi conceived of the original idea (and is also Principal Investigator of the PRIMERA research programme). MF and SMcGi led in drafting the manuscript. CM, AG, GD, MK, and MD contributed to manuscript revision and important intellectual content. CM led in collating, reviewing and synthesising the literature. MK, MD, MF, and CM co-ordinated service responses. SMcGa and MD liaised with service users.

## FUNDING

The PRIMERA research programme was funded by the Health Service Executive (Mental Health Division). In February 2021, additional funding was secured from Maynooth University's Higher Education Authority Covid-19 Costed Extension Fund.

<sup>3</sup><https://emergingminds.com.au/>

## ACKNOWLEDGEMENTS

We would like to thank the clinicians and families involved in the PRIMERA research and from TFNI who contributed their feedback on their experiences during the COVID-19 lockdown.

This contribution places itself within the emergency context of the COVID-19 spread. Until medical research identifies a cure acting at an organic level, it is necessary to manage what the emergency generates among the members of the Community in interactive terms in a scientific and methodologically well-founded way. This is in order to promote, among the members of the Community, the pursuit of the common aim of reducing the spread of infection, with a view to community health as a whole. In addition, being at the level of interactions enables us to move towards a change of these interactions in response to the COVID-19 emergency, in order to manage what will happen in the future, in terms of changes in the interactive arrangements after the emergency itself. This becomes possible by shifting away from the use of deterministic-causal references to the use of the uncertainty of interaction as an epistemological foundation principle. Managing the interactive (and non-organic) fallout of the emergency in the Community is made possible by the formalisation of the interactive modalities (the Discursive Repertoires) offered by Dialogical Science. To place oneself within this scientific panorama enables interaction measurements: so, the interaction measurement indexes offers a range of generative possibilities of realities built by the speeches of the Community members. Moreover, the Social Cohesion measurement index, in the area of Dialogical Science, makes available to public policies the shared measure of how and by how much the Community is moving towards the common purpose of reducing the contagion spread, rather than moving towards other personal and not shared goals (for instance, having a walk in spite of the lockdown). In this index, the interaction between the Discursive Repertoires and the “cohesion weight” associated with them offers a Cohesion output: the data allow to manage operationally what happens in the Community in a shared way and in anticipation, without leaving the interactions between its members to chance. In this way, they can be directed towards the common purpose through appropriate interventions relevant to the interactive set-up described in the data. The Cohesion measure makes it possible to operate effectively and efficiently, thanks to the possibility of monitoring the progress of the interventions implemented and evaluating

their effectiveness. In addition, the use of predictive Machine Learning models, applied to interactive cohesion data, allows for immediate and efficient availability of the measure itself, optimising time and resources.

## INTRODUCTION

The span between the end of 2019 and the beginning of 2020 saw the global diffusion of the infection caused by the new SARS-CoV-2 virus (Coronaviridae Study Group of the International Committee on Taxonomy of Viruses, 2020). It is characterised by its high diffusion, speed, and easy mutation. This last aspect makes it difficult to know the mutation pattern of the virus' RNA in order to identify an effective therapy system. It is not possible to explain how the virus changes (Giovannetti et al., 2020), what its incubation span is, the duration of the infectious period (Anderson et al., 2020), or the difference of symptoms between infective people (Chen et al., 2020; Lu et al., 2020). While waiting for medical research to identify effective ways to treat and prevent COVID-19 at an organic level, the spread of the virus becomes an opportunity to make a scientific analysis of what is generated interactively in the human community, the *Communitas*, in terms of public health.

*Communitas* is in fact defined as the mass of interactions in continuous change, triggered by members of the human species who inhabit and live in a certain dimension (geographical-territorial and/or virtual), towards the incessant search for a common and shared goal (Turchi and Cigolini, 2017). Currently, a shared aim involving the world population, the *Communitas*, is reducing the contagion spread of COVID-19. Such an aim, then, involves and requires accountability to each species member, enhancing the social cohesion of the whole community.

How can the scientific world contribute to the management of human interactions in an emergency situation, such as the current pandemic, in pursuit of the common purpose of public health, in terms of Social Cohesion?

The necessity, in scientific terms, lies in the need to promote a shift from the use of deterministic-causal criteria to the methodologically valid management of the uncertainty of interaction: this makes it possible to pursue the common goal, which currently concerns the whole human species, in parallel with research and action at the medical and organic level, and also to consider and manage changes in the interactions themselves in the future, when the medical emergency will be over. This contribution therefore proposes a fundamental shift from what science currently makes available to the Community to manage interactions in an epistemologically and methodologically well-founded way. From the common perspective of reducing contagion, interaction is the cognitive process at the basis of the scientific panorama (and not only of the exchange or communication act): *interaction*<sup>1</sup> is the perpetual process in

which two or more elements, in uncertainty, generate more or less stable interactive arrangements, which in turn are subject to changes (Turchi and Gherardini, 2014a).

Such interaction setups, constantly changing, always tend towards, at different degrees, the Social Cohesion of the Community. This, within the theoretical and epistemological framework we are outlining, is defined as the “whole of the modalities, at discourse level, configuring realities that concur to the shared management among the Community members of the key aspects anticipated, thanks to common goals.” (Turchi and Cigolini, 2017). The above definition, in terms of analysis of the Community members' interactions, allows for the availability of interactions measurement tools, including the Social Cohesion Measurement Index. The latter offers scientific data to calibrate the construction of the COVID-19 emergency management modalities on the interactions of the Community itself. The Social Cohesion Index, specifically, permits to obtain a measure of it in terms of the modalities with which the population narrates the current medical emergency situation, allowing researchers to consider the extent to which narratives on Covid-19 are oriented to the protection of citizens' own interests, rather than the promotion of public health. Such an index offers then a scientific datum that can be used to gauge the COVID-19 emergency management modalities construction based on interventions on the Community interactions. Therefore, in the absence of data describing what is happening at an interactive level, the strategies employed to manage the medical emergency risk are random, and to be subject to the personal opinion of the ones fielding them. This bears the risk that the key aspects, found within the interaction configurations, are not managed, and in turn contribute to the fragmentation between the members of the Community, leading to a lesser cohesion for the pursuit of the common goal. Having the discursive data of Social Cohesion available allows, therefore, to enhance the contribution of each citizen, using it for the sake of “Public Health.” Thus, the interactive contribution of the *communitas* citizens allows the promotion of community cohesion and the accountability towards a common goal. To this purpose, there are many scholars who have set out and defined the accountability phenomenon, such as Zuliani (2006), who sets out eight stages people undergo due to a natural disaster. One of these is the so-called “honeymoon stage” and another one is the “hero stage” where citizens help each other in a team and there is a climate of optimism.

In order to deepen the idea of “contagion reduction aim,” it is necessary, first, to distinguish between what concerns the organic

<sup>1</sup>“Diachronic process of different typology (energetic, metabolic, dialogic) by means of which, starting from two or more elements generated by the same process (previously or at the same time), assets/configurations, in which the elements can

or cannot be more distinguishable, are generated” Turchi and Gherardini, 2014a, p.141.

medical dimension of the individual and what concerns the interactive dimension of the Community in fundamental terms.

In the course of the historical and philological contingencies, the use value of “Health” has been exhausted within medical care, so that Health has assumed the meaning of “condition of well-being” on an organic level, and medical care has been understood as the integrity of the functional anatomical unit, i.e., the body (Turchi and Vendramini, 2016). In this way, Health is reduced, on a methodological and operational level, to the intervention on the element that determines the pathological condition of the individual, losing sight of the interactive dimension of the community collective aspect of Health. The distinction between Soundness and Health is made in terms of epistemological, and not only semantic, foundation<sup>2</sup>: Sanity refers to the physical and biological integrity of the individual organism, while Health is based on interactions between the members of the Community. Therefore, a criticality is identified, in terms of repercussions on the management of interactions, in the superimposition of foundation and epistemological plans, distinct in the conception of Soundness and Health, which in the current emergency scenario is undermining the modalities of medical emergency management.

If the aim is to contain the spread of the virus and safeguard the capacity of the health care system to respond, as a common good, research on the virus in medical terms is one way of pursuing the purpose. This does not, however, subsume the strategies with which to manage the repercussions already in place on the interactive level (economic, psychological, cultural, social, etc.) that the emergency itself generates, also in terms of changing interactions between members of the Community after the medical emergency is over.

The epistemological distinction of the words thus enables action to be taken in foundational-methodological terms in the management of the impact at Community level towards the common purpose. In the face of praxis that are placed in an exquisitely sanitary dimension of care of the biological organism of the individual, the diffusion of COVID-19 shows how a series of strategies implemented by the population on the interactive level of the whole Community is developing (for example, the neighbour who makes himself available to shop for the condominium’s elders). As with the various medical emergencies that have emerged over the course of human history, the virus has forced the human species to modify its interactive modalities, in order to compensate for their decrease against the quarantine and social distancing measures: it is on the level of interaction (therefore not only on that of research at an organic level) that the human species can effectively pursue the common goal of reducing the spread of the virus. It is on this level that the COVID-19 emergency, as far as it can be managed on the organic-sanitary level, will generate changes in the way members of the Community interact: for example, the “fear of contagion” may cause some members to maintain the rule

of social distancing even after the emergency has returned. It may therefore change the value attributed to what before the emergency was considered certain and taken for granted: for example, being able to go on a trip, to see a loved one, to have an internet connection at home.

The current impact of the COVID-19 emergency in the community has highlighted how the interaction between the many elements that characterise events in human history reveals the uncertainty of their evolution. The interactive elements of the current world situation can therefore be placed within an uncertain panorama, of which the virus itself is a manifestation: this Principle of Uncertainty (Heisenberg, 1963, 2015) shows how it was not possible to predict the phenomenon of COVID-19 and the extent of its effects on Health, in terms of interactions.

By adopting uncertainty as a Principle, described as the non-possibility to predict future events because the very starting conditions are uncertain, the current situation configures itself as an emergency situation. The emergency in fact is “everything that is produced as a follow up to an event that can to some extent change the arrangement of a community, sticking to a purely descriptive plan of what happens” (Turchi et al., 2015).

Considering this Epistemological Principle as a scientific basis, the below describes how the configuration of the current pandemic presents fundamental and methodological criticalities to be considered and on which to intervene on a management level. This allows one to direct oneself towards the promotion of Community Cohesion on the whole, through referring to interaction measurement data that can support the spread reduction of SARS-CoV-2 virus.

## PROMOTING SOCIAL COHESION AS A COMMUNITY NEED

The scientific panorama wants to trace the knowledge of the virus (Santosh, 2020) through the continuous collection of epidemiological data, in order to identify a constant characteristic of the virus. In monitoring changes in the epidemic, through databases that provide an overview of the epidemic situation (Li et al., 2020), it emerges that the data collected on an epidemiological level are constantly changing, varying according to the study and the elements taken into consideration (Anderson et al., 2020). For example, the WHO considers that the main transmission pathway is through close contact with symptomatic people; however, it does not exclude that it can also happen with asymptomatic people, claiming their rarity on the basis of the frequency of collected data (Istituto Superiore di Sanità, 2020). These aspects make the criticality of fragmentation of the epidemiological data collected traceable, given the diversity and uncertainty of contextual and environmental characteristics that differ from country to country and from individual to individual.

The collected data, although uncertain, are used to make estimates and forecasts of the epidemic trend on which to base political and economic choices for the management of the fallout of the emergency, through the use of mathematical-statistical models taken as reference (Consiglio Nazionale delle Ricerche, 2020). From a clinical psychological point of view, the research panorama highlights a series of possible psychological

<sup>2</sup>Epistemology is defined as “the branch of general theory of knowledge that deals with problems such as the foundations, limits, nature, and conditions of validity of scientific knowledge; it is the study of the general criteria that allow us to distinguish scientific judgements from those of opinion typical of metaphysical and religious constructions, of ethical evaluations.” (Turchi and Della Torre, 2017).

disorders (depression, anxiety, stress, psychiatric syndromes, etc.; Asmundson and Taylor, 2020b; Brooks et al., 2020; Loveday, 2020), also labelled *ad hoc* (Coronaphobia; Asmundson and Taylor, 2020a), which it considers to be the direct consequence of quarantine and isolation measures. The same happens within social psychology, which offers data on bias, stigma, and racist processes towards the Chinese population and between individuals in the same community (Chung and Li, 2020; Wen et al., 2020). These statements are based on studies carried out through the use of statistical data (Wang et al., 2020) taken as reference in order to explain what the COVID-19 emergency causes among members of the Community. The same data, in this way, is looked at and used through lenses that are always different, so that they will always give different results, even if they are used in order to predict what will happen in the future. Once again, psychological research focuses on human behaviour as an element to be considered in order to determine the spread speed of the virus (British Psychological Society, 2020). Such behaviours, however, remain subject to the uncertainty of interaction, so it is not possible to predict whether the behaviour under study will be implemented, how, and what its impact on the spread of the pandemic will be. Recalling the Principle of uncertainty of interaction, which generates temporarily stable and subject to change settings, the criticality can be traced in the foundations of epidemic management choices based on deterministic predictions, built on continuously changing medical outcomes. In this way, the management modalities do not take into account the uncertainty given by the interaction of the contextual elements of the data base offered, predicting what will happen on an interactive level. Predicting what will happen in managing interactions decreases the social cohesion degree. The prediction alone defines with certainty what will happen after a series of events. Thus, it does not allow individuals to design alternative strategies to handle unexpected realities. Anticipating, instead, a range of possible interactive key aspects that could happen in the community, would allow to manage at the same time, in a cohesive way, the whole community. Social cohesion is the chance that every citizen contributes his/her role in the community, through anticipation (instead of prediction) of the possible key aspects and management strategies, aimed at the pursuit of a common goal. On the contrary, setting out a single future scenario, instead of outlining at different degrees the possible ones, allows to reify what was predicted instead of managing what can happen for a common goal.

For example, when the quarantine isolation of citizens and the closing of commercial and economic activities are decreed by law (Wilder-Smith and Freedman, 2020) it is not possible to predict (and therefore establish future certainty) that a part of the citizenship will lose its job or receive no income from its commercial activity. However, this may still happen. When such management is anticipated and carried out, in the light of each community member taking charge of the common goal pursued, other than the exclusive personal aim, the community cohesion degree rises, and the community will not get fragmented. This, in turn, increases the chances to find solutions and strategies previously not available. These are interactive realities that enable, by the previous example, to find other ways to

receive income from one's own business or finding another job; differently, such modalities would not allow safeguarding not related to the citizen. So, where the citizen loses his/her job and does not have any income, in the employment of the sole prediction of what will happen, and thus in the decrease of the interactions, he/she can configure himself/herself as a "desperate person, with no other chances to live with," contributing to the interactive use of such a label to the fragmentation of the community.

Thus, basing interactive management choices in terms of prediction leads to an array of interactive fallouts that fragment community cohesion, increasing the chance of a rise of conflict creation and more fallouts, of which we offer below some examples. Adherence to the regulations, for managing the spread of the virus (quarantine, isolation, closure of economic, cultural, and educational facilities, etc.; Maxwell et al., 2020), as well as to the directives for the use of protective devices (World Health Organization, 2007, 2020), interactively eludes the regulations requirements: law decrees are becoming every day more coercive or connoted by the "prohibition" mode rather than the descriptive one of possible actions linked to the virus reduction aim. The Community is therefore not made part of the management but is continuously considered to be the mere executor of the restrictions imposed. This contributes to the making of a fragmented community, creating conflicts. Specialised literature unveils that having a third, superordinate aim, in the event of dangers for the whole community (see natural emergencies or catastrophes) where everybody can give his/her contribution and participation, reduces conflict generation (Sherif et al., 1961). Thus, by taking responsibilities for the sake of each member, Community Health becomes the chosen strategy to promote the social cohesion aim (Bifulco and de Leonardis, 2005). The above-mentioned process enables, also in methodological terms, to overcome the aggregation of individual preferences (and thus of the personal aim), towards a more general look, oriented to the Community (Boltanski and Thevenot, 1991).

All this becomes possible if the pandemic "emergency" reality is not considered as an entity, detached from the observer, but as created by the interactions among the speakers that narrate and build the meaning (as for catastrophic reality, see Berger and Luckmann, 1969).

Orienting the Community towards a common purpose then becomes necessary, when the interaction between the members of the species cannot be completely "segregated," precisely because it is related to a plan of uncertainty and randomness, and not organic determinism. In fact, adherence to the prescriptions is promoted by relying on the moral values of the individual and her or his "motivation" (Anderson et al., 2020) through information campaigns, and not on the basis of a scientific, epistemologically founded method of interaction management. We therefore leave it to the individual to interpret the information he or she receives, thus opening up the possibility that, despite quarantine, the citizen may decide, for example, to have dinner with friends, without him or her contemplating the possible repercussions that this action will have on the national health-care system, and therefore on the Community as a whole. Since the citizen is

not adequately trained in the management of virus transmission, he or she relies on his or her own beliefs and opinions on the extent of the emergency, which are different from those of other members of the Community (see in this direction the propagation of fake news, the increase of controversy and contradictory interpretations of regulatory bans, comments offered to the social pages of institutional representatives, etc.). In this way, the fragmentation of the Community's interactive management modalities jeopardises the conservation of the species. Fragmentation focuses mainly on meeting the needs of the individual ("I need to get out and walk, I'm going for a walk") and not on the common need of its members ("I could create a voluntary service that would allow the families of COVID-19 infected people to stay in contact with them, however isolated they may be in a hospital ward"). In the face of these examples, the fragmentation of emergency management strategies, built *hic et nunc*, without scientifically basing the operational mode of scenarios that could be effective for the management of interactions, is critical. This may affect the possibility of the population moving in a cohesive manner, towards the pursuit of the objective of virus reduction, thus the very effectiveness of the interactive repercussions of the medical emergency management process. Consider, for example, the increase in infections following the issuing of the Italian Prime Minister's Decree amending even slightly the previous provisions: "use of suitable devices" and "it is possible to play sports near your home" is interpreted as "then I can go jogging as long as I wear a mask and cover my mouth and nose when I meet someone." Given the above definition of *Communitas*, the pursuit of this common objective will in fact be all the more effective the more interactions between the members of the Community will increase, in the construction of emergency management modalities, towards *Social Cohesion*. Doing so makes it possible to promote, among the members of the Community, competencies enabling them to take on the role of citizens capable of contributing to the pursuit of the common objective. Managing in a shared way, therefore, what happens in the face of the medical emergency, brings with it the need to identify the critical interactive aspects of the situation in which you find yourself. Citizens can thus be put in a position to act on the problems anticipated, in synergy with political and administrative institutions. In this sense, each one is a node within a network of interactions, therefore able to manage what happens, sharing the aim of reducing the spread of the virus. This can be observed, for example, in the part of the population that has mobilised to build alternative oxygen masks to those used until now in the medical sector, starting from the criticality found in the availability of oxygen masks in hospitals.

## THE DIALOGICAL SCIENCE

The Principle of Uncertainty of Interaction, and the construct of Social Cohesion, therefore become useful references for structuring and implementing ways of managing what happens interactively, in the period of medical emergency. It becomes necessary, at this point, to place oneself within a scientific panorama capable of building knowledge from interactions.

Just as it is not possible to perform a surgical operation without any anatomical knowledge, in the same way it is not possible to manage what a medical emergency generates at an interactive level, between the members of the Community, without any knowledge of the uncertainty of the interactions that configure the emergency reality, with repercussions in terms of its Health.

It has become necessary to move towards the explicit dimension of scientific sense (Wittgenstein, 1999; Turchi and Cellegghin, 2010; Turchi, 2002) which offers a common and well-founded basis, from which to build effective ways of emergency management, in interactive terms.

The proposal for interactive repercussions management described below is placed within a *conceptual realism*<sup>3</sup>, in which the interactive reality of *Communitas* does not exist in itself but is built in the act of knowing it. Referring to the uncertainty principle of interaction, it is not possible to know the state of reality, but rather the process of its generation (Turchi and Vendramini, 2016), which is thus linked to "how" it is configured, and not to "why" the cause for which it exists in itself.

Therefore, starting from the shift from mechanistic paradigms to interactionist paradigms (Khun, 1962; Salvini, 1998; Marhaba, 2002; Turchi et al., 2007; Salvini and Salvetti, 2011), in order to be able to base the choices of world emergency management on scientifically based data, the proposal of this paper takes shape in Dialogical Science<sup>®</sup> (Turchi, 2009; Turchi et al., 2012b; Turchi and Gherardini, 2014b; Turchi and Orrù, 2014; Turchi and Vendramini, 2016; Turchi and Cigolini, 2017; Turchi and Della Torre, 2017)<sup>4</sup>. This takes charge of the discursive or dialogical process of knowledge (Turchi, 2013): it is therefore placed within the incessant flow of a process, which every time it is shown takes shape through contents. Content is configured as, precisely, "what it contains," the product, which is or is not there, of a certain procedural dimension, always present (Turchi and Cellegghin, 2010). For example, government action to make masks available, free of charge, to residents of an Italian region, remains a content, a product, which is linked to a process of managing the emergency fallout in the Community. The process, in this case the management, does not stop, and takes shape in the specific contents, the actions that are implemented: in order to manage what happens in the Community at an interactive level, it is then also possible to make available a bonus for babysitter salaries, hospital construction, and fundraising for the healthcare system. This is due to the uncertainty of the product or content, so that the form the process may take varies continuously based on the interactions within the Community. The interactive-dialogical process therefore generates configurations of realities (Turchi, 2013) with variable

<sup>3</sup>"Concepts of realities on the basis of which the scientific community generates knowledge products" (Turchi, 2017).

<sup>4</sup>"Science that has as its object of knowledge the use of the symbolic units that compose ordinary language, which gives form to discursive configurations; [it is] that cognitive apparatus that formalises the dialogical process (or discursive process)" Turchi and Gherardini, 2014b, p. 215.

stability through the interaction between rules<sup>5</sup> of use of ordinary language.

Ordinary language<sup>6</sup> (Wittgenstein, 1964, 1976, 2009; Foucault, 1967; Gadamer, 2000) is the object of investigation of Dialogical Science, as a generator of reality configurations of all those who belong to *Communitas*. The discursive reality thus can be described in terms of process, starting from the rhetorical-argumentative links that describe it as such (Bruner, 1991). The conceptual shift occurs, therefore, in considering *Communitas* not as a set of individuals but as a set of discursive productions that interact to generate discursive reality arrangements for the management of the medical emergency. How can management choices, based on medical data, take charge, scientifically, of discursive reality configurations?

The Dialogical Science research program allows to generate knowledge about interactions thanks to the formalisation of the rules of use of ordinary language. A formal language is built (Turchi and Orrù, 2014) out of the ways in which ordinary language is used in interactions, thus describing the ostensible property<sup>7</sup> of language. The formalisation of the interactive-discursive rules allows to obtain scientific data of a discursive type: this is possible by establishing, a priori, the rule of use of ordinary language. The configuration of sense of reality that is generated, in the use of these rules, is already defined a priori, regardless of the use of the language itself. Changing the rule, therefore, changes the sense of reality that is generated, and therefore the data that is offered (Turchi and Celleghin, 2010). This is also what happens within mathematical algorithms: by changing the value of the symbolic units used, the product of the algorithm will be different from the previous one. In the formalisation of the ordinary language, the same change occurs in the sense of the configuration of reality, generated by the data offered by its measurement. These data are in fact organised in the 24 Discursive Repertories (R.D.)<sup>8</sup>, available in ordinary language to configure meaning reality. According to the studies conducted in this field (Figure 1 and Annex 1—Periodic and Semi-radial Table of Discursive Repertories—Glossary), there are 24 possible and available RD for the human species. From research conducted in literature it emerged, in fact, that against a discursive space available to interactive individuals<sup>9</sup> (that is each of the 24 RD characterised by specific process properties peculiar and distinctive), some RD aggregations of those (Mariotti Culla and Turchi, 2007) outline profiles and degrees of social cohesion. Therefore, against the 24 possible

discursive modalities, a cohesion interactive setup is created, whenever the observation of some of those is privileged against other ones (such as the Targeting, Description, Consideration, and Proposal). Vice versa, as for conflict setups<sup>10</sup>, experimental texts have evidenced some modalities among the 24 available, that emerge with less frequency compared to other ones.

The interactions among the R.D. generating discursive configurations are organised within the Periodic and Semi-radial Table of Discursive Repertories (Figure 1), according to their generative properties of sense reality. The Table represents the main guiding tool in the analysis of the properties with which the ordinary language shows itself, and the extent to which the Community is inclined to change, in the management of what the medical emergency generates, at an interactive level. How much, therefore, moves in terms of Social Cohesion, to manage in a shared way and in anticipation of what happens, in pursuit of the aim of reducing the spread of contagion. In particular, as evidenced by the graphical representation of the Semi-radial Table, some modalities defined as maintenance ones (red colour) have been isolated, allowing the creation and maintenance of conflict profiles. These include Certify reality, the Cause of action between the discursive items, Judgement, and Comment. Other modalities, defined as generative ones (in green) represent social cohesion configurations among the interactive individuals. Last, but not least, hybrid modalities have been described (in yellow), that by themselves do not create conflict configurations but when associated with the maintenance ones they speed them up, increasing the degree of conflict exercised by the interactive individuals.

## THE MEASURE: THE GENERATIVITY AND DIALOGICITY INDEXES

Starting from the rules of the formal language it uses, Dialogical Science offers the theoretical-methodological elements able to measure the discursive configuration in a precise kairos (instant, moment). This makes it possible to manage the uncertainty of the interactions that are generated in the Community, in the face of the medical emergency: in view of the measure, it becomes possible to intervene by orienting the interactions themselves towards Social Cohesion. The measurement is offered by assigning to each R.D. two units of measurement: the Dialogical Weight (PD) and the Dialogical Moment (MD). The first offers a measure of the Generativity Index<sup>11</sup> (Turchi and Orrù, 2014, p. 2), that is “the ability of the Repertory to generate different and multiple discursive configurations” (Turchi and

<sup>5</sup>“Intrinsic characteristic of uncertainty that in its manifestation finds its own structure that tends to stabilise and become distinguishable and denominable in a language (except then interact with the whole and become a further element that generates uncertainty)” (Turchi and Vendramini, 2016).

<sup>6</sup>Ordinary language is the whole of symbolic units and rules of application that govern its use, at the basis of the discursive process.

<sup>7</sup>“The property of language to assume a different value every time the symbolic unit is used” (Turchi, 2009).

<sup>8</sup>“A finite mode of constructing reality, linguistically understood, with pragmatic value, which groups together even more enunciated (called “archipelagos of meaning”), articulated in concatenated sentences and diffused with a value of assertion of truth, aimed at generating (building)/maintaining a narrative coherence” Turchi and Della Torre, 2017, p. 91, Turchi and Orrù, 2014, p. 13.

<sup>9</sup>(Turchi and Orrù, 2014).

<sup>10</sup>By conflict it is meant the interactive setup of high fragmentation risk; here, the Veneto Region community members interact on the grounds of strongly personal aims and references, therefore with a very low/void orientation towards common and third goals. Since the personal aim interacts with the personal stance of another Community member, one excludes the other and their co-existence is not contemplated.

<sup>11</sup>The formula that allows to calculate Generativity (G) has been constructed as  $G = \Delta p \Delta m D$ , in which  $\Delta p$  indicates the weight of the configuration;  $\Delta m$  indicates the moment in which the configuration is traced; and  $D$  indicates the constant, the quantum of Generativity, that is the discursive space that can be generated (in which  $D \geq \Delta p \Delta m$ ).

Cigolini, 2017), with a value between 0 and 1; the second offers a measure of the Dialogicality Index, that is the type of link that is created between the R.D., and the “strength” of this link in terms of narrative coherence<sup>12</sup> (Turchi and Cigolini, 2017). Both measurement indexes describe which discursive modalities interact, and in what way, in the generation of a certain reality configuration. The Generativity and Dialogicity measurement indexes can indeed be measured in anticipation (before the implementation of an intervention), in itinere (during the development of the intervention), and *post hoc* (after the intervention has been completed), presenting scientific data that can be used to pursue the intervention objective that is set in the most effective way.

Thanks to the availability of the measure of the interactions, generated by the *Communitas* members, it is therefore possible to intervene on them. Starting from the measurement indexes presented, it has been possible to build methodological praxis of the dialogical operational model, able to intervene on the

<sup>12</sup>“The intrinsic and organising property of the elements that constitute the discursive productions, to maintain congruence and uniformity in such a way that it is not possible to generate a contradiction in narrative terms, generating a configuration that, by common sense, is set as given and certain” (Turchi and Gherardini, 2014b).

interactive events of the Community (Turchi and Della Torre, 2017). Among them the anticipation (and not the certain prediction of a single possibility, as happens on the medical level) of a range of interactive scenarios is scientifically based (Turchi et al., 2013b). These could be described as critical in pursuing the shared aim of reducing the spread of the virus: for example, the possibility that elderly and lonely people may find it difficult to have access to what they need (shopping, medications, etc.), or that some members of the Community may not conform to the legislative requirements. *Anticipation*, a necessary step for the management of critical aspects from the perspective of Social Cohesion, is therefore a methodological practice on which to build emergency management methods, starting from the measurement of interactive data, and no longer only medical data, and the trajectory of narrative coherence traced by the speeches themselves. For example, it is possible to measure the citizen’s contribution to the Community when he says that he “feels extremely lonely because he is in need of hugging someone,” so he decides to go out despite the quarantine measure, or else, when he says that “although this situation makes me feel lonely and I am not used to it, it can be an opportunity to think about how to make people in quarantine feel less lonely.” Therefore, in the view of what has been measured, it is possible to anticipate the trajectories of interactive development of both

statements, and to calibrate the management strategies of the critical scenarios anticipated, before they actually occur, that can increase the degree of contribution to Public Health and therefore to *Communitas* Social Cohesion. Through the use of anticipation of a range of future possibilities, the members of the Community are in a position to consider more possibilities for the pursuit of the shared purpose. The measure therefore enables these possibilities to be considered in terms of scientific data on which to base management choices of possibilities themselves.

Methodologically, therefore, it becomes necessary to collect, observe, and analyse the text produced by the members of the Community: this makes it possible to measure the configuration of the reality under investigation, through the use of R.D. and measurement indexes. As already presented, on a theoretical point of view, in the previous section, experiments conducted with a control group who were asked to generate conflict setups against a verified actor, it emerged that when a party exercises the cited maintenance modalities, the other party uses in turn the same discursive maintenance modalities, but among all those privileged we find Justification and Certify reality. Also, when conflict setups are described, as those cited in the discursive productions, Evaluation, Description, Consideration, Opinion, and Proposal modalities decrease. That is, the conflict discursive configuration (maintenance, red) erodes the available social cohesion part (generative, green). So, the range of possible interaction setups spans between two polarities, conflict and social cohesion: the more modalities creating conflict are isolated, the fewer social cohesion discursive configurations can be created.

Therefore, each text, produced as regards the study object, and therefore, in this paper, concerning the medical emergency linked to the Covid-19 spread, contributes to the Community social cohesion level. The assumptions regarding how the virus spreads, the stances towards the legislative decrees issued, the moods linked, for instance, to worrying about oneself and the loved ones, and the behaviours and the precautions adopted to diminish the contagion risk, are all considered in the analysis. These all become specific items, with particular content, within the interactive-dialogic process of building reality configurations. All these, to a different extent and with varying force, concur to the generation of a particular community setup creation—more or less cohesively—for the pursue of the virus spread reduction aim. What has been produced by Dialogical Science in terms of measuring reality configurations has been implemented in several research and intervention projects, including a study completed in 2011 in the Italian territory of L'Aquila following the emergency generated by the natural catastrophe of the earthquake of April 6, 2009. The collection and analysis of the text, through study protocols with open questions to 2000 inhabitants of the territory affected by the earthquake, measured Health indicators of discursive interactions, and therefore of social cohesion, in terms of citizens' competence in the management of the emergency and participation in community life: they draw a description of how the participants configure their social and interactive reality in terms of Community Health in facing the “catastrophic event” (see Turchi et al.,

2015). The collected data showed a configuration oriented to the maintenance of the “catastrophe” reality, as it is, mainly linked more with the use of Repertories such as Certify reality, Opinion, and Judgement, and less to Repertories such as Description or Targeting.

Data allow then the implementation of public policies that place citizens in the perspective of shared management of the critical aspects generated in response to the catastrophe, thus directing them to the perspective of Social Cohesion. Another application took shape within a 2011 study (Università degli Studi di Padova, 2011) describing the process of discrimination (“stigma”) against people affected by HIV within the Italian territory, conducted on a survey group of 1,267 respondents (among people affected by the virus, family members, health and social workers, and citizens not affected by the virus), who were administered an open questions set protocol. The researchers, through a series of evaluation indicators and the availability of indicators to measure the degree of stigma against people with HIV, have obtained data on how the members of the Community, in their role, narrate the interactions related to the object of the survey. The subjects involved in the study employ maintenance discursive modalities, through narrations like “Every day is a struggle to survive” (Certify reality R), or “It will be hard to achieve a normal family condition” (Prediction R). In particular, the cognitive plan in which we have set ourselves has made it possible to measure the Generativity of the stigma towards people affected by HIV at a national level and the Dialogicity of the narrative coherence of the participants in relation to the construct of the survey. The fluctuation in the value of the process of discrimination therefore provides the starting point for managing stigma within the Community, intervening on the interactions and roles involved more or less directly with respect to the issue towards a shared management of this critical aspect, therefore in the perspective of Social Cohesion.

A final example of what has just been described is the InOltre Service, an essential level of assistance within the Veneto Region (Italy) also based on the assumptions of Dialogical Science. The service was born in 2012 with the aim of “promoting the Health of the territory through the management of the implications of the socio-economic asset” (Turchi and Cigolini, 2017; Turchi et al., 2019). The availability of a measure of the interactions and the reach of the objective described above make it possible to take charge of the repercussions of emergencies at an interactive level in anticipation: this is done in terms in which it allows flexible intervention, depending on the changes that are generated in the Community, directing users towards the pursuit of the common purpose in the management of critical aspects in a shared way. Thanks to the use of the anticipation practice, it has in fact been possible to extend the service, over time, from entrepreneurs in crisis or bankruptcy, to savers victims of the banking crisis, to citizens in critical biographical moments, to Italian citizens during the emergency COVID-19. Taking charge of the user base is made possible and effective by the availability of text measurement indexes on which to base anticipations of the users' narrations, regardless of the content they offer.

The text<sup>13</sup> productions of the service users, that approach the service due to reasons linked to the pandemic, during the phone calls that the service receives and records, could then employ discursive modalities mainly of the maintenance type as Prediction, Judgement, Cause of action, and Comment, offering narrations such as “I’ve tried everything, I try to fill my days with things to do to keep well during quarantine, but in any case I feel bored” (Certify reality R. + Contraposition R.). The use of Hybrid Repertoires, such as Possibility (“I could take advantage of the quarantine to get a new hobby”) could also be collected.

The measurement indexes obtained in the applications described above therefore make it possible to have available a datum related to whether or not the Community’s narratives are open to different discourses on the configuration of the reality under investigation (whether it is an “earthquake,” “banking crisis,” “HIV,” or “COVID-19” emergency). The datum makes it possible to describe the Community members’ discursive modalities and to evaluate the direction in which they are oriented. The more interactions increase and are directed towards the construction of alternative sense realities to those available, the greater is the possibility that the members of the Community manage critical aspects in a shared way towards the pursuit of the common goal. At public policies level, having available measurement indexes becomes useful to build medical emergency management interventions, specifically gauged against the discursive modalities fielded within the Community and the anticipation of the future community setups. Moreover, it serves to assess their effectiveness and efficiency, both in the short and long term, to increase social cohesion. That is, interventions that take into account, at each stage, the stance and the opinions of the Community members about the medical emergency, the behaviour, and the actions taken for its management (how such discursive modalities are oriented for the pursue of the virus spread reduction common goal in the most cohesive way).

In 35 years of activity, the Dialogical Science research program has conducted research and interventions in different fields, such as psychiatric (Turchi et al., 2016), sports (Turchi et al., 2008, 2010a), social (Turchi et al., 2012a; Iudici et al., 2018b), economic (Turchi et al., 2008), penitentiary (Turchi et al., 2013a), emergency (Turchi et al., 2015), health (Iudici et al., 2018a), community (Turchi and Romanelli, 2019), mediation (Turchi et al., 2010b), geriatric, and engineering, collecting, about 200,000 fragments of text. Now, thanks to its theoretical-methodological structure, the research program has also been able to be inserted within the medical emergency of COVID-19. Over the course of time, the research program has taken the opportunity to have the interactive measure of the reality narrated by the members of the Community available in an almost immediate way, thanks to Machine Learning technology (Turchi et al., 2020). By using Machine Learning technology, it is possible to increase the capacity of text analysis through the methodology used in Dialogical Science, thus being able to deal with Big Data on specific geographical or thematic areas/contexts/areas. The output data of the analysis carried out through Machine Learning

allow to obtain and manage different and uncertain discursive configurations in their manifestation, through a predictive model that identifies the Discursive Repertoires used in the text, so as to be able to measure the indexes and subject of the search, contemplating and calculating the margin of error of the measurement itself. This is made possible thanks to the use of Artificial Neural Networks (NNs), enhanced by the use of particular NNs, i.e., Recurrent Neural Networks, designed to accept vector sequences as input and produce, as output, and as integrations of the entire sequence submitted to them. This makes it possible to name the Discussion Repertoires in a digital way.

What has been described allows researchers to intervene on the emergency reality available from computerised data that do not stop at the logical-grammatical analysis of the text but offer an overview of how the language configures reality, optimising time and resources. In the critical interactive emergency situation of COVID-19, this enables the quick and efficient availability of the interactive scientific data needed to calculate the Social Cohesion Index. The above enables the political-management roles to set up and structure management modalities precisely gauged to the interactive “status” of the *Communitas* members, as for Public Health in the current medical emergency period (Heymann and Shindo, 2020). For instance, it is considered how the extended use of protective masks during the social distancing period has been perceived, against its effectiveness and the effects it has on people, or else, the various opinions, either expert-like or not, related to the present and future outcome of the pandemic on physical and mental health and on interpersonal relations. In this sense, to have this kind of data available, precisely gauged and quickly analysed, and therefore always up-to-date and pertinent, enables the management roles previously mentioned to monitor, assess the activities, and choose the initiatives and policies implemented in the territory tailored for the citizens, both at the time of measurement and with a future perspective, thus promoting social cohesion of the Community and reaching the highest effectiveness and efficiency levels.

## THE MEASURE: THE COHESION INDEX

Starting from the theoretical foundations and the formal language of interaction, Dialogical Science makes available the immediate processing of interactive data, on which to base management choices at the level of public policies: there is a measure of how *Communitas* citizens are using the interactive modalities available to them in relation to emergency management and how they are moving in pursuit of the aim of reducing the spread of the virus, whether or not this is in a cohesive manner. In this direction, the progress of the Dialogical Science research program has made the index measuring Social Cohesion available.

As we previously saw, the Community aim during the Covid-19 pandemic is the contagion spread reduction. Considering this context item, i.e., a text item, concurring to (is part of) the studied discursive configuration, we asked ourselves what is the use (the

<sup>13</sup>Collected in accordance with Italian privacy regulations.

value) of what the Community offers (in terms of discursive productions) for the defined object<sup>14</sup>. The study question for the measurement of the social cohesion level is then: what is the use value of the discursive configuration observed, against the common goal of the reduction of the contagion spread? The index shows how much the discursive configuration of the Community member is oriented towards the management of critical issues in the pursuit of the shared aim or, vice versa, how much it is moving away from it, thus moving towards the fragmentation of interactions, which can affect the pursuit of the common objective. In order to make the Cohesion construct measurable, the two dimensions in which it has been declined are the anticipation of future scenarios<sup>15</sup> (variable *x*) and shared management (variable *y*), the two variables that are constantly changing according to the objective to be pursued. The common goal is always present and may vary depending on the context.

Once again, the Discursive Repertories are configured as the elements able to offer a measure of Cohesion, in relation to the role they play towards the two variables defined above. It has therefore been defined which Repertories, and to what extent, are included within the definition of Social Cohesion, in its dimensions of shared objective, anticipation of critical aspects, and shared management of the same (see definition on page 1).

It is assumed that the use of some Repertories contributes to the pursuit of the common goal, the use of others less so. The Repertories, by interacting with each other, make a degree of cohesive contribution that varies according to their use in pursuit of the common goal of reducing the spread of the virus. If the discursive elements are aimed at pursuing different objectives than the one set, then the degree of cohesion is assumed to decrease. Conversely, these will increase it.

In order to offer a measure of how it contributes to Social Cohesion, each Repertory of the Table is associated with a value, the “Cohesion weight,” expressed in positive or negative terms. If expressed in negative terms (for example, the Repertory of Judgement, associated with the value  $-2$ ), it always contributes to a decrease in the degree of Cohesion (as in the following text: “Council members are by no means available and Police forces are sometimes not collaborative enough with citizens”). If expressed in positive terms (for example, the Repertory of Description, associated with the value  $+9$ ), it always contributes to an increase in the degree of Cohesion (as in the sample text “The neighbourhood population consists mainly of elderly people and students”). If the symbol associated with the value is  $\pm$ , the Repertory may or may not contribute to the degree of Cohesion depending on the orientation to the objective set (as in the text: “All this chaos in the city must be

cleared”—Certify reality’s Repertory, configuring a stagnant and unchangeable reality).

By associating the Discursive Repertories with the variables in which Social Cohesion is declined, they are considered in increasing order, according to the degree to which the properties of the R.D. themselves contribute or not to the variables, and therefore in a wider sense, to Cohesion. The Anticipation Repertory is one that increases Cohesion to the highest degree (“Considering how the number of infections is decreasing, the government may decide to relax the containment measures by making specific provisions with which each business can re-open”). The Proposal Repertory is one of those increasing the variable of shared management to the maximum degree (“Since we cannot spend Easter with our loved ones, we can have a party among us tenants and involve family members online”). In this way, due to the R.D. used in the analysed text and their Cohesion weight, the variables oscillate within a continuum from 0 to 10 (Figure 2) which accounts for how the Community is moving to reduce the spread of the virus (i.e., the degree of Social Cohesion), through the output data resulting from the application of the index itself. It is thus possible to describe whether the Community narratives are pursuing the objective of Cohesion in terms of shared Responsibility<sup>16</sup> or whether they are generating fragmentation, pursuing personal and implicit goals.

Getting to the core of this last-mentioned aspect: since Discursive Repertories’ Dialogic Weights give evidence of the capacity to create “other” discursive configurations, different from the one already available in the dialogic process, a discursive configuration with high Dialogic Weight (Turchi and Orrù, 2014) makes possible in the language use an interactive movement aiming at the pursue of the set aim. At the same time, considering also that each Discursive Repertory is linked to the other ones according to the Dialogicity Index, the Dialogic Moment, a low degree of discursive configuration Dialogic makes a low capacity of the Repertories to create relations, indicating that the dialogic process can only minimally change (see the Periodic Semi-radial Table); a high degree of Dialogicity, instead, evidences a discursive configuration where the Repertories come more into relation with each other, therefore they get together making more convertible (high ostensive value) the attribution of the use value of a reality status (including the one set as the defined aim).

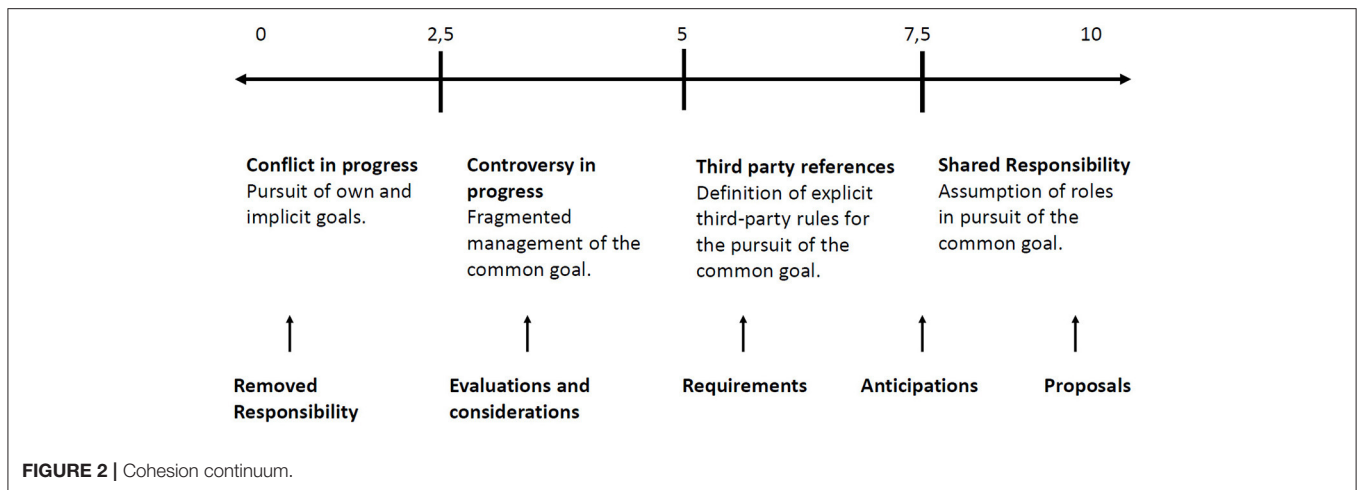

Hence, a high Weight and high Dialogic Moment is an indicator (in the uncertainty assumed as a Principle) of a high range of possibilities to generate reality sense with a high ostensive value; this brings a high uncertainty degree of the dialogic process trend, even against the adherence chances to the Targeting. A low Dialogic Weight and low Dialogic Moment configuration indicates, instead, that there are not many chances to generate reality sense (and therefore of adherence to the Targeting); such chances produce configurations that depict a reality sense, at high maintenance and exclusive level. We can

<sup>14</sup>The defined goal/objective, as part of the discursive space, can modify and change content; however, the adoption of the Targeting Repertory as an observer does not change.

<sup>15</sup>In the absence of empirical-factual causal links, it is not possible to “predict” what will happen, but one can rely on the narrative coherence of a discursive process in order to anticipate which configurations of reality could be generated compared to the available one (Turchi and Della Torre, 2017). The anticipation of future scenarios allows the members of a community to build shared management choices to go in the direction of the common goal.

<sup>16</sup>“Configuration of the interactive asset of the Community in which each member, or aggregation of members of the same, can build its own dialogic node in the interactive asset and thus contribute to its development, towards the generation of Social Cohesion for the entire Community of belonging” (Turchi and Gherardini, 2014b).

state, then, that the highest degree of adherence of a discursive configuration to the Targeting Repertory<sup>17</sup> is obtained from the wider (configuration possibilities) range that can be produced by employing ordinary language.

Operationally, we will name the Discursive Repertoires of the Table, considering the adequacy of the reported text with respect to the pursuit of the common objective of reducing the spread of the virus. This adequacy is observed in relation to the shared management, i.e., in the definition and adherence to third-party and explicit management rules.

The cohesion output measured by the index is calculated using the following formula:

$$\text{Cohesion Index} = C = \left( \frac{\sum dw}{\sum dm} \right)$$

From the formula, the highest adherence contribution to the Targeting Repertory is created from the use of the Description Repertory, while the minimal contribution is produced from the Justification Repertory use. It is by virtue of the formula result that the social cohesion construct continuum is defined.

The results of the analysis of the texts produced so far by this tool offer, for example, the starting point from which to develop intervention projects on interactions between Community citizens, but also the monitoring of the intervention itself, as well as the evaluation of its effectiveness (in the gap between the result before and after the intervention). The data analysis thus becomes employable in parallel with regulatory-institutional management, in order to increase its impact of effectiveness in interactive terms. The Cohesion Index is used within the Social Cohesion Observatory, a University project aimed at sharing with the Community data concerning the measure of social Cohesion of the Community in an emergency situation, while supporting the Veneto Region in its choices related to the pandemic fallout management.

The Cohesion Index, together with the measurement indexes of discursive interactions regarding a precise configuration of

reality (see examples above), offers a common lens of observation of what happens interactively as a result linked to the COVID-19 spread medical emergency—for instance, the discursive productions about this world crisis, the actions taken, the adopted behaviours, the found criticalities—the indexes make it possible to have available data that can be shared, on the basis of which the effects of the medical emergency can be taken into account interactively in the Community and their management can be scientifically based. The data offered by the Cohesion Index allows the population, starting from the institutional and political roles and task forces built specifically for the management of the emergency, to have data about how the Community is narrating what is happening: for instance, describing and offering shareable considerations, generalising issues, judging what is implemented in the territory, expressing opinions and points of view as regards the perceived concern, etc. Likewise, it allows to consider what possible developments could meet the configuration of the emergency reality in terms of change and its management, against such employed interactive modalities.

An application of the Social Cohesion Index took place in 2019 within the Municipality of Padua (Veneto): within the study conducted, several territorial hubs (citizens, services, businesses, and municipal administration) were involved, including the University. The survey protocols analysed produced data on how respondents narrate their role within the network of interactions in which they are embedded. In both districts considered in the study (Santo-Portello and Arcella), the calculated Generativity gave the output related to the degree of Cohesion: the respondents configure their role according to modalities that keep reality equal to itself, closed to the generation of alternatives (PD equal to 1.03885—**Figure 3**—and 1.605—**Figure 4**). This data constitutes what the public administrative apparatus can refer to in the construction of political choices for the management of the Community, to direct the narrations of the population towards the pursuit of a common objective, in view of Social Cohesion.

By decreasing what the Cohesion Index can offer in terms of measurement, it is possible to assert how, in the uncertainty

<sup>17</sup>As for the Targeting Repertory, it really is a high Dialogical Weight and a medium Dialogical Moment.

FIGURE 3 | Cohesion value—Santo-Portello District.

FIGURE 4 | Cohesion value—Arcella District.

of the interaction, every configuration of discursive reality that takes place in the infinite interactions contributes to generate narratives such as “I am not even sick, I would like to go out to dinner but you can’t, it’s like being locked in a cage,” but also “considering that from home I can’t move for legislative provisions, I could take advantage of it to propose a service for the less well-off in medical emergency situations.” Concerning the Social Cohesion construct and its measurement index, the first text exemplified above offers a personal position of the speaker, oriented to the satisfaction of the personal interests of the individual; the second textual example offers a proposal of a citizen oriented to the management, in terms of Shared Responsibility, of the critical aspects emerged interactively, towards the pursuit of the common goal of reducing the spread of the virus. The measure of Social Cohesion is therefore based on what is made available in the discursive modalities of language.

## CONCLUSIONS

The theoretical-methodological proposal described so far, focusing on the Community’s Cohesion and Health dimensions, brings added value to the management of the medical emergency repercussions. The value comes real by the measurement, through numerical data, of the interactive setup characterising the Community in this emergency period pursuing the common goal of reducing the SARS-Cov-2 contagion spread. The focus is placed on the dialogic interactive process leading and concurring to the creation of discursive productions, stances, behaviours, and actions related to the current situation where the human species lives. Added value that, again, is found in the chance, thanks to such measurements, to anticipate even the possible scenarios that could happen against the discursive modalities currently employed by the Community members, allowing for more effective and efficient management. This is made possible starting from the epistemological distinction between Soundness and Health, which makes it possible to consider the former within a purely organic panorama of individual body care, and the latter as part of an interactive plan involving all members of the Community: considering this scientific-fundamental distinction and the formalisation of the interactive-discursive modalities made available by Dialogical Science, the proposal indeed offers indications and rigorous tools for measuring and analysing the emergency context, as well as the possibility of monitoring effectiveness evaluations of the interventions implemented within the network of interactions between the members of the Community (Turchi and Gherardini, 2014b). The Cohesion Index also makes it possible to have the measurement of interactions available, offering shared and common data on which to base the construction of what allows management of the critical issues generated by the medical emergency at an interactive level, brought both by citizens and delegates of the various stakeholders. Such an index, in fact, enables the policy makers and the various management roles to effectively move in favour of the Community living in the territory, i.e., promoting the contribution towards a shared and cohesive management of the current emergency. To say it in simple words, having a datum describing and measuring how and by how much the community interacts, cohesively, adhering to prescriptions related to mask use in social distancing situations, enables the above-mentioned roles to adjust and precisely gauge the legislative prescriptions and their communication in order to maximise their efficacy. Moreover, these data enable the political-administrative roles to find management modalities that can be shared with the delegates of the various labour categories, opening up to scenarios that allow keeping the territory and the Community inhabiting it cohesive and Healthy.

These processes are enhanced in terms of efficiency and cost-effectiveness through the use of Machine Learning, which allows you to have the interactive scientific data you need to operate immediately available, including the margin of error of measurement, on a par with mathematical models. The availability of a scientifically founded measure makes it possible to manage the fragmentation of the way in which medical emergencies are managed, shifting them to the dimensions of

anticipation (and no longer prediction) and shared management with a view to Community Health and Cohesion. In taking charge of interactions between the members of the Community in times of emergency, it becomes possible to effectively support organic research in the medical field, offering the possibility to operate in the management of what happens interactively in the Community, i.e., what is not on a purely organic level.

In perspective, therefore, public policies are in a position to invest in the effectiveness of scientifically based interventions that support the political-administrative roles in the involvement of the Community to manage what happens within it, enhancing the effectiveness of normative prescriptions. At the same time, an efficiency criterion is met when public policies are in a position to manage, by optimising costs, the resources available in an appropriate and coherent way with the Community's own interactive arrangements. These changes can be found in various contexts, such as education and training (distance learning, through internal platforms), work (smart-working), soundness (construction of new intensive care beds or extended working hours for health workers), transport, economy, and so on. At an interactive level, what is generated in the face of the COVID-19 emergency also concerns the interactions between the members themselves, decreased and modified by the measures of isolation, quarantine, and social distance, and compensated by remote communications (video calls, teleconferences, instant messaging, etc.).

A limit to be considered and to be managed during the application of the index and of the naming method of the discursive Repertoires is the human expertise applied to the texts reading and naming process. The naming expertise is taught through *ad-hoc* courses for the application of the naming algorithm, available in literature since 2009 (Turchi, 2009).

Precisely to try to manage this limit, over the last 2 years a research project has been started to measure the human naming mistake, through a collaboration between the FISPPA Department and Padua's Mathematics Department. Such key data

for research enables making the current work (and the research) more accurate.

Finally, we anticipate how, once the medical emergency is over, it will be possible to trace the changes that it has generated in interactive terms in the *Communitas*, which can already be described from the narratives of its members. Through instruments for measuring and evaluating the effectiveness and efficiency of interventions, the proposal of Dialogical Science allows to support public policies through the management in anticipation of the infinite interactive possibilities related to the post-emergency period and the promotion of change in the direction of Community Health.

Kant L and Norman E (2021) Working Under the Gun: A Theoretical Analysis of Stressors Associated With the Re-negotiation of Norms and Control of Work Tasks During COVID-19. *Front. Psychol.* 12:577769. doi: 10.3389/fpsyg.2021.577769

The COVID-19 pandemic has led many of the world's nations to impose numerous preventive and mitigative measures to increase social distance, including various forms of home isolation and quarantine. A central premise for the current paper is that the COVID-19 situation is likely to constitute a massive re-negotiation of social and organizational norms, which may lead to psychological distress at the individual, family and interpersonal level. Virtually overnight, people have to re-define what is expected and deemed appropriate by a given group member in a certain social setting. This goes for all kinds of general social interaction, such as societal, even multinational medical demands on social distancing. Simultaneously it also goes for a sudden, gargantuan re-division of labor in a complex global system. We provide a theoretical analysis of the potential consequences of re-negotiation of norms from the perspective of four sets of psychological theory: Theory of professions; organizational strategic crisis responses; the job-demands-resources model; and theories addressing the interplay between norm violations and psychological distance. From these theories we derive three suggestions that the discussion centers around: (1) The COVID-19 situation leads to a massive re-negotiation of norms related to work, (2) The COVID-19 situation diffuses the demarcation between the various professional arenas and the private sphere, and this diffusion enhances the stress associated with norm conflict, and (3) Norm conflicts are enhanced by digitalization. Our discussion centers on potential stressors associated with the renegotiation of norms, and also includes a few suggestions for practice. For each theoretical suggestion, we give examples of how the suggestion may manifest itself with respect to (a) the work task, (b) the individual's relationship to their leader and/or organization, and (c) interpersonal relationships. We finally point to some theoretical and applied implications.

**Keywords:** benign violations, job stress, crisis management, norms, dual thresholds, counterproductive work behavior, professionalization, leadership

## INTRODUCTION

The COVID-19 pandemic has led many of the world's nations to impose numerous preventive and mitigative measures to increase physical distance between people, including various forms of home isolation and quarantine. By March 30th 2020 it was estimated that such measures affected 43% of the planet's population across 78 nations (Norwegian News Agency, 2020). We argue that such measures may cause a number of social norm negotiations, re-negotiations, and conflicts (e.g., Asch, 1951; Cialdini and Trost, 1998), and we address conflicts that may arise when the majority of the workforce suddenly is instructed to work from home during a situation like the COVID-19 pandemic.

Our main argument is that the current situation is likely to constitute a massive re-negotiation of social, organizational, and behavioral *norms*, which may lead to psychological distress at the individual and interpersonal level (cf. Thompson and Hart, 2006). The interpersonal level includes family, work, and other social interaction. Virtually overnight, people have to re-define what is expected and deemed appropriate by a given group member in a certain social setting. This goes for all kinds of general social interaction, such as societal, even multinational medical demands on social distancing. Simultaneously it also goes for a sudden, gargantuan re-division of labor in a complex global system. What happens to *the work task* stands front and center in understanding the re-division of labor (cf. Abbott, 1988).

In this paper, we address the potential consequences of this re-negotiation for workers in organizations. We are above all interested in the “social construction and sensemaking” close to the individual, which happens at the *nano level* (Thompson and Hart, 2006, p. 231). In other words our focus lies with *behavioral norms* created at the nano level, not the moral principles created at the macro level (Thompson and Hart, 2006).

## RESEARCH QUESTION AND AIM

We address the following research question: What type of role/work stressors is the COVID-19 situation most likely to entail for those who have had to work from home as the result of societal and organizational responses to the pandemic? We provide tentative answers to this question, formulated as a set of suggestions, by combining four sets of psychological theory. In addition, we formulate two more specific propositions that can be tested empirically and that can be used to inform practice.

Our primary aim is to combine existing psychological theory from different areas of psychology in order to provide a theory-based discussion of the types of role/work stressors that are likely to be associated with the COVID-19 situation. A secondary aim is to suggest some theoretical links between the four theoretical approaches, with a particular focus on how the COVID-19 situation exemplifies the general applicability of the Benign Violation Theory to situations of norm violations (cf. Kant and Norman, 2019).

Our discussion centers around the following theoretical suggestions: (1) The COVID-19 situation leads to a massive

re-negotiation of norms related to work, (2) The COVID-19 situation diffuses the demarcation between the various professional arenas and the private sphere, and this diffusion enhances the stress associated with norm conflict, and (3) Norm conflicts are enhanced by digitalization. Our discussion centers on potential stressors associated with the renegotiation of norms, and also includes a few suggestions for practice.

Four features of the COVID-19 crisis are central for our further analysis. First, it is *global*. Second, its nature and the mitigation efforts lead to direct authority-ordered imperative *changes for many forms of social interaction, including working life*, as well as indirect changes through organizational strategic crisis responses. Third, *the pandemic is but one of several associated crisis trajectories* (e.g., Oxfam, 2020). Fourth, the pandemic alone appears to have a *long duration* (Kissler et al., 2020; Moore et al., 2020). Combined with associated crisis trajectories the duration appears more certain and likely even longer.

## THE SCOPE OF OUR PAPER

COVID-19 affects the entire planet. A large part of the population, if not all, has been or will be affected by some form of quarantine measures. During shelter-in-place and quarantine measures, work has to be adjusted or radically changed. Such changes demand social renegotiation related to work. The changes related to work have some commonalities, and some differences. Commonalities may range from hygiene measures to changed work tasks, new job demands, and ambiguous norms. Differences are for the purposes of this paper above all whether it is possible to work from a distance or not.

This paper specifically addresses stressors for those who are currently employed, but who have had to *work from a distance* during the pandemic. For whom, amongst other stressors, ambiguity between the private and the work sphere increases, as does ambiguity between their work sphere and that of household members.

Thus, our paper does not address work life for essential workers who still have a job and have to do it physically present. For instance, health care workers, store clerks, transport operatives, garbage disposal workers, farmers, and many others. We do also not discuss stressors specific to *workers without a choice*, e.g., many in the “gig economy” who are forced out regardless of risks, or even while sick. If they do not work they cannot feed themselves or their dependents. The latter group may also include a larger proportion of those who quickly face unemployment.

However, in spite of the somewhat narrow focus, the implications of our work are potentially broad. This is due to the fact that investigating the chosen population promises more than knowledge for practical solutions during the COVID-19 crisis. It also holds promise for the future, far beyond a couple of 100 million privileged workers today. Understanding social renegotiation of distance work, is for instance relevant: (a) in light of a general digitalization trend; (b) as a seemingly necessary strategy during any future pandemic; and (c) as a

potential strategy against other dilemmas for a rapidly increasing world population, including global warming, large conflicts, and commuting logistics in urban mega-cities.

The aim is to put forward some theory-based suggestions for how the pandemic is likely to influence work life for the individual. Overall, this attempt exemplifies how it is possible to analyze complex situations by combining different sets of psychological theory. We do not aim to present a new theoretical framework to integrate different theories, but rather to show how different theories applied to a larger problem together can constitute the basis for empirically testable suggestions. Since the paper was written at the very start of the pandemic, it does not incorporate empirical evidence of what is so far known about the actual consequences of the pandemic. However, empirical verification or falsification of our suggestions can and most likely will be dealt with by a follow-up paper.

## THE SEARCH FOR RELEVANT THEORY

Our motivation for writing this paper was a deep sigh shared with millions around the globe. In line with everyone else who had to change aspects of their work life from one day to the next, we experienced stress, norm conflicts, and mismatched experiences in relation to our own work obligations and in relationship to work life of other family members. This made us curious as to how we can use psychological theory to understand the stressors and conflicts that characterize work life during a pandemic, and to make predictions about what types of norm conflicts are likely to arise at different levels of analysis.

The selection of relevant theories was based on a combination of different criteria. First, we wanted to include theories that address *norms* for appropriate vs. inappropriate behavior. Second, we searched for theories that were *universal* rather than COVID-19 specific, yet sensitive for crisis conditions. Third, theories had to be applicable to *working life*—in the sense that they describe processes that are regular responsibilities of leaders and managers, and address outcomes of stress and conflict that are likely and measurable among workers. Fourth, they should describe how *dilemmas* may be addressed through choices or negotiations. Our aim was to address a set of theories that would jointly cover a range of levels of analysis (i.e., individuals/dyads/groups/organizations/societies), and that would be complementary to each other and preferably be possible to link to one another.

## THEORETICAL FRAMEWORK

Based on the aforementioned criteria, we selected four theoretical frameworks which constitute the starting point for our analysis. First, we consider *theory of professions* (e.g., Abbott, 1988), which describes general mechanisms of control of work tasks, applicable in dramatic as well as less dramatic times. Mechanisms can be applied from macro to micro levels of analysis; from the societal to the workplace; between as well as within organizations. Secondly, we consider *strategic organizational responses to crisis* (Wenzel et al., 2020), which in turn may strongly moderate

contextual conditions for nano level norms and control of work tasks. Thirdly, we consider the *job demands and resources* model, the JD-R (Bakker and Demerouti, 2007) which can aid understanding how re-negotiation of norms and control of work tasks, as well as the organization's response to crisis may manifest in terms of objective and perceived job demands and resources at the individual nano level. Theoretically and empirically, job demands and resources are typically investigated at the workplace and affecting individuals or small groups. Fourthly, we consider models addressing *psychological distance and behavioral norms*, which can help understand causes and effects of perceived norm violations, not the least at the dyadic and individual level.

## Theory of Professions

Some of the potential conflicts that occur during re-negotiation of norms (e.g., De Dreu, 2010) during COVID-19, may be understood in light of *theory of professions* (e.g., Abbott, 1988). This ecological and systemic theory ranges from lower levels of analysis such as a workplace to societal levels.

A profession can be defined as “any occupation that competes for a work via (...) cultural activity” (Abbott, 2010, p. 176). Professionalization theory has *control over the professional task* as a pivotal point. For example, the medical profession has the exclusive control over sticking knives into people—a strong jurisdiction supported by societal level laws, public opinion, and by procedures and division of labor at the workplace arena. As pointed out by Scott (2008), occupational groups also compete about control over advanced technologies and new kinds of knowledge. Professionalization theory outlines a systemic and perpetual contest over such control. Clearly the COVID-19 situation leads to issues concerning control of professional tasks, advanced technologies and new kinds of knowledge.

Professionalization theory is well-suited to explain how the system of professions is influenced by various crises, as well as political or technological changes. Thus, the processes may work over time, or in intense bursts.

The mechanisms may work on a societal level, on a legal arena, or on a workplace arena. Furthermore, the mechanisms are the same *between* professions and *within* professions. Thus, domino effects may occur on several levels, and between and within entities.

Various external shocks, such as technological or demographical events, may reshape the conditions of the perpetual conflict in which professions normally exist (Abbott, 2010, p. 176). The COVID-19 situation clearly involves such “shocks.” The scale, the number of simultaneous and consecutive shocks, and speed associated with COVID-19 are notable. Severe shocks force different types of organizations to choose strategic crisis responses (see the section “Strategic responses to organizational crisis”).

An important point is that legitimate control of professional jurisdictions (Abbott, 1988) requires *legitimacy*—“the belief that authorities, institutions, and social arrangements are appropriate, proper, and just” (cf. Tyler, 2006, p. 376). Legitimate professional control may connote a jurisdiction or area of authority which is defined by law, but also by perceptions in the public eye, or by *psychological contracts* (cf. Thompson and Hart, 2006)

at the workplace arena. How people think about such social arrangements greatly influence their willingness to defer to them (Tyler, 2006).

An individual's behavior may be guided by personal conviction. However, notions of professional theory, legitimacy, and psychological contracts clearly point to the power of shared thinking on effective behavioral norms. In the case of stretching, breaching or fully breaking existing psychological contracts, we need to understand how perceived legitimacy and according deference to contracts may begin to waver.

To sum up, changes relating to control of work tasks may relate to who controls the work tasks; who or what has oversight, surveillance, and sanctioning rights (Dzieza, 2020); the relative importance of different work tasks; the status associated with various roles/tasks; the boundaries between professional and private tasks and responsibilities. Changes may also shift the balance of tasks performed in physical proximity vs. distally/digitally. We now turn to each of these shifts.

## Strategic Responses to Organizational Crisis

An organizational crisis occurs when the normal organization, resources, points of reference and sense of meaning are no longer sufficient (cf. Pearson et al., 2007; Narotzky and Besnier, 2014). This would be the case for many organizations during COVID-19. In times of crisis the regular division of labor is not enough, especially when the process of crisis escalation is vague and prolonged (Jacques et al., 2007; Buchanan and Denyer, 2013). Management may thus be uncertain about appropriately mobilizing crisis responses, thus displaying passive or *laissez-faire* leadership (Lewin et al., 1939; Skogstad et al., 2007). The daunting task of controlling the uncontrollable during crises, can even lead to destructive passivity.

In a recent review, Wenzel et al. (2020) present an overview of papers that address ways in which organizations can respond to crises. Wenzel et al. identify four broad categories of organizational strategic responses to crises. These are *retrenchment*, *persevering*, *innovating*, and *exit* (Wenzel et al., 2020).

*Retrenchment* involves reducing costs, assets, products, or overhead (Pearce and Robbins, 1994, p. 614, in Wenzel et al., p. 9). This causes the organization's business activities to narrow. A potential result is often a net loss for the organization, and may be detrimental in the long run. A different strategy is *persevering*, where attempts are made to sustain the organization's activity. It can be seen as a "status quo" strategy. In the initial stages of a crisis, *persevering* may be a rational strategy for various reasons, including the need for more information about the estimated nature and duration of the crisis. However, as pointed out by Wenzel et al. (2020, p. 10), this strategy only works in the medium run, with "slack resources" available. Passivity could be seen as a variety of *persevering*. *Innovating* involves a change, broadening, or renewal of the organization's scope of business activities. Wenzel et al. (2020) argue that *innovating* is likely to be beneficial in the long run, and sometimes key to survival of the organization. *Exit* means that the organization discontinues

with its activities. Whether an organization chooses this strategy depends on a number of factors, including the nature of the crisis and strategies at earlier stages of the crisis. Sometimes, exit is unavoidable. At other times it may be a deliberate strategy.

With a scope as in the current pandemic, all types of organizational responses, even initial *persevering*, may eventually lead to great change. We propose that these organizational responses constitute central vessels bringing the change into the work arena. In particular, vessels for change concerning the control of work tasks, and the demands and resources associated with work tasks.

## The Job-Demands-Resources Model

Thirdly, closer to the individual, the *Job-Demands-Resources model* (JD-R; Bakker and Demerouti, 2007), sheds further light on processes concerning work tasks: how changes in demands and resources influence what happens from an organizational level of analysis down to the individual. A sense of control is part of the backdrop to the JD-R model and its resources, for instance as manifested by the name of the earlier *demand-control model* (Karasek, 1979) which the JD-R extended.

The JD-R model has been central for understanding the interplay between two categories of factors that determine the level of stress in a given job situation. Both categories of factors can refer to physical, psychological, social, or organizational aspects of the job. On the one hand, *job demands* refer to job aspects that come at a cognitive and/or emotional cost and may lead to stress, because they require sustained effort or skills. *Job resources* refer to those job aspects that help the person to achieve their work goals, reduce job demands, and/or stimulate growth, learning, and development. Job resources can counter the effect of job demands, but are also valued in their own right (Bakker and Demerouti, 2007). Importantly, both sets of factors can operate at different levels of analysis, including at the work task, leadership/organizational, and interpersonal level. An important assumption of the JD-R model is that job strain and job motivation are influenced by two different psychological processes. Thus, it can be seen as a dual process model (Bakker and Demerouti, 2007). Job demands and resources also interact. For instance, according to the "buffer hypothesis," job resources can modify the negative effect of job demands on perceived stress (Bakker and Demerouti, 2007).

The JD-R model also acknowledges that *personal resources* (Bakker and Demerouti, 2007) can mediate the relationship between job resources and job engagement, but not buffer job demands on their own (Xanthopoulou et al., 2009). This is relevant during the COVID-19 pandemic, with workers exposed to both increased social demands and reduced job resources.

Bakker and Demerouti (2007) point out that job stress and motivation not only predict job demands and resources, but can also be outcomes of the two. For instance (poor) worker behavior may lead to increased demands and reduced resources over time. Also, a dark perception of demands and resources may lead to a deteriorating work climate and objective worsening of demand-resource combinations. Such reversed causation requires attention to other causes of job stress and motivation.

We suggest that the fourth theoretical framework below is useful for this end.

## Models Addressing Psychological Distance and Behavioral Norms

When norms are re-negotiated, this implies changes to what is perceived as acceptable vs. unacceptable, both at the nano level, interpersonal level, and societal level. When psychological contracts are stretched in a manner that violates one's expectations, this violation may be perceived as either benign/legitimate/acceptable or malignant/illegitimate/unacceptable.

*The Benign Violation Theory* (henceforth BVT; McGraw and Warren, 2010; McGraw et al., 2014) explains how emotional responses to norm violations depend on whether the violation is regarded as benign or malignant. This is originally a theory of humor, but can be applied to other situations in which a norm violation leads to emotional reactions (Kant and Norman, 2019). For something to be regarded as funny, two types of appraisal must be present simultaneously. First, something must violate expectations of how something "ought" to be, e.g., violating a linguistic norm. Second, this violation must be perceived as benign rather than malignant and hurtful. As Kant and Norman (2019) argue, other dual threshold models of social behavior describe a similar process where behavior may violate some expectations or norms, while being acceptable in a sweet spot prior to passing into the unacceptable. For instance, concerning anger in organizations (Geddes and Callister, 2007), leadership, or extra-role behavior at work (e.g., Spector and Fox, 2010).

In this paper, we refer to "mismatched experiences" and/or "mismatched sweet spots" in cases where a norm violation is perceived as benign by one person and malignant by another, resulting in different emotional reactions. The term psychological distance is important for understanding norm violations and mismatched experiences (Kant and Norman, 2019). According to *the construal level theory (CLT)* of psychological distance (Trope and Liberman, 2010), something or someone may feel closer or further away in terms of geographical distance, social distance, temporal distance, and hypotheticality. Something which is further away is represented more generally and abstractly, whereas something which feels closer is represented more concretely.

Telecommuting in general, and the COVID-19 situation in particular may influence psychological distance in all its dimensions. Geographical or physical distance to coworkers and leaders is typically increased, particularly so during the pandemic with mitigation strategies against contagion. Interaction frequency may go down, but also increase through online work environments. Social distance—not the least in terms of power asymmetry—may increase, become more unclear, and conceivably also decrease. Psychological distance to people in the same household may move in an opposite direction. The psychological distance to work tasks may also change.

Of special interest here is *leadership distance*, which can be understood in terms of three dimensions, namely, *leader-follower physical distance*, *perceived social distance*, and *perceived task interaction frequency* (Antonakis and Atwater, 2002). Leader-follower physical distance refers to the geographical distance

between leader and follower. Perceived social distance refers to differences in status, rank, authority, social standing, and power. These are assumed to influence perceived intimacy and social contact. Perceived task interaction frequency refers to how often the leader and follower interact, either face to face or digitally.

Geographical and temporal distance moderates norm violations (McGraw et al., 2014). When something *feels* close to us, it takes a smaller violation for it to be considered malignant. A higher intensity is possible when distance is greater. Sweet spots in leader-follower interactions related to the dimensions of leadership distance have also been substantiated empirically (Vanderstukken et al., 2019; Gouldman and Victoravich, 2020; Hernández et al., 2020).

Third, differences in perceived psychological distance between two parties may cause mismatched experiences of whether a violation is benign or malignant (Kant and Norman, 2019). Also, the relative distance to the norm-violation itself (here the work task or changes in demands or resources) works in the same way. For instance, the psychological distance to other parties or to a norm-violation will likely be experienced differently by a high-power party—such as a leader, an official, or a member of a dominant social group, compared to a low-power party—such as a worker, citizen, or member of a subordinate group. The changes and renegotiations during COVID-19 should therefore be considered in terms of their potential for mismatched experiences.

## DISCUSSION

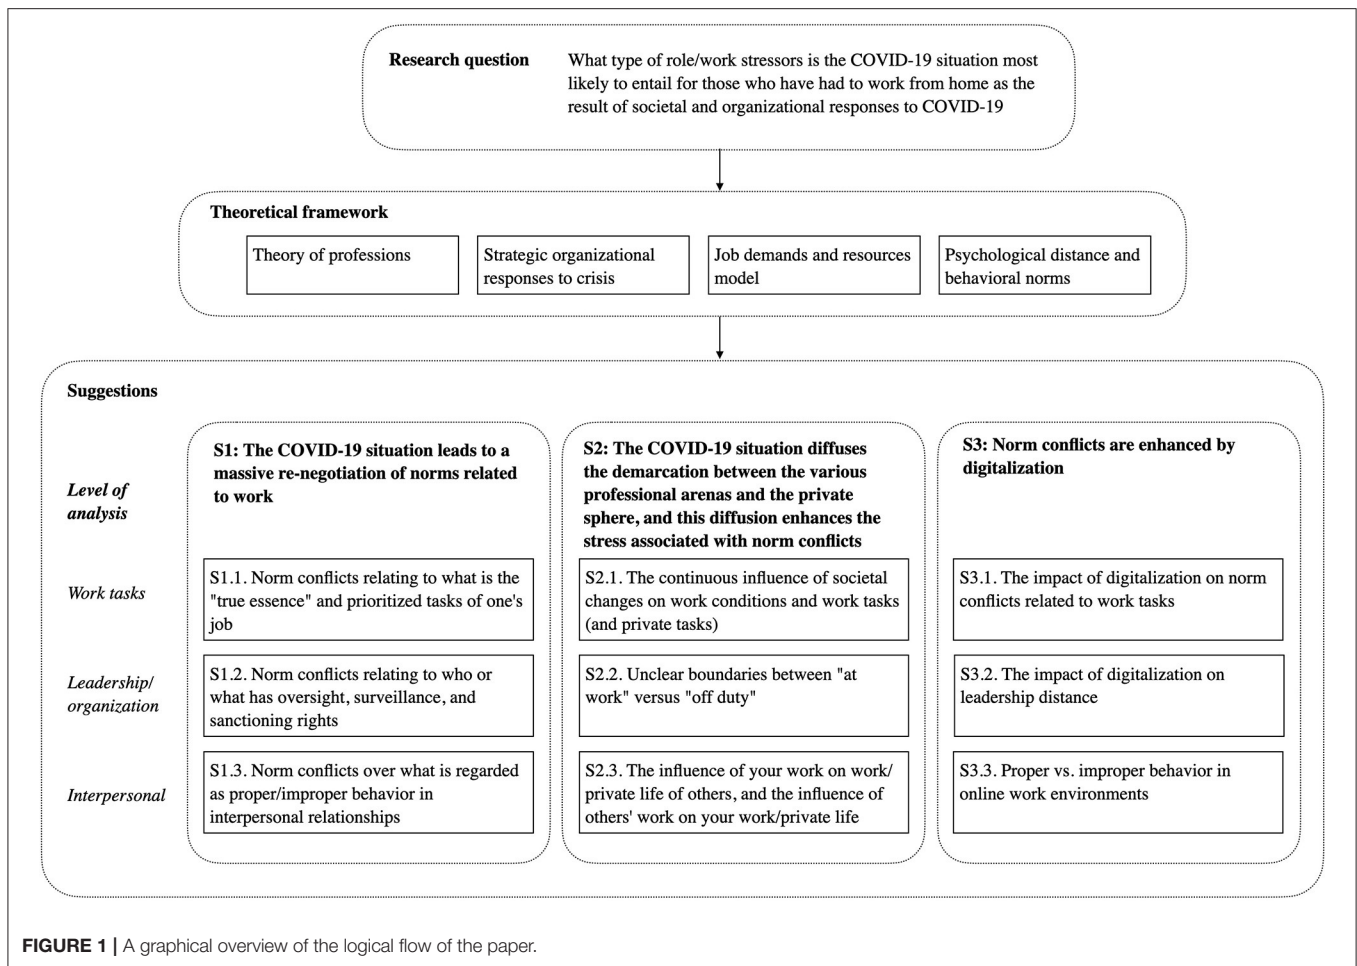

We now present 3 theoretical suggestions for what type of role/work stressors the COVID-19 situation is most likely to entail for those who have had to work from home as the result of societal and organizational responses to COVID-19. The stressors are related to different factors over which people currently have to re-negotiate. These suggestions are derived from our knowledge of the four sets of theory presented in the previous section of the paper.

For each suggestion, we first give a general introduction to what the suggestion implies at a general level. We then provide 3 sets of examples, at the level of the *work task*, *leader/organization*, and *interpersonal relationships*, respectively. We supply a graphical overview of the suggestions in **Figure 1**.

### Suggestion 1: The COVID-19 Situation Leads to a Massive Re-negotiation of Norms Related to Work

The COVID-19 situation involves multiple, massive changes at the societal, organizational, dyadic, and individual levels. People have to reorient themselves about what is expected, acceptable, etc. We refer to the process of establishing new norms as "re-negotiation of norms." We will address 3 sets of factors over which people now have to re-negotiate. There may also be other factors.

Using the terminology of the Benign Violation Theory (McGraw and Warren, 2010), norm re-negotiation implies that what yesterday was acceptable behavior, may today be unacceptable. To use the terminology of BVT: The dual

thresholds have moved. Different parties may experience different shifts in dual thresholds, the contextual premises, and psychological distance to other parties and to the subject matter. In line with our hypotheses put forward elsewhere (Kant and Norman, 2019) we therefore expect *widespread and frequent experienced norm violations* of both benign and malignant nature during COVID-19. Above all, we expect many *mismatched experiences*, where one party perceives a violation where the other does not.

Moreover, we suggest that *the mere re-negotiation of norms could itself be seen as a stressor*. Re-negotiation is a general stressor in society, and a variable that increases perceived job demands in connection to work (cf. Bakker and Demerouti, 2007). By this we mean that both *uncertainty* ("Is task X important anymore?" "By which authority am I to do the old X or the new Y?" "Will I get paid for doing X or Y?") and *change* ("It seems I can't carry on doing what I normally do.") might demand more of the individual. The *result* of this re-negotiation ("I have to do more of Y and less of X." "I seem to have less autonomy doing Y") could also be demanding.

The violation of norms is likely to be strenuous: cognitively as represented in the previous questions, and by a more than usual

need to suppress, enhance or fake emotions (cf. Glasø et al., 2006; Gailliot et al., 2007; Bushman et al., 2014).

Importantly, norm re-negotiation could take place overtly—with people being aware that re-negotiation takes place. Yet, it might also occur covertly—with people being unaware of the re-negotiation process or how their communication might be perceived. Regardless of people's awareness of the process, we expect that most people are tired, confused, and step on each other's toes more than before.

We specifically hypothesize that the intensity of social renegotiation is positively correlated with the slope of change in crisis intensity (both increasing and decreasing slopes). We provide a tentative, graphical overview over how we hypothesize the intensity of re-negotiations of norms will vary across different stages of a crisis (see **Figure 2**). Our overview builds on established research on how a crisis is known to develop (see references in caption to **Figure 2**). Simply put, we predict re-negotiation to peak while societies close down as well as when they are opening up. During lock-down, particularly with prolonged duration, temporary settlements will calm things down. During a de-escalation phase (e.g. Fink, 1986; Mitroff, 1988) we however hypothesize greater variance in norms and

behavior, than during the escalation. Thus, norm conflicts may increase even more during de-escalation.

### The Level of Work Tasks: Norm Conflicts Relating to What Is the “True Essence” and Prioritized Tasks of One’s Job

The first set of factors over which workers have to re-negotiate, concerns the work tasks. Some central questions are: *What is the “true” essence of my job? Which are the prioritized core tasks? What is true in a short term crisis vs. a long term one?*

#### Changes in Nearly all Aspects of Work Tasks

Physically moving one’s workplace from the site of the organization to one’s home, may require brutal prioritization of certain tasks at the cost of others. First, there might be work tasks that simply cannot be conducted from a distance or digitally, i.e., by telecommuting. Second, the work situation might lack sufficient time and resources to do all the tasks one normally is responsible for. In theoretical terms—a sudden shift in job demands and resources (cf. Bakker and Demerouti, 2007). Possibly related to limitations to technical equipment, or having to distribute one’s time between work and taking care of quarantined household members. Third, the organization’s crisis response (cf. Wenzel et al., 2020) could cause changed task prioritization.

#### What Is the Essence of My Job?

Especially with organizational retrenchment or innovation crisis responses, workers are forced to consider the “true” essence of their job. Some might have to do the tasks of the lost workforce. Someone in an organization suddenly re-defining its goals and priorities, might have to use their skills differently. With an organization that attempts the perseverance strategy, the initial phase will likely lead to differentiated work-load and prioritization of work tasks within the organization. Some, like crisis managers and IT-technicians, may have an intense workload with both old and new work tasks. Others may have very little to do, and ambiguous conditions for taking initiative, prioritizing, and even being visible (cf. Elsbach et al., 2010).

#### Unclear Expectations and Lack of Choice

One thing is what happens to explicitly defined tasks, i.e., tasks that are clearly described and with clear expectations. Another is what happens to tasks that are less clearly defined, and to possible flexible space in between tasks. With a crisis and some response strategy declared, the first casualty in professional control and autonomy (cf. Abbott, 1988) is likely the flexible space in between work tasks, much like the short seconds in between tasks at the conveyor-belt (cf. Dzieza, 2020). Less clearly defined tasks may still be expected to be performed, but without time or other resources. New tasks may similarly have been added, without time, resources, or even pay. The teacher may have to do janitorial and cleaning tasks in the partially opened school, at the same

time as having to be a purchaser of IT gear at home, performing janitorial tasks at home, and providing tech-support for the home-schooled children. This in addition to revising curriculum and pedagogical methods to suit the new constraints either in a partially opened school, or in an entirely virtual format.

Meeting the expectations heavily dictated by the organization's chosen strategic crisis response (cf. Wenzel et al., 2020) may thus be a conflicted battle between nominal core tasks on one hand, and implicit, new, and other people's tasks on the other. This, while interstitial "empty" time slots likely have disappeared.

What if a worker tries to say no? Strongly attempting to enforce previous "peacetime" division of labor and work tasks may be perceived as a malignant violation (cf. Kant and Norman, 2019) by leaders and colleagues, even by family members in a shelter-in-place situation.

Should workers display *counterproductive work behavior* (CWB, Spector and Fox, 2010), then increased job demands and reduced job resources could follow, as specified in the JD-R model (Bakker and Demerouti, 2007). Their *negative perception* of available JD-R may also lead to a deterioration. A mismatched perception as described by Kant and Norman (2019) with psychological contracts violated (Thompson and Hart, 2006) may thus lead to both of those mechanisms for reversed causation in the JD-R (cf. Bakker and Demerouti, 2007). If violations in the eyes of workers are experienced as *illegitimate* (cf. Tyler, 2006) worker behavior or perception may be even worse.

### ***Re-negotiation as an Opportunity***

For some, renegotiation is an *opportunity*. Turmoil provides opportunities to grab new jurisdictions for entire professions (Abbott, 1988), and new market shares and innovations for organizations (Wenzel et al., 2020). Also, at the workplace level, individuals may completely fulfill every expectation, thus demonstrating that they are essential workers and at least should be prioritized to continue having a job. They may even display desirable *extra-role behavior* such as *organizational citizenship behavior* or OCB (Spector and Fox, 2010) meriting for new responsibilities or even promotion. Incidentally, we consider the latter to be a potential for the reversed causality in JD-R. Yet, the opportunities for the worker may lead to violations from the employer to be experienced as benign, and thus help them cling on to the edges of the best JD-R quadrant (average strain and high motivation) rather than dropping into the worst as perhaps otherwise expected (cf. Figure 7 in Bakker and Demerouti, 2007, p. 320). Thus, the same basic mechanism of shifting norms—moving goal posts—may explain why leaders suddenly may perceive the worker's helpful OCB as harmful CWB, and why workers suddenly may perceive constructive leader behavior as destructive (cf. Einarsen et al., 2007). This mechanism may be a useful contribution in answering the question Spector and Fox (2010) pose about the relationship between OCB and CWB.

The first step for taking advantage of the opportunities is probably hitting the sweet spot of one's leader, and perhaps colleagues. Can it be an acceptable violation in the short term? Then perhaps it can be a winning gamble in the long term. To a degree this poses an individual level parallel to the organizational strategic crisis responses. Yet, many are not at liberty to choose at

all. They may instead experience extreme versions of professional or workplace lock-in (Aronsson et al., 2000).

### **The Level of Leadership/Organization: Norm Conflicts Relating to Who or What Has Oversight, Surveillance, and Sanctioning Rights**

The second set of factors over which re-negotiation now takes place, concerns power distribution: During the COVID-19 pandemic, who or what has oversight, surveillance, and sanctioning rights? For the focus of the current paper, these questions mainly concern the individual's work tasks. However, an understanding of oversight, surveillance, and sanctioning rights of an individual's work tasks also requires power distributions at a societal level.

### ***Above and Beyond the Call of Duty***

At a workplace arena, norm conflicts get close to the actual work tasks and the individuals performing them. Irrespective of the organization's strategic crisis response (cf. Wenzel et al., 2020), there will likely be discussions around demands beyond what workers are contractually obliged to do, to ensure the survival of the organization or to help clients. Such requests "above and beyond the call of duty" tap into the realm of extra-role behaviors such as OCB and CWB (Spector and Fox, 2010). Such requests are vague in the sense of being open ended, lacking contractual descriptions, and not waiving the worker from doing all the regular tasks. Especially workers who experience threats to their employment, may attempt to meet both the nominal and the vague OCB expectations. In terms of the JD-R model this constitutes an increase in demands, reduction of resources and control (cf. Bakker and Demerouti, 2007), which in itself approaches unhealthy work conditions (Karasek, 1979). If combined with fear of losing one's job, the *lock-in effects* come into play, further straining the worker (Aronsson et al., 2000). Who actually asks for the OCB, judges and sanctions whether it has been fulfilled, is likely to be unclear to the individual worker. If it is equally unclear which resources are available, and where their responsibility begins and ends in relation to other work tasks of other workers—the norm conflicts have truly landed in the individual.

### ***Exploiting Norm Conflicts***

Norm conflicts can also be exploited, both by individuals and groups, including professions. When previous jurisdictional settlements are upended opportunities may reveal themselves (Abbott, 1988). Individuals or groups may be able to get defined as an essential worker, or expand their jurisdiction into more attractive and lucrative tasks. Organizations may be able to grab market shares or venture into new markets. We must remember that (a) norm conflicts carry the seed of both threats and opportunities, and (b) they exist in a system, where movement in one part often influences other parts. This realization is helpful not only in understanding resistance or absence of it toward change (cf. Oreg, 2006). It is also helpful in practice to avoid these processes stealing unnecessary energy.

## The Interpersonal Level: Norm Conflicts Over What Is Regarded as Proper/Improper Behavior in Interpersonal Relationships

In a situation where norms are negotiated or re-negotiated, there is a potential that the perception of norms and norm violations differ between individuals (Kant and Norman, 2019). Thus, to understand norm re-negotiation, we need to also turn to the interpersonal level.

### *Norm Violations: the Line Between the Acceptable and the Unacceptable*

Everyday social interaction at work may be tricky. For instance, while one person might find it acceptable to start the working day an hour later than usual during the lockdown, another might find the same behavior unacceptable. Moreover, a norm violation seen by one person as benign, could be perceived as malignant by another. Using the same example, even if two people agree that the COVID-19 situation should not influence when the working day starts, one person might find it funny that another person gets up an hour late, while another could find it unacceptable and annoying. In terms of the BVT (McGraw and Warren, 2010), the “sweet spot” of different people is mismatched. The risk of this could be increased for a number of reasons during COVID-19. Multiple norms are re-negotiated, and for many people in telecommuting conditions, re-negotiation also takes place largely without face-to-face communication. Accordingly, it becomes more difficult to perceive each other’s subtle social signals, including those that communicate what is acceptable and unacceptable. In essence, the limited cues known from virtual teams and telecommuting gets paired with low skills in virtual social interaction (cf. Arvedsen and Hassert, 2020), and paired with an entire norm-system in turmoil.

Re-negotiation of norms in combination with less face-to-face interaction increases the risk of norm violations, which has a number of potential implications. One is that humor becomes a riskier activity. When moment-to-moment social feedback is lacking, it also becomes more difficult to judge what is morally/ethically correct. Another is that leader–follower interaction and leadership pertaining to interpersonal behavior becomes more difficult.

### *Interpersonal Difficulties in Crisis Organizations*

Three phenomena can illustrate how organization or group level norm conflicts may cause difficulties at the interpersonal level. If awareness, leadership, and crisis management training are lacking, then navigating the new developing norms is likely to be tricky. Knowing basic dance steps is simply advantageous. If no one knows a single step—someone is bound to get stepped on.

First, leadership in crisis may become *heterarchical* as opposed to hierarchical (Nesse, 2017), with multiple formal and informal leaders assuming and giving responsibilities away. In a trained organization this may work well (Nesse, 2017). However, the potential vagueness, role ambiguity or outright role conflicts (Wong et al., 2007) may prove highly troublesome in organizations or teams that are unfamiliar with these new roles (cf. Espevik et al., 2006).

Second, *shared mental models* are important cognitive phenomena during crises (Cannon-Bowers et al., 1993), necessary for establishing of clear roles, shared situation awareness and shared mental models about goals and solutions. Carrington et al. (2019) showed that in prolonged crises, many shared mental models about solutions emerged from the ranks or from lower management levels. If higher management and the organization are unable to communicate and listen well, the best solutions may be overlooked, or even considered malignant violations.

Third, organization level thresholds for behavior, e.g., concerning displays of emotion, may change. A crisis rigged organization is different from the everyday organization. The sense of urgency and narrowed scope of objectives may change norms for interpersonal behavior. Empirically, the dual thresholds (cf. Geddes and Callister, 2007; Kant and Norman, 2019) was found to shift for crisis managers’ aggressive behavior (Larsson et al., 2001): expressing some anger and other emotions was more tolerated, even expected. Yet, the maximum acceptable expression was reduced. In other words, more welcome to show, but with a stricter upper limit. However, workers may be less welcome to show any aggression—needing to inhibit, to perform emotion work in order to keep their job (cf. Glasø et al., 2006). The norms for displaying other emotions may similarly be shifted in line with dual threshold models (cf. Geddes and Callister, 2007; Kant and Norman, 2019). Displays of joy in a hospital ICU-unit, or jokes at the COVID-19 presidential task force press briefings may have changed norms.

### *Emotional Responses to Perceived Malignant Violations*

In addition, follower frustration and their behavior may bring existing norm conflicts to the surface, particularly in the eyes of leaders. If we consider that workers may experience the re-negotiation process, the (limited) level of support from leaders and the organization (cf. Bakker and Demerouti, 2007), the resulting work tasks (see section The Level of Work Tasks: Norm Conflicts Relating to What Is the “True Essence” and Prioritized Tasks of One’s Job) and associated new control as *malignant violations* (cf. Kant and Norman, 2019) the perceived strain would likely increase even more. If the worker experiences malignant violations, the most immediate outcome is *emotional responses* (cf. Warren and McGraw and Warren, 2010). Merely *inhibiting emotions* is literally energy draining—each act of inhibition gnaws on one’s glucose level (Gailliot et al., 2007), and could result in the display of counterproductive behavior (Bushman et al., 2014). Even under normal circumstances, workers and leaders engage in a lot of *emotion work*—inhibitions and exaggerations of actual emotions (Glasø et al., 2006). It is fair to expect that emotion work gets even more intense when uncertainty is high, when norms are unclear, and when employment is at risk, as during COVID-19. As mentioned in The Level of Work Tasks: Norm Conflicts Relating to What Is the “True Essence” and Prioritized Tasks of One’s Job, the strain of inhibition and emotion work, and the emotions themselves may fuel both perception and behavior, which may have a detrimental impact on job demands and resources (cf. Bakker and Demerouti, 2007).

Extra-role behavior may be both desirable and highly undesirable. Perhaps a steep curvilinear effect may be found in high turmoil/crisis conditions. It is conceivable that some OCB—above and beyond the normal call of duty—is expected, but not much, lest you quickly irritate colleagues and leaders by doing anything but the core tasks.

## **Suggestion 2: The COVID-19 Situation Diffuses the Demarcation Between the Various Professional Arenas and the Private Sphere, and This Diffusion Enhances the Stress Associated With Norm Conflicts**

A premise that might shape the nature and outcome of re-negotiation of norms, is the fact that societal restrictions following COVID-19 has caused different arenas to be “merged” into people’s homes. Discussions and negotiations normally belonging to the societal and organizational arenas, now occur in the home arena. For instance, active negotiations with one’s boss about the distribution of work tasks, could occur in the bedroom. Board meetings have people working from their living rooms, kitchens, bedrooms, etc.

One implication is that the demarcation between various professional arenas and the private sphere, is diffused. In the following, we exemplify how this diffusion may enhance the stress associated with norm conflicts at the 3 levels of analysis.

Our suggestion is that the technological and demographic changes (or “shocks”) occurring as a direct or indirect result of COVID-19, may reshape the conditions of the perpetual conflict professions normally exist in (Abbott, 2010). They also influence work and private conditions of individuals more and quicker than under normal circumstances.

According to theory of professions the struggle about control of work tasks occurs in 3 arenas: the workplace, the public arena, and the legal arena (Abbott, 1988). In the current pandemic, the private sphere is no longer separate from the classical three arenas: This demarcation becomes more diffuse and permeable. Re-negotiation appears to occur in all three arenas as well as the private sphere, simultaneously or nearly so.

We will mainly discuss re-negotiation of social norms in the work arena for people currently working from home. In addition, we point to how the COVID-19 situation challenges professionalization theory’s assumption that changes occur at a higher pace in the work arena, followed by the public and legal arenas. For example, some recent changes in the work arena could be seen as direct consequences of more rapid societal changes.

### **The Level of Work Tasks: The Continuous Influence of Societal Changes on Work Conditions and Work Tasks (and Private Tasks)**

The COVID-19 situation is like a rhinoceros in a china shop: some professional tasks are put on hold over night (e.g., restaurants, hairdressers, and travel workers), whereas others have a corresponding increase in demand (e.g., health care nurses, laboratory testing, producers of antibacterial liquid),

and new ones previously unclaimed ones have emerged (e.g., new business ideas like 3D-printing of face visors on a 1,000 home computers).

The theory of professions (Abbott, 1988) describes how radical changes in control of professional tasks lead to domino-effects, conflicts and re-negotiations. Accordingly, we would expect all three arenas of jurisdictional contest to be in turmoil during COVID-19. Moreover, the changes in all arenas may occur in different ways and in a different order than normally.

Typically, the legal arena is slow to change, the public arena is more dynamic, and the workplace arena is the most dynamic. Presently the workplace arena not only has moved into your home, it is also in minute-to-minute flux, the public arena is changed every week or even day, and the legal arena is also moving fast with new legislation swiftly made. Furthermore, one could hypothesize that the typical sequence has changed. Instead of laws generally being changed after public opinion, authorities have established laws before or even contrary to public support. Authorities set normal laws aside, and start using rarely used or even obsolete laws.

A common sequence during COVID-19 has been that the prime minister has executed direct orders—for schools to shut down, people to shelter-in-place, curfews, and so on. Accordingly, the prime minister’s order created an involuntary serviced office in your bedroom. Suddenly a number of organizations who never interact had to collaborate: the employers and schools of the household members sent their work tasks into the same bedroom. A need for resources emerged, for desks, Wi-Fi, and computers. Issues of ethics, health, and security unanswered, and which organization would be responsible for anything else than the demands on their workers. In theoretical terms: with great ambiguity concerning job demands and resources (Bakker and Demerouti, 2007), contracts psychological (Thompson and Hart, 2006) and legal alike, as well as norms for appropriate behavior (Kant and Norman, 2019).

However, societies seem to approach formulating, implementing and communicating their influence differently. The clarity and firmness vary, reminiscent of the norms of tight and loose cultures (cf. Gelfand et al., 2011). China and Norway implemented clear and strict rules early, e.g., with laws and police sanctions against staying at summer houses in Norway. Sweden implemented recommendations, which seemed more to play on internalized norms, lest one was to suffer shame and annoyed looks. The federal administration of the US, however, presented vague, inconsistent and contradictory statements, particularly from President Trump himself. Trump’s statements were often in stark contrast to those of medical expertise and other officials (cf. Brennen et al., 2020; The Lancet, 2020). The gradual opening of societies has largely followed similar patterns. How well these strategies will work is a question for future research. We hypothesize that the looser strategies will increase variance in norms and behavior, and accordingly result in more norm conflicts, in particular as societies open up. Thinking ahead and creating predictability is part of elementary crisis management in order to proactively combat the main problems, and also part of minimizing the turmoil associated with re-negotiation of norms.

Societal changes in the public arena may also influence work tasks. Poor workers who have no choice to telecommute, may work under the gun to provide for their families (cf. CNN, 2020; Lind, 2020). They may be forced to work under conditions contrary to authority recommendations, or to view the latter as illegitimate (cf. Tyler, 2006) and end up at the state legislature of Michigan with guns.

Public events may lead to sudden changes for entire professions and their work tasks (cf. Abbott, 1988). An example concerns the debate on professional tasks for the US police force which surged following the killing of George Floyd by police, in the midst of the pandemic (Hill et al., 2020). Strong arguments were made to “defund the police”, in terms of stripping funds and professional tasks such as dealing with substance abuse, marital interventions, homelessness, and many other tasks from the heavily funded and heavily armored police.

### The Level of Leadership/Organization: Unclear Boundaries Between “At Work” vs. “Off Duty”

In the COVID-19 situation, a vast number of (mostly) office workers have had to move their workplace to the home arena. For most, this has happened suddenly and without sufficient time to make optimal adjustments to technical equipment, furniture, etc. In addition, many have household members in a similar situation. For instance, one’s partner might be working from home, and children in the household be home schooled or stay at home because childcare is closed.

In this situation, drawing the line between being “at work” vs. “off duty” may feel even more difficult than usual. One reason is reduced physical distance between the home and work arenas. Combined with various government recommendations/regulations that restrict people’s opportunities for transport, leisure activities and social contact, this could result in feelings of constantly being “trapped” in a semi-work situation where it is difficult to declare to oneself and to others that “I’m off duty.”

### Perceived Psychological Distance to the Organization

Related to this is the perceived distance between the individual and the organization. Chen and Li (2018) have specifically looked at employee-organization psychological distance, in an attempt to better address interpersonal psychological distance, which they argue is limited in CLT (Trope and Liberman, 2010). Chen and Li (2018) constructed and tested a self-report inventory to measure the various dimensions of employee-organization psychological distance. We here briefly outline each of these suggested dimensions. *Experiential distance* refers to how the individual perceives the future of the organization, based on how they assess a current experience or trend. *Behavioral distance* is the individual’s perceptions about their affinity for the organization. *Emotional distance* refers to individual’s emotional experience in corresponding and interacting with the organization. The authors exemplify this as the perceived “sense of oneness,” “sense of honor,” and “sense of experience.” *Cognitive distance* is the individual’s perceived affinity for their organization, in terms of value orientation and personality consistency. *Spatial-temporal distance* refers to how close the individual feels that

the organization is in space and time based on their level of involvement and understanding. Finally, *objective social distance* is the felt distance to the organization based on how closely one identifies with it.

### COVID-19 Leading to an Increase in Emotional and Spatial-Temporal Distance to the Organization

Working from home during COVID-19 might in particular increase the employee’s emotional and spatial-temporal distance to their organization. The organization’s “affinity” for the worker may be reduced if the worker is less visible (cf. Elsbach et al., 2010). If the organization is at risk, it could also increase experiential distance. At the same time, other forms of employee-organization psychological distance could be reduced in the current situation. This applies in particular to cognitive distance, cf. the fact that any major crisis could force an organization to re-define and/or communicate more clearly around its core values.

As described earlier (The Level of Work Tasks: Norm Conflicts Relating to What Is the “True Essence” and Prioritized Tasks of One’s Job), COVID-19 may influence distance to the work task. Especially for telecommuters, the work task may come extremely close, invading every aspect of private life. This could be even when the organization itself and its members would feel unusually distant. Norm violations include not only two parties, but a violating act such as a changed work task or job demand. Kant and Norman (2019) suggest that psychological distance needs to be considered between the two parties, the violating act, and the relative relationship between the three. Thus, we think that adding the work task and the relative distance between the task, the organization and the individual worker, may be an interesting amendment to the Chen and Li (2018) view of the relationship to the organization as an interpersonal relationship between two parties.

Overall, leaders should attend to decreasing psychological distance to job resources, and to increasing psychological distance to job demands (cf. Bakker and Demerouti, 2007). At least markedly protect against unnecessary invasion of private, off duty life. This may be hard for leaders in a crisis situation, where their knee-jerk reactions are likely to attempt increased control, and sending out signals whilst having limited capacity to respond.

### The Interpersonal Level: The Influence of Your Work on Work/Private Life of Others, and the Influence of Others’ Work on Your Work/Private Life

We now turn to the possible impact of unclear organizational boundaries and expectations upon the interpersonal level. How does work influence one’s private life during COVID-19? And when several people are working from the same household, and several organizations are represented in the same home, how does one person’s work influence the private life of others?

The consequence of working from home might differ between individuals. Kossek (2016) identifies 3 different styles that people adopt for dealing with work-life boundaries in a digital age. The styles represent different ways of dealing with 5 trends of modern work life: that work and non-work roles are increasingly blurred and overlapping (i.e., “boundarylessness”); that people are increasingly forced to work non-standard and specialized

hours (“work-life customization”); the lack of control over when one is “on” vs. “off” work (“psychological control over working time”); an increase in interruptions between work and private life (“work—life fragmentation”); and the fact that people have multiple social identities (“diversity and inclusion”).

During COVID-19, people previously not working from home have now been forced to do so. This may impact various job demands and expectations about being “virtually present” at different hours than before. Thus, COVID-19 is likely to impact several of the 5 trends identified by Kossek (2016): in particular boundarylessness, work-life customization, psychological control over working time, and work-life fragmentation.

The 3 “work-life boundary management styles” identified by Kossek (2016) are integrator, separator, and cyler. An *integrator* is someone who has frequent work to non-work interruption behaviors and/or frequent non-work to work interruptions, either because this is their preference (“fusion lover”) or because they feel they have no other choice (“reactor”). A *separator* has a low frequency of both work-to-non-work and non-work-to-work interruptions, either by conscious choice (“divider”), or because the nature of the workplace prevents such interruptions (“captive”). A *cyler* is someone who periodically, be it weekly or seasonally, separates between work and non-work, and at other times integrates the two.

Based on these distinctions, one might predict that working from home would be less stressful for integrators or cyclers, but more stressful and difficult for separators. Moreover, the extent to which one’s private life is influenced by other household members’ work might depend on the other person’s management style, as well as the degree of correspondence between one’s own and the other person’s work-life boundary management styles.

### Suggestion 3: Norm Conflicts Are Enhanced by Digitalization

So far, we have addressed and exemplified the types of norm re-negotiations taking place during COVID-19 (Suggestion 1), and how the stress associated with such re-negotiations may be enhanced due to the diffusion of the demarcation among various professional arenas and the private sphere (Suggestion 2). We now turn to the role of *digitalization*. In our view, the role of digital communication has the potential of enhancing norm conflicts and ambiguity. During COVID-19, digital communication is common when working from home. Obviously, the following arguments apply to the COVID-19 telecommuters. However, because digital communication has the same benefits and limitations regardless of geographical distance between different parties, the following arguments apply beyond the mitigation-efforts of COVID-19: to anyone communicating digitally, such as everyday telecommuters or members of a virtual team.

#### The Level of Work Tasks: The Impact of Digitalization on Norm Conflicts Related to Work Tasks

It is difficult to give general descriptions of how increased digitalization influences people’s work tasks. This would depend on a broad variety of factors, including the nature of the work, the degree of active collaborations, and the degree of autonomy. Here

we mainly discuss how increased digitalization could enhance norm conflicts related to work tasks.

When previously “off-line” tasks suddenly have to be conducted online/digitally, the workload of that task could change. Certain things become easier and less time-consuming with digitalization, others harder and more time-consuming. For instance, online meetings can sometimes be more efficient than face-to-face meetings. In contrast, follow-up on the work of individual pupils in a school class can be more time-consuming than the same follow-up in a classroom. At a more general level, digital teaching could benefit some children and disadvantage others.

Digitalization could also change interactions and division of labor in the workplace. Signals may be sent out, with people *ghosting* you, that is overlooking messages, posts and requests. Ghosting is far easier in the virtual context than face to face. Personal ability to explicitly ask or even demand help may not be enough to counter lack of resources in form of clear roles (cf. Xanthopoulou et al., 2009). However, with clear organizational support, such personal resources may mediate into efficient team work.

Certain professions face particular concerns during COVID-19. For example, counselors and therapists conducting confidential conversations with clients that now have to be conducted using online meeting platforms. Similarly, leaders having meetings about sensitive topics online. Although digital tools may have advantages also in these types of situations, e.g., because of efficiency or logistics, they also come with some risks and ethical concerns.

A fundamental challenge is how to best interact with and deal with larger groups. The one-on-one conversation may be quite easily replaced. Group processes, however, often need more preparation, a high grasp of technical demands and resources, and a well-adapted pedagogical process.

#### The Level of Leadership/Organization: The Impact of Digitalization on Leadership Distance

##### *Automated Leadership*

Digitalization in general is full of automated functions, defining tasks, times, sending reminders, insisting on follow-up, and so on. This is true also of digital resources in work-at-home conditions. We are accordingly convinced that automated functions vastly *increase interaction frequency*. Various gadgets can go “ping” in your pocket at virtually any time. The *physical distance is accordingly vastly reduced* for the automated leadership. The automated boss becomes more present, perhaps even looming, and unrelentingly so (cf. Dzieza, 2020). It is however an open question whether the automated boss can be considered socially close (cf. Antonakis and Atwater, 2002). Our suspicion is that the inhuman faceless quality of most *automated systems is more akin to an extremely socially distant lord*, than an empathic team leader. The automated leadership will potentially make greater relative impact amongst white collar workers during the COVID-19 changes, in a fashion previously experienced mainly by blue collar workers (cf. Dzieza, 2020). There are clear parallels to the scientific management/Taylorism in the early 1900-hundreds. The image of the conveyor belt

literally swallowing the Tramp in Chaplin's "Modern Times" springs to mind. In light of the COVID-19 crisis, we note that such mechanistic organizational models are "designed to achieve predetermined goals ... have difficulty in adapting to change ... [and] are *not* designed for innovation (Morgan, 1998, p. 32)."

### **Human Leader Through Digital Interface**

The human leader is likely to be more physically distant in the work-at-home condition. Here the digital interface may reduce this distance, for better and for worse. For the better through possible personal contact. For worse, by unprecedented invasion of the private sphere. Interaction frequency may both increase and decrease. Many interactions could be experienced as part of the automated leadership. The digitalization influence on social distance is perhaps the most difficult to predict in terms of directionality. Digitalization may likely act as a catalyst. That is, dependent on how leaders, formal or informal, use the digital resources. What the subordinate needs and expects is likely important to begin with. The leader could use the digital resources to increase or decrease social distance. Dependent on whether this does match or mismatch the needs of the subordinate, it could lead to either a desirable or an undesirable change in social distance. Accordingly, the leader may be experienced as both active or passive, as both constructive or destructive in this regard. If the subordinate acts with mismatching OCB or with CWB, the leader may through the digital interface be less able to appropriately and constructively remedy the situation.

### **The Interpersonal Level: Proper vs. Improper Behavior in Online Work Environments** *Empirical Value of Clear Norms in Online Work Environments*

Gajendran et al. (2015) found that telecommuting in general lead to higher perceived autonomy and was positively related to various outcome measures. This study was conducted some years ago, and in a setting where telecommuting was less common. For the purpose of our paper, the most important finding is that normative appropriateness of telecommuting was a central mediating variable. An important implication for the COVID-19 situation is that the norms of telecommuting matter. With the overarching changes of norms we argue in the wake of COVID-19, also veteran telecommuters may experience drops in performance and autonomy. It may for instance be more motivating to feel special, almost unique, in using these resources. When everybody does it, then there is a need to find other ways to increase workers' felt autonomy and motivation.

### **Matching the (Machine) Management Expectations**

Elsbach et al. (2010) showed how *passive face time* has increased the view of subordinates as good employees, eligible for pay raises and promotions. It is not clear whether this also happens during and after the COVID-19 distance work. Is it still as proper for coworkers to hang around digitally and just showing their faces? Or will actual results weigh more? Face time as a proxy for organizational commitment may increase gender inequality (Stamarski and Son Hing, 2015), and would matter

for caretakers of children. Now, strategies for appropriate subordinate appearances, may even with telecommuting include literal passive face time. An example is attending video meetings without contributing substantially. Yet, coworkers may struggle for new alternatives, such as inserting empty meetings into the digital calendar. All such struggles should be taxing. Initial performance increases may simply be reflective of initial absence of skills in digitally displaying passive face time. Furthermore, should subordinates fail to figure out new strategies, they may well experience the Tayloristic effects described by Dzieza (2020): "To satisfy the machine, workers felt they were forced to become machines themselves." Thus, worker strategies in these new telecommuting conditions may indeed be interpreted as inefficient shirking, but also as strategies rewarded with career advantages (cf. Elsbach et al., 2010), and strategies to preserve humanity and health (cf. Dzieza), and to preserve or gain professional control of work tasks (cf. Abbott, 1988). It is also conceivable that subordinate behavior seemingly at odds with the machine or management definition of efficiency may be expressions of valuable emerging *shared mental models* of crisis solutions: Carrington et al. (2019) reported empirical findings that shared mental models during prolonged crises tended to emerge bottom-up, rather than top-down from management.

We have thus outlined a number of functional explanations of subordinate behavior which may fail to match the expectations of the automated or human management systems. Curiosity and cautious interpretation among managers and researchers seem called for.

### **Matching Interpersonal Expectations**

Interpersonal proper behavior may be more ambiguous for most people new to the virtual environment (cf. Arvedsen and Hassert, 2020). Many cues are different than in real life: When to speak, when not to, when to raise your voice in affect, when not to. Particularly cues for "reading the room," including pheromones or peripheral vision or small sounds may be heavily reduced or even absent. When relative power may be changed, for instance by new formal or informal leaders emerging, and old leaders receding into the background the potential for mismatched sweet spots will likely increase (cf. Kant and Norman, 2019).

### **Examples of Specific Testable Propositions Derived From Our Suggestions**

It is now time to give a few examples of specific propositions that can be derived from the above suggestions in combination. The suggestions in turn rest upon the selected four sets of theory.

Our aim is not to give an overview of every proposition possible to derive from combining our suggestions. Instead, we will exemplify two possible propositions, each relating to some of the suggestions outlined in *The COVID-19 Situation Leads to a Massive Re-negotiation of Norms Related to Work, The COVID-19 Situation Diffuses the Demarcation Between the Various Professional Arenas and the Private Sphere, and This Diffusion Enhances the Stress Associated With Norm Conflicts, Norm Conflicts Are Enhanced by Digitalization*.

The following propositions aim to show the practical applicability of our arguments. Researchers may be able to

generate many other propositions based on the rationales of our suggestions. Propositions could be used as a basis for testable hypotheses and study designs. In addition, they could be used by leaders and other practitioners to inform day-to-day decisions, when they find themselves in notable changes, such as the ongoing pandemic. We attempted propositions that specify under which conditions certain of our theoretical suggestions are likely to emerge (Sutton and Staw, 1995).

Before testing any of the propositions, one needs to be aware of the importance of timing, as also highlighted by Sutton and Staw (1995). For both researchers and practitioners, the timelines presented in **Figure 2** can be used to inform decisions on which questions to ask and which outcomes to expect, at different points in time. It can be used to indicate at which stage the crisis may have a confounding influence on other measures. For instance, in high intensity phases, through a higher likelihood of emotional responses such as irritation, anxiety, and fear; through lower psychological safety in their team at work (Edmondson, 1999); through higher role ambiguity and role conflict; or through lower identification with the organization.

### Proposition 1

*Automated leadership is more likely to be experienced as negative during intense norm re-negotiation phases (cf. Norm Conflicts Are Enhanced by Digitalization, cf. Figure 2). Therefore, each single leadership action will have an increased risk of being experienced as malign.*

By automated functions we do not mean technology itself, but functions in the organization, in software and other digital systems which may be experienced as leadership functions (cf. The Level of Leadership/Organization: The Impact of Digitalization on Leadership Distance). Rather than being perceived as job resources or tools for workers controlling work tasks such exposure to automated leadership will be experienced either as reduced job resources or increased job demands.

Rationale for this proposition can be found in our theorizing above. The likelihood of automated leadership being experienced as negative will increase with: intensity of renegotiation of norms in certain phases (**Figure 2**); signals invading the private sphere of the worker, or the private sphere of innocent third party household members (cf. The Interpersonal Level: The Influence of Your Work on Work/Private Life of Others, and the Influence of Others' Work on Your Work/Private Life); the close distance effect of high frequency of interaction (cf. The Level of Leadership/Organization: The Impact of Digitalization on Leadership Distance); signals carrying little face value of importance to the worker (cf. The Level of Work Tasks: Norm Conflicts Relating to What Is the "True Essence" and Prioritized Tasks of One's Job); reducing the workers' control of work tasks [cf. The Level of Work tasks: The Continuous Influence of Societal Changes on Work Conditions and Work Tasks (and Private Tasks)] or job resources in comparison with job demands (cf. The Level of Leadership/Organization: Norm Conflicts Relating to Who or What Has Oversight, Surveillance, and Sanctioning Rights).

Leaders or practitioners considering the proposition in an ongoing crisis, may just like researchers want to keep track of

and measure the phenomenon. Considering their responsibility of caring for both the survival of their organization and their employees, they may want to:

(a) Reduce automated leadership to a minimum, particularly functions with limited proven benefit to the organization and high likelihood to encumber the workers. In this, they should take pains to protect the workers private sphere. (b) Strictly prioritize critical tasks, and to communicate clearly around these. Communication and discussion on the topic of what the current norms for desirable and undesirable behavior are should be done on a regular basis. (c) Show empathy and concern for the real threats workers likely discern on the horizon. This would reduce unnecessary resistance against organizational change (Oreg, 2006) by building trust, but above all display a uniquely warm and beneficial aspect of human leadership countering the detriments of automated leadership we hypothesize.

### Proposition 2

*Organizations which take pains to proactively deal with the intense norm re-negotiation phases and associated issues will fare better than organizations which do not take such pains. Organizational outcomes may include, but not be limited to: organizational survival, increased profit or other results, increased market shares, increased reputation; increased innovation; lower turnover; increased trust in management; lower sick-leave; increased identification with the organization; increased psychological safety; increased team cohesion; increased leader-member exchange; increased role clarity; decreased role conflict; lower reports of destructive leadership; higher reports of constructive leadership.*

Rationale for this proposition can be found in our theorizing above. Ways in which organizations can deal with norm negotiations may include: timely efforts to parry both escalation and de-escalation phases (cf. The COVID-19 Situation Leads to a Massive Re-negotiation of Norms Related to Work; **Figure 2**); efforts aimed at acknowledging threats and stressors experienced by workers; efforts aimed at fair and explicit re-negotiation of norms (cf. The COVID-19 Situation Leads to a Massive Re-negotiation of Norms Related to Work); minimization of low priority stressors (cf. The Level of Work Tasks: Norm Conflicts Relating to What Is the "True Essence" and Prioritized Tasks of One's Job); minimization of non-critical automated leadership (cf. The Level of Leadership/Organization: The Impact of Digitalization on Leadership Distance); maximization of low distance human leadership supporting workers (cf. The Level of Leadership/Organization: The Impact of Digitalization on Leadership Distance); minimization of signals invasive of the private sphere (cf. The Interpersonal Level: The Influence of Your Work on Work/Private Life of Others, and the Influence of Others' Work on Your Work/Private Life).

Leaders or practitioners considering the proposition in an ongoing crisis, may just like researchers want to keep track of and measure the phenomenon. Considering their responsibility of caring for both the survival of their organization and their employees, they may want to: use best practice in general crisis management (e.g., Lunde, 2014)—specifically to use mental time travel (Nyberg et al., 2010) anticipating the high

intensity phases of norm re-negotiation. Then to let this guide preparatory focused and prioritized efforts in line with the previous paragraph. Above all—passivity is not an option!

## CONCLUDING REMARKS

The COVID-19 pandemic poses great uncertainty. There are uncertainties about the duration and extent of the pandemic, and of the preventive and mitigative measures. We have argued that the COVID-19 pandemic and its associated crisis trajectories represent a context of massive re-negotiation of norms in a number of arenas. Due to the uncertain nature of COVID-19, the re-negotiation of social norms may appear correspondingly fleeting. People will wonder how long they will have to be working from home, whether the new norms will be carried into the future, and/or whether these will dissolve when life returns to normal. We have discussed possible implications of this impermanence.

This paper provides explanations of ongoing, urgent issues causing substantial changes in the norms of working life. This allows for the general predictions we have provided in our three main suggestions, with subsequent more specific suggestions. Using these will allow researchers to easily build yet more specific propositions, which we have given two examples of. Further theoretical development and empirical testing may be done on this foundation.

The individual theories from which our suggestions are derived, are well-established and empirically supported. Our contribution is to clarify where the selected theories have connections, and how they together may hold even greater explanatory value than alone. We expect the phenomena we describe to have distinct effects. Our suggestions connect to well-documented general advantages, for instance creating role clarity, psychological safety, and resolving jurisdictional contests. Therefore, they could be applied by leaders who are facing norm negotiations during the intensity-changes of this pandemic or other significant crises (cf. **Figure 2**).

Our analysis is theoretical. Our suggestions and discussion points are derived from applying and combining ideas from 4 different theoretical approaches. Our hope is that our theoretical analysis can be used as a framework for understanding how people's work conditions are affected by COVID-19. The suggestions derived from our theoretical analysis can also be used as a starting point for empirical studies. A limitation related to the choice of a theoretical genre, is that we could have applied other theories, provided other examples and looked at other levels of analysis.

A number of factors may modify the renegotiation of social norms, many of which have not been discussed here. These include *culture* (e.g., tight and loose; Gelfand et al., 2011), social distance (Kant and Norman, 2019), and leadership distance (Antonakis and Atwater, 2002). In the current situation, the most obvious modifying factor is *digitalization*. With social distancing measures, work-related communication largely occurs digitally. The situation also opens for leaders controlling/surveilling their

workers by digital means. We therefore also address some concerns arising from the fact that for most telecommuters, relevant interactions relating to social norm re-negotiation during COVID-19 take place *in digital worlds* and *simultaneously* in people's homes. We suggest that re-negotiation of norms in the COVID-19 situation may be influenced by norm conflicts caused or enhanced by so-called "disrespectful technologies" (Diefenbach and Ullrich, 2019).

Even though this paper specifically addresses stressors for people currently employed, it is important to acknowledge the stress, uncertainty, and economical difficulties that now face those unemployed as a result of COVID-19. Our investigation centers around those who relatively speaking are fortunate during the COVID-19 pandemic. The challenges we address are about processes demanding change, adjustment and renegotiation; in confined spaces; where the demands of many organizational bodies meet. In the paper, we have gone into depth about each of our theoretical suggestions, provided illustrative examples and provided interpretation of relevant data. Our aim is to contribute to existing theory, including theory on negotiation of norms, professions, digitalization, and benign violations. Because we point to potential risk factors of psychological distress, our analysis also has long term applied value for clinical and organizational psychology. It is our hope that our analysis also is of value, as nearly half of the world in June 2020 craves to understand how to deal with the dilemmas we have described.

## AUTHOR CONTRIBUTIONS

LK conceived of the presented idea and had the main responsibility for developing the theoretical arguments in line with existing literature. LK also had the main responsibility for writing up the paper. EN provided input into the organization of arguments, took part in discussions, and contributed to the write-up. Both authors contributed to the article and approved the submitted version.

## FUNDING

LK's contribution was partially funded by AFF, and also supported by UiB.

## ACKNOWLEDGMENTS

We would like to thank the two reviewers and the editor for very helpful comments and suggestions, and Sami Lill of Ubersuperduper.com for graphical assistance with **Figure 2**. We would also like to thank AFF and UiB for supporting this project. Witnessing our respective children's teachers dealing with various stressors and norm conflicts during the first lock-down inspired our initial theoretical discussions and kicked off our curiosity to explore what became the research question of this paper. We thank them for this inspiration along with their efforts to find solutions.

In February 2020, an inpatient in Peking University People's Hospital (PKUPH), China, was confirmed positive for the novel coronavirus. In this case, 143 hemodialysis patients were labeled as close contacts and required to be placed under the hospital-based group medical quarantine (HB-GMQ) for 2 weeks by the authorities. After the case was reported, false or misleading information about the case flourished on social media platforms, which led to infodemic. Under this context, PKUPH adopted patient-centered humanistic care to implement the HB-GMQ, through the synergy of administrative, healthcare, logistical, and other measures under the model of patient-centered care of the Massachusetts Medical Society (MMS). As a result, all the patients tided over the HB-GMQ with no COVID-19 infection and no unanticipated adverse events, and all met the criteria for lifting the HB-GMQ. According to the questionnaires taken during the HB-GMQ, a high level of satisfaction was found among the quarantined and no symptomatic increase of anxiety and depression in the patients before and during the HB-GMQ, by comparing the Zung self-rating anxiety scale (SAS) and self-rating depression scale (SDS) conducted in December 2019 and on the 12th day of the HB-GMQ. This article is to brief on PKUPH's experience in implementing patient-centered humanistic care tailored to hemodialysis patients under the HB-GMQ, and to validate the hypothesis that patient-centered humanistic care is effective and helpful to help them tide over the HB-GMQ, so as to shed light on how to implement the HB-GMQ and cope with the HB-GMQ-induced problems in other hospitals.

**Keywords:** humanistic care, measures, COVID-19, hospital-based group medical quarantine, hemodialysis patients

## INTRODUCTION

Humanism in medicine is fundamental to excellent patient care (Chou et al., 2014), which is an aspect imperative to quality healthcare (Muneeb et al., 2017). Generally, humanistic care is referred to as a patient-centered approach emphasizing a positive and trusting relationship between the caregiver and a patient, characterized by collaboration, dignity, empathy, and trust. In 1988, the Picker Institute in Britain coined the term “patient-centered care” to call attention to the need for healthcare practitioners and systems to provide care not only from a clinical perspective, but also from the patient and family perspective (Gerteis et al., 1993). In 2001, the Institute of Medicine defined patient-centered care as “providing care that is respectful of, and responsive to, individual patient preferences, needs and values, and ensuring that patient values guide all clinical decisions” (Institute of Medicine Committee on Quality of Health Care in America., 2001). In this sense, when patient-centered approach and attitude are adopted, patients are partners with healthcare practitioners who will focus more on emotional, mental, spiritual, social, and financial needs of patients, rather than just on their clinical needs. And patient-centered care can be achieved by devoting visit time to non-medical aspects of the life of the patients, maximizing quality face-to-face time in patient interaction, empathizing with the patient, and involving the patients in decisions about their care (Draeger and Stern, 2014).

A large body of research supports the hypothesis that patient-centered humanistic care is fundamental to excellent patient care. Everhart et al. (2019) believed that “patient-centered care and patient- and family-centered care (PFCC) improve patient and family satisfaction, patient self-management, and physical and mental health outcomes.” Delaney (2017) reiterated the benefits of humanistic medical care and stressed that the patient-centered approach, as a primary approach to healthcare, can enhance healthcare, and patient satisfaction.

The outbreak of the novel coronavirus, which began in 2019, has become a global pandemic and posed a significant threat to global health. To resist the spread of the virus, quarantine and isolation are deemed as critical measures that have been put in place across the globe. On February 18, 2020, an inpatient in Peking University People’s Hospital (PKUPH) was confirmed positive for the novel coronavirus, leading to hospital-based group medical quarantine (HB-GMQ) of 143 hemodialysis patients for 2 weeks.

Unlike putting healthy people under the HB-GMQ, it was challenging for PKUPH to take care of vulnerable hemodialysis patients in terms of healthcare, psychology, dietary, etc. First, most hemodialysis patients are elderly people who have more or less psychological disorders, underlying diseases, and comorbid conditions; delicate care and emergency preparedness should always be considered in the workplace for any unexpected event. Second, hemodialysis patients are subjected to unusual emotional stress and have a wide variety of psychological problems (Levy, 1979). All hemodialysis patients were in a state of distress and worried about the possibility of infection. Third, quarantine might have further aggravated their preexisted psychological

problems, as it often comes with distressing side effects, including post-traumatic stress disorder (PTSD). Fourth, following a kidney-friendly diet further increased the difficulty of providing care to these patients, as dietary requirements differ from patient to patient depending on the state of the condition. Faced with all these challenges, PKUPH, in adherence to COVID-19 protocols and recommendations and advice for the healthcare settings and public by the World Health Organization (WHO) (2020) and the Chinese health authorities, adopted a patient-centered humanistic approach and attitude to implement the HB-GMQ under the model of patient-centered care of the Massachusetts Medical Society (MMS).

Although the outbreak of infectious diseases such as SARS, MERS, EBOLA, and COVID-19 stimulated related research, there still remains little research on the psychological impact on hemodialysis patients and how to implement the HB-GMQ for those who are directly exposed to infectious diseases. Therefore, the purpose of this study was to validate the hypothesis that patient-centered humanistic care is effective in reducing anxieties or depression in hemodialysis patients, increasing their satisfaction and compliance with the HB-GMQ.

## METHODS

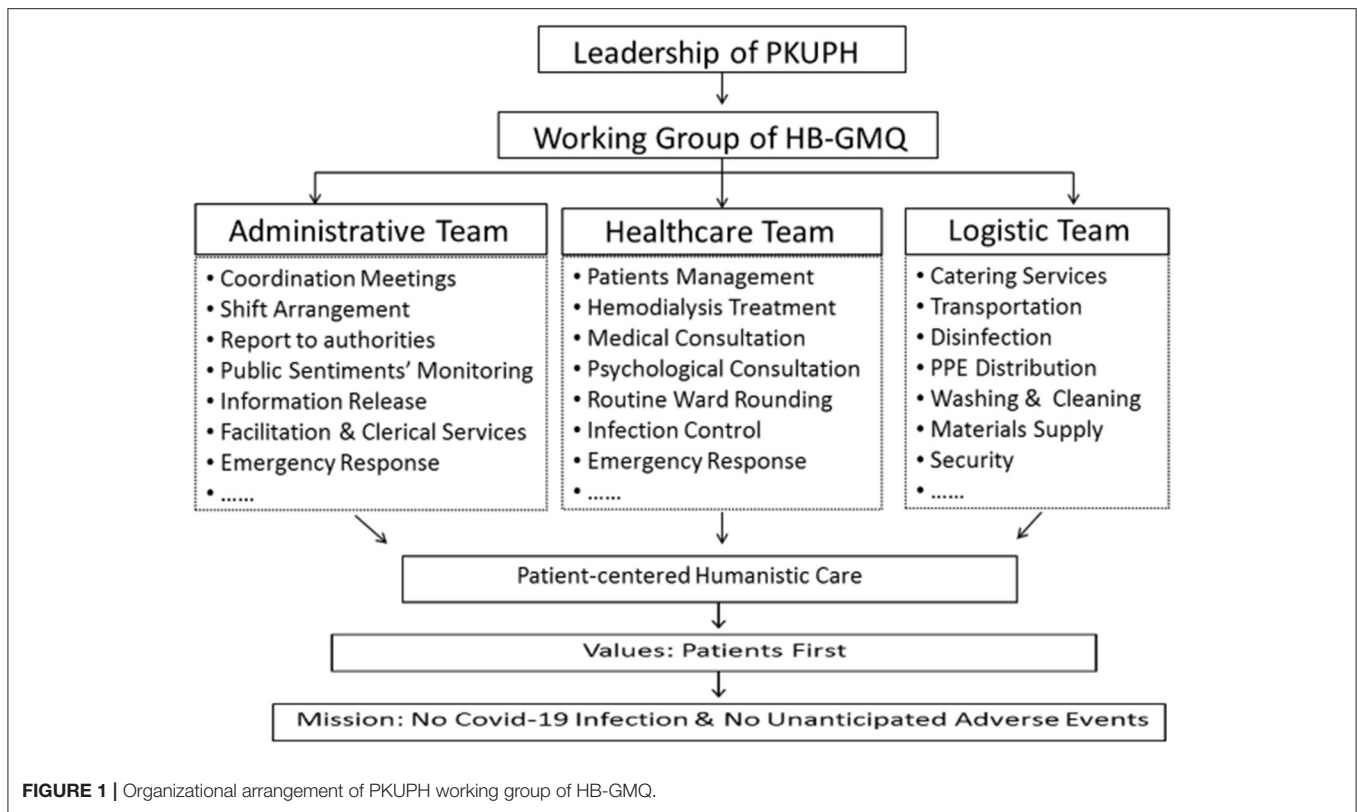

### Setting and Sample

After the case was reported, 143 hemodialysis patients were labeled as close contacts and required to be quarantined by the authorities. PKUPH, under the guidance of the governments at different levels, immediately set up a working group to manage the HB-GMQ and adopted patient-centered humanistic care approach to help these patients safely tide over the quarantine. The study was performed on a designated campus called Baitasi Campus for a 14-day period since the quarantine had been imposed on February 18, 2020. The inclusion criteria were as follows: (1) regular hemodialysis  $\geq 3$  months; (2) under the HB-GMQ; and (3) informed consent and signed informed consent form. The exclusion criteria were as follows: (1) acute blood loss or acute infection within 3 months; (2) cardiovascular and cerebrovascular accidents, rheumatic immune diseases, or uncontrolled malignant tumors occurred within 3 months; (3) people with mental illness; and (4) people with severe cognitive impairment. And the withdrawal criteria were as follows: (1) patients who failed to complete the HB-QMG and (2) withdrawal from the study upon the request of subjects.

Before the quarantine, the nucleic acid amplification test (NAAT) was given to the close contacts and the results were all negative. During the quarantine, the patients received maintenance hemodialysis as they did in the past. After 14 days, patients with no clinical symptoms of COVID-19 and no severe health conditions could be discharged.

At the initial phase of the HB-GMQ, the demographic characteristics of conditions of the patients were sorted out from medical records. With the information, medical staff could make informed decisions, pay special attention to those with severe conditions, provide expert medical consultations, and render individualized care accordingly.

## Patient-Centered Humanistic Care Provided by PKUPH During HB-GMQ

Leaving a familiar and comfortable home environment for the HB-GMQ would be difficult for the most hemodialysis patients. The call for the HB-GMQ would result in anxieties or distress on the patients, which in turn would project undesirable emotions onto someone else and hamper the implementation of the HB-GMQ. Initially, two patients in this case were unwilling to be quarantined for one reason or another. Persuaded by the communities and the local governments, they finally accepted the HB-GMQ. In order to stabilize the emotions of the patients, prevent their symptomatic increase of anxiety and depression, avoid their misunderstandings toward quarantine arrangements, and help them smoothly tide over this special period, PKUPH formed a working group and incorporated patient-centered humanistic care into the day-to-day routine management, healthcare, and logistics, trying its best to provide convenience as much of the home environment as possible. During the HB-GMQ, the working group put patients first as the core values and aimed to achieve the objectives of “no COVID-19 infection and no unanticipated adverse events.”

A working group led by two vice presidents of PKUPH was soon established after the case was confirmed. Heads from different executive departments and medical specialists from different fields of practice were mobilized to establish a coordination mechanism (Figure 1). In accordance with COVID-19 protocols and guidelines of the WHO and Chinese

health authorities, PKUPH provided patient-centered care under the model of patient-centered care of the MMS, which is presented in Table 1.

## Instruments

During the HB-GMQ, PKUPH practiced patient-centered humanistic care through the synergy of administrative, medical, logistical, and other specific measures under the model of patient-centered care of the MMS. The model of patient-centered care of the MMS involves seven indicators: (1) mission and values aligned with patient goals; (2) full transparency and fast delivery of information; (3) care is collaborative, coordinated, accessible; (4) family welcome in care setting; (5) psychological comfort and emotional well-being are top priorities; (6) patient and family always included in decisions; (7) patient and family viewpoints respected and valued. The PKUPH's patient-centered humanistic care under the model of patient-centered care of the MMS is presented in “Patient-centered Humanistic Care Provided by PKUPH during HB-GMQ” section.

In order to assess the effectiveness of the PKUPH's approach of patient-centered humanistic care, electronic satisfaction questionnaires were administered by nurses in charge to 143 hemodialysis patients to fill out on the 14th day of the HB-GMQ, and the differences in hemodialysis patients' anxious or depressive symptomatology before and during the HB-GMQ were recorded by the Zung self-rating anxiety scale (SAS) and self-rating depression scale (SDS) conducted in December 2019 and on the 12th day of the HB-GMQ.

**TABLE 1** | PKUPH's patient-centered humanistic care under the model of MMS.

Indicators under the model of patient-centered care of the MMS	PKUPH's approach
Mission and values aligned with patient goals Care is collaborative, coordinated, accessible	PKUPH put the quarantined hemodialysis patients first, with the mission of “no COVID-19 infection and no unanticipated adverse events during the HB-GMQ.” During the HB-GMQ, routine dialysis treatment, expert medical consultations, and routine ward rounds were provided. Nephrologists and nurses were available 24 h, and a multidisciplinary team composed of specialists from different fields of practice was established to meet and respond to the healthcare needs of the patients during the HB-GMQ. Moreover, relatively fixed positioning of medical staff was arranged in the hope that all medical staff can grasp all the information and the characteristics of each patient to avoid poor information sharing due to handovers.
Psychological comfort and emotional well-being are top priorities	Nephrologists and nurses at PKUPH were required to pay attention to the physical and mental well-being of the patients during rounding, and render timely psychological counseling and emotional support according to patient-specific symptoms and psychological survey scale. Second, PKUPH provided health education about the coronavirus for the quarantined during the HB-GMQ aiming to increase their awareness of prevention and relieve their worries about the virus. Third, nephrologists and nurses at PKUPH increased the frequency of daily visit and created a group chat on social network APP to collect the claims of the patients and timely responding to their requests, such that strengthened the communication between the patients and improved the patients-medical staff relations. Fourth, to follow a renal diet, the catering staff tried every means to come up with a diet that was tailored to the needs of the patients, and met their individualized diet needs under the guidance of nephrologists and nutritionists. Fifth, the working group connected with local authorities to solve the issuing of the quarantine pass, formulate return-to-community plan, and tackle the problem of community inaccessibility.
Family welcome in care setting	Each patient was allowed to bring a family member to live with them during the HB-GMQ. Their family members were not allowed to visit home and return back to the hospital during the HB-GMQ period.
Patient and family always included in decisions	Treatments and therapies were provided based on the discussions with the patients and family.
Patient and family viewpoints respected and valued	Respected and valued the patients and their family's decisions and collaborated to facilitate the HB-GMQ-induced problems.

NEJM (2020). NEJM Catalyst (catalyst.nejm.org) © Massachusetts Medical Society.

The left column of this table explains the model of patient-centered care of the MMS, and the middle column of this table describes PKUPH's approach under the model of patient-centered care of the MMS. The picture in the right column of this table shows a 72-year-old hemodialysis patient bowed to the working staff to show his gratitude to the care he received during the HB-GMQ. Photographed by Lian Zu (Health News, 2020).

The patient satisfaction survey investigated seven aspects of satisfaction: (1) hospital meals, (2) living environment, (3) dialysis treatment, (4) transfer services, (5) hospital hygiene, (6) material supply, and (7) overall experience of the HB-GMQ. The level of satisfaction was divided into five categories: very satisfactory, satisfactory, ordinary, unsatisfactory, and very unsatisfactory. To avoid potential source of bias, data of “unsatisfactory” and “very unsatisfactory” were also recorded in the study. The detailed information is presented in the “Result” section.

The Zung SAS and SDS are methods of measuring levels of anxiety and depression in patients who have anxiety-related and depression-related symptoms. Both are self-administered surveys with 20 questions on the scale. Under the SAS and SDS, each response was scored on a scale of 1–4 (none or a little of the time, some of the time, a good part of the time, most or all of the time). Under the SAS, the authors divided the rough score by 80 to get the anxiety severity index scores, which range from 0.25 to 1.00, with 0.50–0.59 in Mild Anxiety Levels; 0.60–0.69 in Moderate to Severe Anxiety Levels; 0.70 and above in Severe Anxiety Levels. Under the SDS, the authors divided the rough score by 80 to get the depression severity index scores, which

range from 0.25 to 1.00, with 0.50–0.59 in Mildly Depressed; 0.60–0.69 in Moderately to Severely Depressed; 0.70; and above in Severely Depressed (Wu, 2015).

## Procedures

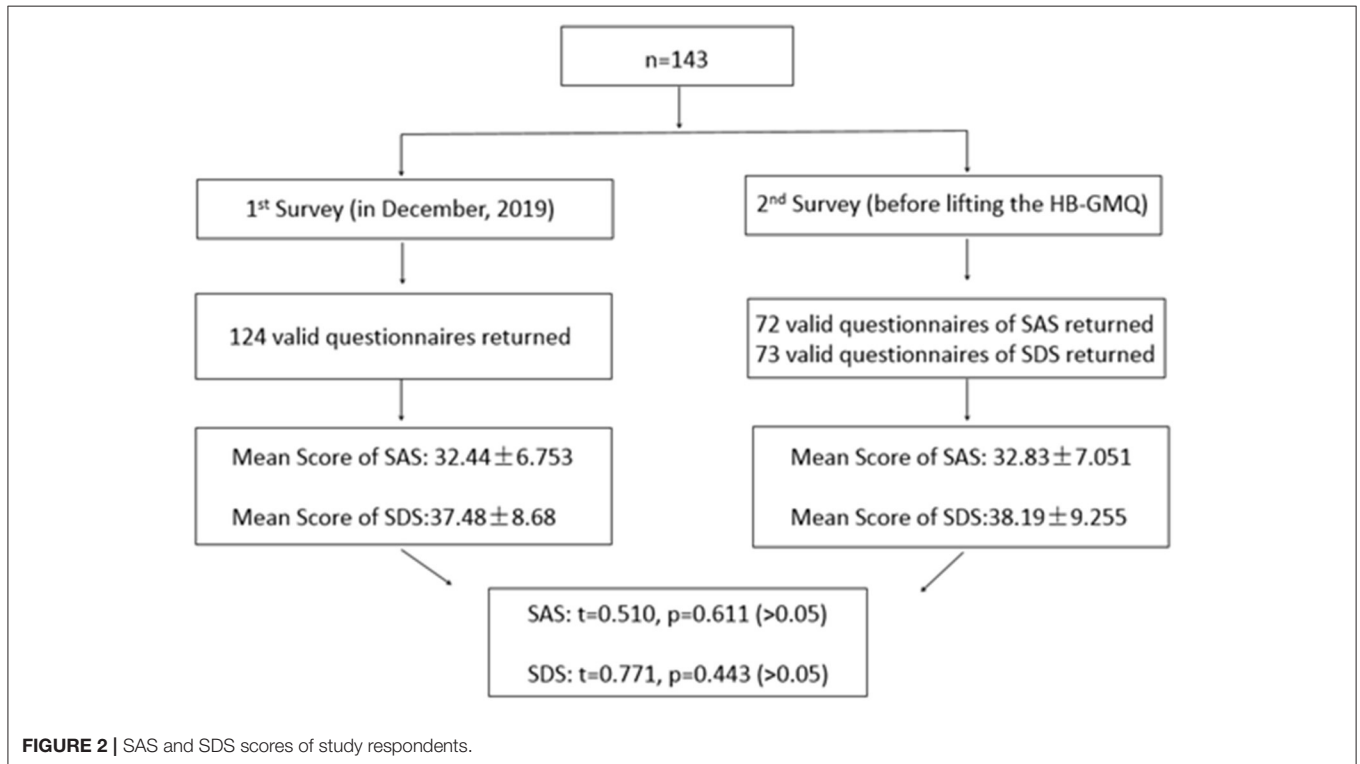

The best way of measuring whether the practice was patient-centered or not lies in the assessment made by the patients themselves. To evaluate the effectiveness of the implementation of patient-centered humanistic care practiced by PKUPH during the HB-GMQ, satisfaction questionnaires were administered to 143 hemodialysis patients on the 14th day of the HB-GMQ by nurses in charge (Table 2).

At the Hemodialysis Center of PKUPH, it is a routine job for nurses to collect the patients' data of SAS and SDS on a regular basis to evaluate the level of anxiety and depression. To compare the differences in the anxious or depressive symptomatology of the patients before and during the HB-GMQ, the data of SAS and SDS that were obtained in December 2019 were used to compare with the data that were collected on the 12th day of the HB-GMQ in 2020 (Figure 2).

All the above-mentioned procedures were conducted after the patients signed the consent form. And those who were involved

**TABLE 2** | Data of patient satisfaction questionnaire.

Satisfaction survey questions	Very satisfactory	Satisfactory	Ordinary	Unsatisfactory	Very unsatisfactory
Are you satisfied with the hospital's meals?	28 (21.54%)	48 (36.92%)	39 (30%)	9 (6.92%)	6 (4.62%)
Are you satisfied with the room you are in?	32 (24.62%)	59 (45.38%)	28 (21.54%)	8 (6.15%)	3 (2.31%)
Are you satisfied with the dialysis treatment process?	84 (64.62%)	45 (34.62%)	1 (0.77%)	0	0
Are you satisfied with the hygiene of the hospital?	56 (43.08%)	59 (45.38%)	10 (7.69%)	4 (3.08%)	1 (0.77%)
Are you satisfied with the transfer services during the dialysis process?	70 (53.85%)	52 (40%)	4 (3.08%)	2 (1.54%)	2 (1.54)
Are you satisfied with material supply of the hospital?	60 (46.15%)	65 (50%)	4 (3.08%)	0	1 (0.77%)
Your overall satisfaction with the care during GMQ period?	51 (39.23%)	64 (49.23%)	10 (7.69%)	2 (1.54%)	3 (2.31%)

in the data collection of SAS and SDS in December 2019 provided written consent to join the study during the HB-GMQ in 2020. For those who were not convenient to fill out the questionnaires during maintenance dialysis, the nurses in charge shall help them fill out the questionnaires.

### Statistical Analyses

In the analysis of the satisfaction survey, categorical variables were presented as numbers with percentages. In the analyses of SAS and SDS, differences in the anxious or depressive symptomatology of the patients before and during the HB-GMQ were examined by using a paired *t*-test. The statistical significance level was set at 0.05. The hemodialysis management system (Copyright 2006, Beijing Whole Way Technology Co. Ltd) was used for data entry and scoring. Other data were entered into an EXCEL worksheet. The SPSS software package (version 22.0, SPSS Inc., Chicago, IL, United States) was used for statistical analyses.

## RESULTS

### Demographic Characteristics of Participants

A total of 143 hemodialysis patients were enrolled in the study. Of them, 94 are male patients (65.7%), and 49 are female (34.3%). The median age of them was 59.5 years, ranging in age from 30 to 93. The proportion of those over 60 years reaches 53.1%, of which one case is >90 years, 13 cases are 81–90 years, 24 cases are 71–80 years, and 38 cases are 60–70 years.

After combining through the medical records of these 143 hemodialysis patients, at least 75 patients (52.4%) had underlying diseases and comorbidities, 44 patients (35%) had a history of cardiovascular and cerebrovascular diseases, and 22 patients had a history of cancer (15.5%), with cirrhosis in two cases and gastrointestinal ulcer in one case. Twenty-five cases with severe illness were screened out among the 143 patients, and their information was fully shared by the medical

staff. In addition, 24 patients had their relatives accompanied during the HB-GMQ.

### Patient Satisfaction About HB-GMQ

On the 14th day of the HB-GMQ, electronic satisfaction questionnaires were administered to 143 hemodialysis patients, and 130 valid questionnaires were returned. About 99.23% of the respondents agreed that timely solutions were provided when they need help; 96.92% believed that medical staff responded to their questions concerning medical or living needs; 99.23% agreed that the healthcare team assisted them with meal delivery, water fetching, etc. Overall, 115 patients gave very satisfactory or satisfactory (88.46%), 10 patients gave ordinary (7.69%), and five patients gave unsatisfactory (3.85%) (Table 2). Among the unsatisfactory patients, the main reason for “unsatisfactory” was due to the lack of freedom caused by the HB-GMQ.

### Comparison of SAS and SDS Scores Before and During HB-GMQ

In December 2019 (before the HB-GMQ), mental health of 124 cases was effectively assessed by using SAS and SDS, which is a routine job for the Hemodialysis Center of PKUPH. On the 12th day of the HB-GMQ in 2020, SAS and SDS questionnaires were sent to 143 patients. The valid sample size that can be self-paired in the data before and during the HB-GMQ was 72 in SAS and 73 in SDS.

In the study, the authors found that there were no statistically significant differences in anxious or depressive symptomatology of the patients before and during the HB-GMQ by comparing the SAS and SDS scores assessed before the HB-GMQ with those assessed during the HB-GMQ (Figure 2).

## DISCUSSION

Our study showed that a high level of satisfaction about the HB-GMQ was found among hemodialysis patients. This was mainly due to the successful implementation of patient-centered humanistic care for the quarantined. In order to ensure the smooth execution of the HB-GMQ, 32 coordination meetings were organized, 11 medical and nursing regulations and processes were formulated, 2,292 N95 masks and 11,100 surgical masks were consumed, 10,794 sets of meals were offered, and 265 staff members were on site providing services to the quarantined during the HB-GMQ.

During the entire process of the HB-GMQ, patient-centered humanistic care played a crucial role in the successful implementation of the HB-GMQ and in the achievement of the following results: First, patient-centered humanistic care could attenuate negative and reluctant reactions of patients to the HB-GMQ, and gain cooperation and understanding of the patients about the HB-GMQ. Second, patient-centered humanistic care could help build a positive and trusting relationship between the patients and healthcare practitioners during the HB-GMQ. Third, patient-centered humanistic care could alleviate the anxieties or worries of the patients who already suffered from psychological disorders or emotional

instabilities caused by the kidney disease. Fourth, patient-centered humanistic care could increase the compliance of the patients with the HB-GMQ and their satisfaction about the HB-GMQ services. Fifth, patient-centered humanistic care could ensure positive public sentiments toward the outbreak of the pandemic of coronavirus and the HB-GMQ and curb the fearmongering and negative sentiments on social media. Finally, through providing patient-centered humanistic care, the working group had developed growing know-how and insight into addressing key issues related to the management of contagious diseases.

From PKUPH's experience, a sound organizational structure, adequate human and material resources, scientific infection prevention and control, delicate individualized patient care, a complete plan for emergency preparedness, and a multidisciplinary rescue and treatment team constituted the fabric of the HB-GMQ project and determined the final fulfillment of the mission of “no COVID-19 infection and no unanticipated adverse events.”

There is a growing body of evidence showing that most patients undergoing hemodialysis have varying degrees of psychological problems, such as depression and anxiety (Ng et al., 2015). Avdal et al. (2020) also validated that problems of financial losses, social exclusion, stress, fatigue, depression, and anxiety may occur in the patients undergoing hemodialysis and peritoneal dialysis. Besides, the suddenly imposed HB-GMQ might have further aggravated the patients' preexisted psychological problems. Unfamiliar surroundings, misunderstandings toward the HB-GMQ, the fear of the consequences of this infection, and worries over undesirable dietary management in the hospital were all HB-GMQ-induced psychological problems.

Previous studies had revealed that the quarantine did have a psychological impact on patients. During the MERS outbreak, a study conducted by Lee et al. (2018) in the Republic of Korea included 73 hemodialysis patients who were experiencing the hospital-based quarantine. The researchers used the Hospital Anxiety and Depression Scale (HADS) to evaluate the psychological impact of the 2015 MERS on 73 quarantined hemodialysis patients. In the Mini International Neuropsychiatric Interview (MINI), four patients were subjected to major depressive disorder (MDD), and eight patients suffered from generalized anxiety disorder (GAD). In the HADS, eight patients (11%) experienced anxiety, and 11 patients (15.1%) underwent depression (Lee et al., 2018). A recent case of Diamond Princess had also revealed that a 2-week coronavirus quarantine did have a negative psychological impact on the passengers and subjected them to anxiety, depression, and other mental health challenges even after disembarkment (Abrams, 2020). Brooks et al. (2020) illustrated five studies comparing psychological outcomes for people quarantined with those who were not quarantined. The results indicated that a relevant high prevalence of symptoms of psychological distress and disorder was found in those who had been quarantined (Brooks et al., 2020).

In our study, the results showed that no statistically significant differences were found in the anxious or depressive symptomatology of the patients before and during the HB-GMQ. This was probably attributed to the following reasons. First, regular hemodialysis treatment was maintained and provided during the HB-GMQ, which met with some patients' needs for receiving in-patient care and alleviated their worries about the possibility of infection during the commute between their home and the hospital. Second, administrative team, healthcare team, and logistic team were in place to ensure their safety during the HB-GMQ. The administrative team was assigned to do multiple tasks: (1) formulating the generic HB-GMQ plan and emergency plan, ensuring orderly execution of the HB-GMQ plan; (2) coordinating efforts to respond to every emergency; (3) monitoring public sentiments; (4) solving anticipated problems in advance; (5) optimizing management processes and measures; (6) dealing with undesirable emotions and feelings of patients; (7) facilitating personal protective equipment; (8) providing nosocomial infection training; (9) reporting to the authorities; (10) communicating with communities for accessibility, etc. The healthcare team included three subteams, namely, nephrology team, multidisciplinary team and nursing team, who were available 24 h a day to respond to every emergency, and get to know the medical and living needs of the patients and tackle their problems in a quick and appropriate manner. When encountering patients with anxious or depressive symptomatology, the healthcare team would mobilize professionals to provide targeted counseling and therapeutic solutions. In doing so, anxious or depressive symptomatology in the patients could be excluded. The logistic team responded quickly to every arrangement of the generic HB-GMQ plan and formulated the procedures for material acquisition, lift using, infection, cleaning, washing, catering, hospitalization, patient transportation, etc. In order to provide a good environment as much of their home, sanitary, and well-ordered wards were ensured, and high-speed Internet access was guaranteed. After their arrival at the HB-GMQ area, daily necessities, such as toiletries, were purchased and distributed to the patients. To follow a renal diet, the catering staff, under the advice of nephrologists and clinical nutritionists, formulated the dietary plan, and updated the menu every day based on the principles of consuming high-quality protein and limiting fluids, potassium, and calcium. These measures well-exemplified the working staff's efforts in providing patient-centered humanistic care for the quarantined. Third, encouraging and allowing family members to accompany the patients could ameliorate their loneliness during the HB-GMQ. This policy was particularly helpful for older adults who are functionally very dependent on family members. Fourth, expenses of boarding and lodging incurred during the HB-GMQ were completely free of charge for the patients. This practice, to a large extent, had relieved the psychological and economic pressure of the patients and increased that of the level of acceptance of the HB-GMQ.

The main strength of this study is that there is no published research report on the implementation of patient-centered humanistic care for COVID-19 closely contacted hemodialysis patients under the HB-GMQ. As the global COVID-19 pandemic

continues, the study could provide a humanistic approach for overcoming a difficult period considering healthcare arrangement and support.

There are also some limitations to this study. First, the intrinsic feature of patient-centered humanistic care lies in its individualized care. The PKUPH's approach to cope with a COVID-19 situation cannot be fully replicated and reproduced by other institutions. Second, the outbreak of the COVID-19 situation in PKUPH was not foreseeable, the knowledge, and perceptions regarding the COVID-19 at that time were very limited, and the suddenly imposed HB-GMQ was not designed—all of these confined the current study to a limited sample size and the specific group of hemodialysis patients. Third, the results may not fully exhibit the whole picture of the psychological impact of COVID-19 on hemodialysis patients and assess the effectiveness of patient-centered humanistic care under the model of patient-centered care of the MMS.

## CONCLUSION

Throughout the process of the HB-GMQ, the concept and approach of humanistic care under the model of the MMS was highly incorporated into routine management, healthcare, and logistics while adhering to COVID-19 protocols and guidelines of the WHO and Chinese health authorities. PKUPH's experience further validated the hypothesis that patient-centered humanistic care is important in implementing the HB-GMQ and effective in helping the quarantined tide over the HB-GMQ, resulting in a high level of satisfaction about the HB-GMQ, and no symptomatic increase of anxiety and depression in the patients before and during the HB-GMQ. With the concerted efforts from different parties, there have been no unanticipated problems, and no infection cases and no preventable adverse events occurred during the HB-GMQ. According to the patient satisfaction survey, most patients held a positive attitude toward the HB-GMQ with a high level of compliance. At the same time, there was no symptomatic increase of anxiety and depression in the patients by the analyses of the SAS and SDS. It is hoped that PKUPH's experience of implementing patient-centered humanistic care could enlighten other hospitals on how to implement the HB-GMQ and address the HB-GMQ-induced problems.

## DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/supplementary material, further inquiries can be directed to the corresponding author/s.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethical Review Committee of Peking University People's Hospital. **Introduction:** The novel coronavirus SARS-CoV-2 belongs to the coronavirus family, a group of viruses that can cause upper respiratory infections in humans. Among other symptoms, it can present as an asymptomatic infection or as a more severe disease requiring hospitalization. Neuropsychiatric symptoms have been described in the acute phase of the illness and as long-term repercussions. We describe the characteristics and interventions in those COVID-19 patients referred to our liaison psychiatry service.

**Materials and Methods:** This is a cross-sectional descriptive study. This study was carried out within the Department of Psychiatry of Cruces University Hospital (Basque Country, Spain). Data from each psychiatric consultation within our consultation-liaison service were consecutively obtained for 1 month from March 17 to April 17, 2020. We recruited data regarding clinical and referral characteristics and psychiatric interventions.

**Results:** Of a total of 721 SARS-CoV-2 hospitalizations, 43 (5.6%) patients were referred to our psychiatry liaison service. The median age was 61 years old, and 62.8% were women. The infectious disease department was the most frequent petitioner (37.2%), and the most common reason for referral was patient anxiety (25.6%). A total of 67.4% of patients received psychological counseling and 55.8% received some pharmacological approach, with a median of 3.7 visits/calls per patient. In addition, 20.3% needed a medication switch due to potential interactions between psychotropics and drugs used to treat SARS-CoV-2.

**Discussion:** In our study, up to 5.6% of SARS-CoV-2 hospitalized patients needed a psychiatric evaluation, especially for anxiety and mood symptoms. Psychosocial factors associated with the pandemic, drugs used to treat the infection, or a direct causative effect of the virus may explain our findings.

**Keywords:** COVID-19, SARS-CoV-2, liaison psychiatry, mental health, psychological counseling

## INTRODUCTION

SARS-CoV-2 is a novel coronavirus first detected in the Wuhan area, China, in December 2019 (1). It has progressively expanded through China and eventually became an international pandemic. Our study took place in the Cruces University hospital, a third-level hospital in Basque Country, Spain. At the moment of this study, in March 2020, our hospital admitted more than 700 inpatients due to SARS-CoV-2 infection, and Spain was, in fact, one of the more severely affected countries (2).

SARS-CoV-2 is a coronavirus (3), which is a group of single-stranded RNA viruses that can cause upper respiratory infections in humans. The COVID-19 symptom spectrum is vast and ranges from an asymptomatic infection in up to 20% of patients to severe pneumonia requiring hospitalization and death (1, 4, 5). Although it primarily affects the airway and the lungs, the virus can also attack the kidneys, the liver, and the central nervous system and cause multi-organ failure. In China, the mortality rate has been estimated to be 1.38%, increasing with age and increasing to 13.4% in those aged 80 or older (5).

Men have a higher mortality rate and an increased risk of admission to the ICU than women (6). Although the organic prognosis is worse, the psychological impact remains better in men: women infected with SARS-CoV-2 report more perceived helplessness than men do (7) and have higher scores in depression and anxiety scales (8). It has to be clarified whether biological or sociocultural variables explain these gender differences.

## Neuropsychiatric Manifestations of the Infection

Like other viruses of this group, the SARS-CoV-2 has shown neurotropic capacity *in vitro* models (9–11), as well as CNS inflammation and demyelination (9). Therefore, psychiatric symptoms are theoretically feasible, but it is unclear whether they come from a direct insult of the nervous system, the psychosocial distress related to the infection, or both.

Preclinical data confirm that COVID-19 is associated with neurological and neuropsychiatric symptoms (12–15). A case series from Wuhan found that 36% of inpatients showed neurological symptoms, mainly dizziness and headache. Some of them also presented with cerebrovascular disease in the course of their illness (16). In a detailed clinical report by Paterson et al. (12), they describe para- and post-infectious encephalitis such as ADEM and transverse myelitis. Taquet et al. (15) recently examined the estimated incidence of any neurological or psychiatric diagnosis 6 months after a first COVID-19 diagnosis, finding an overall percentage of 33% and up to 46.42% on those previously admitted to an intensive care unit. The risk of affective and anxiety disorders increased compared to the control group and the risk of psychosis.

Another important nosology is Post-Acute COVID-19 syndrome, defined as persistent symptoms and delayed or long-term complications beyond 4 weeks from onset. It has been described that in the long term, the symptoms of depression and anxiety are related not so much to the severity of the medical

condition as to the appearance of physical sequelae (17). Post-Acute COVID-19 syndrome courses with fatigue, dyspnea, hair loss, attention deficit, and depression. In up to 60% of patients, the most common symptom is fatigue (18), and 30% may develop depressive symptoms. There is also evidence that coronavirus has long-term repercussions on cognition. Hampshire et al. (19) describe how individuals who have survived COVID-19 respond worse on cognitive tasks than would be expected for their age and academic level.

## Psychiatry Liaison During the Pandemic

Consultation-liaison psychiatry, also known as psychosomatic medicine, is a subspecialty of psychiatry that focuses on the care of patients with comorbid psychiatric and general medical conditions at the request of the medical or surgical treating physician. During the first wave of the pandemic, many centers considered clinical psychologists and psychiatrists non-essential personnel and were discouraged from entering isolation wards of COVID-19 patients (20). For this reason, many psychiatric services reduced their workload (21–23), although there are singular examples of Psychiatry Liaison increased referrals (24).

Psychiatrists had diverse duties during the peak of the pandemic. For example, drugs used experimentally to treat the infection (such as protease inhibitors) interacted with psychotropics through the P450 cytochrome system. As a result, they could prolong the QT interval (25–27), so medication adjustments were necessary. Patients with previous psychiatric history treated with psychotropic drugs were at a high risk of developing adverse effects or abrupt changes in drug levels in plasma through pharmacokinetic interactions, so they required close follow-up during hospitalization. Corticoids used to reduce inflammation carry the risk of severe psychiatric side effects: they can cause affective and psychotic symptoms and increase the risk of relapse in those already diagnosed with a psychiatric disorder (28).

We aimed to describe the profile of SARS-CoV-2 positive patients in which a psychiatry consultation was required in our hospital. We also described our psychiatric interventions during the peak of the pandemic.

## MATERIALS AND METHODS

### Study Design

This is a cross-sectional descriptive study. This study was carried out within the Department of Psychiatry of Cruces University Hospital (Basque Country, Spain), a hospital that comprises 900 inpatient beds and covers 550,000 people. Data from each psychiatric consultation within our consultation-liaison service were consecutively obtained during 1 month from March 17 (4 days after the state of emergency was declared in Spain) to April 17, 2020. A total of 721 hospitalizations of SARS-CoV-2 positive patients took place during this time frame.

### Participants and Sources of Information

In the present study, we used a non-probability sampling method. All COVID-19 inpatients that were consecutively referred to our psychiatry liaison service were selected for

analysis. Sociodemographic variables such as age, gender, and psychiatric history according to the International Classification of Diseases (ICD-10) were extracted from patient history. We considered past psychiatric history as any psychiatric diagnosis of the ICD-10. The severity of pneumonia was assessed using the CURB 65 scale, an instrument used to determine the severity of pulmonary infections that also serve as a predictor of prognosis in the coronavirus infection (29, 30). We also collected the referrals' characteristics, such as date, sources (medical specialties), and primary reasons for consultation. Finally, we took other variables regarding intervention and outcome: psychopharmacological intervention, number of visits, and destination at discharge.

The Service of Preventive medicine provided general data on the number of hospitalized COVID-19 infections.

## Type of Intervention

We carried out two basic types of intervention: face-to-face and telephonic interviews. Following CDC recommendations, whenever possible, telematic communication was preferred to limit healthcare workers' exposure to the virus. We stated that telephonic interviews would initially manage referrals whose objective was crisis intervention or anxiety management. In general, those patients presenting with psychotic symptoms, severe behavioral disturbances, and suicide ideation were evaluated face-to-face from the beginning. We also provided familiar crisis intervention if needed. Medication interactions between COVID-19 treatment and concomitant psychotropic drugs were in all cases assessed and switched to safer options if indicated by clinical guidelines.

## Telephonic Crisis Intervention

A crisis can be defined as a period of psychological disequilibrium triggered by a hazardous event. We followed the guide of the Crisis Intervention by Telephone book by Lester (31). The use of telephone interviews is controversial; some authors stated that its use could even question the profession of psychiatry (32). However, according to the extensive research by Lester, telematic counseling may even be more effective in some situations, such as acute anxiety or those disorganized patients that cannot handle face-to-face intervention. Telephone interviews have unique features: they potentiate patient control and anonymity, facilitating self-revelation and openness; it is an accessible and immediate way of communication and can even promote positive transference (31). A meta-analysis published by Hubley et al. revealed that patients and providers were both satisfied with telepsychiatry. It was comparable to face-to-face in terms of reliability of clinical assessments and treatment outcomes (33).

## Face-to-Face Intervention

Our team was equipped with protective clothing, surgical gloves, face shields, and FFP2 face masks during all face-to-face interventions. In addition, we kept a minimum of 2 m between the staff and the patient and avoided all physical contact with patients and objects inside the room.

## Statistical Methods

Descriptive statistics for the study were performed. Categorical data were reported as frequencies and percentages, while continuous data were presented as median and standard deviation. Statistical analysis was carried out using IBM® SPSS® Statistics version 25.0 (IBM GmbH, Ehningen, Germany).

## Ethics

The Cruces University Hospital Ethics Committee approved this study as part of an ongoing database within our psychiatry department.

## RESULTS

### Patients

We received a total of 43 SARS-CoV-2-positive referrals, of which  $n = 16$  (37.2%) were men and  $n = 27$  (62.8%) were women. In 9.3% of patients, the intervention was requested for a family intervention. The median age was 61 (SD 14) years old. The

**TABLE 1 |** Clinical characteristics of COVID-19 psychiatry liaison referrals.

Sex	Male: 16 (37.2%) Female: 27 (62.8%)
Age (median)	61 (SD 14)
Psychiatric diagnosis	No psychiatric history: 18 (41.9%) F.05 Delirium: 3 (7%) F.07 Organic personality disorders ... 1 (2.3%) F.10 Alcohol 1 (2.3%) F.20 Schizophrenia: 1 (2.3%) F.22 Delusional disorder: 1 (2.3%) F.25 Schizoaffective disorder: 2 (4.7%) F.28 Other psychotic disorders: 1 (2.3%) F.31 Affective bipolar disorder 2 (4.7%) F.32 Depressive episode: 3 (7.0%) F.33 Recurrent depression: 3 (7.0%) F.41 Other anxiety disorders: 2 (4.7%) F.43 Adjustment disorder: 3 (7.0%) F. 69 Borderline personality: 1 (2.3%) F.73 Severe cognitive impairment: 1 (2.3%)
Comorbidities	No coexisting disease: 9 (20.9%) Hypertension: 4 (9.3%) Diabetes: 1 (2.3%) Coronary disease: 1 (2.3%) COPD: 2 (4.7%) Cancer: 1 (2.3%) Chronic renal disease: 1 (2.3%) Two or more: 19 (44.2%) Others: 5 (11.6%)
Treatment	Antivirals: 36 (83.7%) Antibiotics: 28 (65.1%) Corticoids: 20 (46.5%) Immunoglobulins: 1 (2.3%) Hydroxychloroquine: 33 (76.7%) Mechanical ventilation: 10 (23.3%)

median age for men was 62.2 (SD 17.6) and 60.5 (SD 11.5) for women.

A complete list of clinical data is shown in **Table 1**. The majority of patients (58.1%) presented past psychiatric history at the moment of the referral, and most of them (44.2%) had two or more coexisting organic illnesses.

Regarding COVID infection severity at hospital admission, most patients had a CURB 65 score of 0 (37.2%), a score of 1 in 20.9%, 2 in 11.6%, and 3 in 9.3%. A total of 20.9% of patients did not have the score calculated at the moment of hospitalization. Frequent treatments comprised antivirals, hydroxychloroquine, and corticoids (**Table 1**). In 23.3%, mechanical ventilation was needed.

### Referral Features

A total of 721 patients were admitted to our hospital as inpatients due to COVID infection during the study period. Of them, 43 needed a psychiatric evaluation (5.6%) (**Figure 1**). The services requesting a psychiatric consultation and the reasons for it are depicted in **Table 2**. The most frequent source of referrals was the Infectious Disease Department, reaching up to 37.2% of the requests. The most frequent reason was patient anxiety (25.6%) followed by depressive mood (18.6%) and adjustment of medication (18.6%).

### Psychiatric Intervention and Outcome

Patients received a median of 3.7 visits/calls during hospitalization. We visited men a median of 4.1 (SD 1.7) times and women a median of 3.5 (SD 2.5) times, but these differences did not reach statistical significance.

In 58.1% of the referrals, the intervention took place by telephone. The rest needed a face-to-face approach. Regarding

psychotherapeutic interventions, 67.4% received psychological counseling or psychotherapy support services. Psychological counseling was more frequent in telephone interventions than in face-to-face assessments (84 vs. 44.4%), reaching statistical significance ( $p < 0.05$ ).

Over the total amount of patients, antipsychotics were prescribed in 34.9% and benzodiazepines in 20.9%. No other drug classes such as SSRI or mood stabilizers were initiated in any individual. There was a need for treatment switch in 20.9% of patients to avoid the risk of pharmacokinetic interactions. In all cases, safer options were administered until the end of the COVID-19 course of treatment following guideline recommendations.

**TABLE 2 |** Psychiatric diagnosis after evaluation of the referrals.

ICD-10 diagnosis	Percentage
No psychiatric diagnosis	1 (2.3%)
F.05 Delirium	8 (18.6%)
F.20 Schizophrenia	1 (2.3%)
F.22 Delusional disorder	1 (2.3%)
F.25 Schizoaffective disorder	2 (4.7%)
F.28 Other psychotic disorders	1 (2.3%)
F.30 Manic episode	1 (2.3%)
F.31 Affective bipolar disorder 2	2 (4.7%)
F.32 Depressive episode	2 (4.7%)
F.41 Other anxiety disorders	1 (2.3%)
F.43 Adjustment disorder	5 (11.6%)
F.69 Borderline personality	1 (2.3%)
F.73 Severe cognitive impairment	1 (2.3%)
Z code	14 (32.5%)

**FIGURE 1 |** Total daily hospitalized SARS-CoV-2 infections are depicted in vertical red charts. The blue line represents the evolution of daily psychiatry liaison referrals.

**TABLE 3** | Referral features ( $n = 43$ ).

Source (Specialty)	Intensive care unit: 5 (11.6%)
	Internal medicine: 6 (14%)
	Respiratory medicine: 11 (25.6%)
	Infectious disease: 16 (37.2%)
	Gynecology and obstetrics: 2 (4.7%)
	Emergency medicine: 2 (4.7%)
	Cardiology: 1 (2.3%)
Reason	Anxiety: 11 (25.6%)
	Low mood: 8 (18.6%)
	Family crisis: 4 (9.3%)
	Delirium: 2 (4.7%)
	Medication adjustment: 8 (18.6%)
	Follow-up of psychiatric patients: 2 (4.7%)
	Suicidal ideation: 1 (2.3%)

The most frequent diagnosis (32.5%) was *Z-code (Factors influencing health status and contact with health services)* categorized in the ICD-10. Delirium not induced by alcohol or other drugs (F.05) was diagnosed in 18.6% of patients. Finally, there was one manic episode that was categorized as treatment-related and one depressive episode with psychotic symptoms that required psychiatric hospitalization. The complete list of psychiatric diagnoses at discharge is represented in **Table 3**.

Regarding outcomes, hospital-to-home discharge occurred in 27 (62.8%) of patients. A total of 11 (25.6%) remained hospitalized at the moment of the analysis, and 3 (7%) were transferred to another medical hospital. One individual (2.3%) was sent to an inpatient psychiatry facility, and 1 (2.3%) of the 43 individuals died.

## DISCUSSION

In our study, we analyzed the features of the psychiatric referrals during the first wave of the pandemic. In total, 5.6% of the COVID-19 patients admitted to our hospital needed a psychiatric evaluation at the request of the referent doctor. This number is lower than other studies in which 25% of coronavirus-infected patients required a psychiatric assessment (34).

We observed that the referral rate changed over time: it remained low while the hospitalization curve trended upward and increased after the peak of the first wave (Image 1). We hypothesize that during the rising phase of the curve, when little was known about the virus and protocols were in constant change, all referrals were kept to a minimum to avoid medical staff exposure and save protection equipment. On March 31, we implemented a phone-based psychological support program, explaining the increase in referrals. Another explanation may be a general reduction of activity, seen not only in psychiatry but also in other disciplines (35, 36), although we did not specifically evaluate this in our study. For example, Butler et al. found a 40% reduction of liaison psychiatry consultations during the first wave (23). Other studies report a marked decrease

of referrals, specifically during March 2020, which returned to normal afterward (37). These data contrast with studies during the second wave in which the number of liaison psychiatry consultations increased by 18.8% (22).

In our sample, we found a high proportion of acute anxiety and low mood symptoms, in line with previous studies that analyzed the prevalence of depression and anxiety in COVID-19 patients (38–40). Complete isolation during treatment, fear of the unknown, or the lack of emotional support over the hospitalization may explain this finding. Still, the infection already increases the risk of anxiety or affective disorders (13, 41). In addition to this, previous research has established “sickness behavior” (42), a pattern of adaptive behavioral changes that occur in both animals and humans in response to infection or inflammatory processes. It consists of low mood, anxiety, and social isolation, which we also observed in our COVID-19 referrals.

Delirium is a common symptom of COVID-19 disease, ranging from 25 to 33% in previous studies (43, 44). It constituted 18.6% of the diagnosis made in our referrals. Although not reported, most delirious patients presented with florid psychotic symptoms and behavioral disturbances that were, in some cases, a diagnostic challenge. However, other characteristic features such as fluctuating course and attention impairment were almost always present. Delirium is usually multifactorial: the old age of our patients, with a median age of 61 years old, polypharmacy, and the infection itself may contribute to its development.

In our sample, the medication used to treat the infection comprised mainly antivirals and hydroxychloroquine, which were used experimentally during the first wave of the pandemic. Ritonavir is a well-known CYP3A4 inhibitor, and therefore in 20.3% of our total referrals, a change in medication was necessary to avoid interactions. If we consider only those patients with a prior psychiatric history, this percentage goes up to 37.5%. This confirms previous research reporting an elevated risk of pharmacokinetic interactions in psychiatric patients (28), a fact that acquires particular relevance in a SARS-CoV-2 infection setting. In addition, we report a case of first episode of mania presumably attributed to steroid therapy that was effectively addressed with Olanzapine. We did not identify any first psychotic episodes. However, it has been proved that the risk of a psychotic disorder is augmented during the SARS-CoV-2 illness, and there are case reports of new-onset psychosis after infection (15, 45–47).

In our study, we also describe the interventions by our team. Although some centers decided to evaluate all patients face-to-face (34), our protocol stated telephonic intervention would be preferred when possible. Still, 42.9% of patients had to be interviewed face-to-face to carry out an optimal psychopathological exploration, a situation that in all cases required us to wear Personal Protective Equipment (PPE). The median visit per patient was 3.7, but one patient needed up to 17 interventions due to the severity of his symptoms and the longer-than-average length of COVID-19 hospitalizations. In other cases, face-to-face interviews were unavoidable due to the

often scarce and confusing information obtained by phone calls, leading to doubts in the diagnosis.

## STRENGTHS AND LIMITATIONS

We registered all the referrals to our psychiatric liaison service in a snowball fashion; therefore, there is a risk of bias, and the results cannot be extrapolated to the general population. Also, the small sample limits the statistical power of potential comparisons within groups. Nevertheless, the main strength of our study is that it represents a comprehensive picture of the role of a psychiatry service during the first wave of the pandemic, with a specific focus on the interventions by liaison subspecialty. However, as we did not use psychometric scales, it is also difficult to compare results.

## CONCLUSIONS

For psychiatrists working in liaison psychiatry, the novel COVID-19 was a challenge in which the course of action with hospitalized patients had to be reformulated. It forced psychiatrists to change their previous intervention settings and working strategies. More research is needed not only to obtain a complete picture of the psychiatric symptoms of the coronavirus disease but also to understand the different patterns of psychiatry liaison care during the pandemic.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The present study was approved by the Cruces University Hospital Ethics Committee as part of an ongoing observational study in our psychiatry department. This study aims to describe all the patients treated in our unit, both inpatients and outpatients. Due to the exceptional circumstances regarding COVID-19 isolation policies, written informed consent could not be systematically signed and we obtained verbal consent instead. In those patients whose capability was impaired, a legal representative was informed and gave consent. Patient anonymity was in all cases preserved and we analyzed only aggregated data.

## AUTHOR CONTRIBUTIONS

ML-A, JG-B, SF-S, JC-G, and AP-R collected patient data. AA-A collected epidemiological data of total hospitalized infections. ML-A and AA-A analyzed the data. ML-A, JC-G, and MS-H wrote the manuscript. All authors approved the final work.

**Objective:** The outbreak of coronavirus disease 2019 (COVID-19), declared as a major public health emergency, has had profound effects on public mental health especially emotional status. Due to professional requirements, medical staff are at a higher risk of infection, which might induce stronger negative emotions. This study aims to reveal the emotional status of Chinese frontline medical staff in the early epidemic period to better maintain their mental health, and provide adequate psychological support for them.

**Methods:** A national online survey was carried out in China at the early stage of the COVID-19 epidemic. In total, 3025 Chinese frontline medical staff took part in this investigation which utilized a general information questionnaire, the Emotion Regulation Questionnaire (ERQ), and the Berkeley Expressivity Questionnaire (BEQ).

**Results:** At the early stage of COVID-19, anxiety was the most common negative emotion of Chinese medical staff, followed by sadness, fear, and anger, mainly at a mild degree, which declined gradually over time. Nurses had the highest level of negative emotions compared with doctors and other healthcare workers. Women experienced more fear than men, younger and unmarried medical staff had more anxiety and fear compared with elders and married ones. Risk perception and emotional expressivity increased negative emotions, cognitive reappraisal reduced negative emotions, while negative emotions led to more avoidant behavior and more physical health disturbances, in which negative emotions mediated the effect of risk perception on avoidant behavior tendency in the model test.

**Conclusion:** Chinese frontline medical staff experienced a mild level of negative emotions at the early stage of COVID-19, which decreased gradually over time. The findings suggest that during the epidemic, nurses' mental health should be extensively attended to, as well as women, younger, and unmarried medical staff. To better ensure their mental health, reducing risk perception and improving cognitive reappraisal might

be important, which are potentially valuable to form targeted psychological interventions and emotional guidance under crisis in the future.

## INTRODUCTION

Coronavirus disease 2019 (COVID-19), similar to SARS in 2003, has been declared as a major public health emergency (1), and has had a profound influence on personal mental health (2, 3). Up to May 4, 2020, there were 3,349,786 confirmed cases and 238,628 deaths because of COVID-19 worldwide (4). Millions of medical staff worked on the frontline to fight against the disease, making them face a high risk of infection (5, 6) and huge mental pressure (7, 8). Thousands of Chinese medical personnel combated with COVID-19 on the frontline, of whom over 3,000 medical staff were infected with the virus as of February 20, 2020 (8). Therefore, the COVID-19 epidemic can be regarded as a crisis event for the general population especially for those frontline medical staff.

According to Myer and Conte's (9) triage assessment system (TAS) for crisis intervention, reactions to crisis events are divided into three domains: affective or emotional, behavioral, and cognitive. The TAS model offers us an understanding about the type of reactions people experience as well as the intensity of these reactions in crisis. TAS can also provide a quick, accurate, and easy-to-use method that is directly usable in the intervention process and can monitor individuals' progress during the crisis intervention process. Thus, the TAS model is not only a valuable tool in the assessment of individual reactions in crisis but also a guide in the identification of the complex interaction among the three domains (9).

The first and most significant response under crisis is emotional response. Fear, anxiety, anger, and sadness are universal negative emotions among medical staff when facing sudden and arduous public health issues (10, 11). Studies revealed (10) that fear was a prominent emotional response among healthcare workers, and 1.4 times that compared with non-clinical staff (12). Taking the SARS epidemic as an example, frontline medical personnel were more likely to experience stronger negative emotions, such as the fear of being infected themselves or infecting their family members and anxiety of uncertainty (10, 13, 14). Additionally, anxiety was another common negative emotion among medical personnel (15). Medical staff working in emergency, ICU, and respiratory departments were two times more likely to suffer from anxiety (12). As to the gender difference, women had more anxiety compared with men (16). Being female, having frequent contact with patients, inadequate protective supplies, and being overloaded work were all related to the high level of anxiety (17, 18), which might contribute to emotional exhaustion (19). Besides, healthcare workers also experienced anger and sadness during SARS (13). A variety of factors might increase substantial psychological stress on medical staff (11, 13), such as shortage of protective supplies, direct contact with patients, and overloaded work, which might increase the infection rate of medical staff

consequently (17, 20, 21). Although there exist studies on the negative emotions of medical staff during past epidemics, previous studies did not observe the status and sources of negative emotions of medical staff in detail, which is guaranteed to better maintain their mental health, as well as to provide adequate psychological support for them.

Nevertheless, different medical professionals may have different negative emotional responses. Studies reported (22) that nurses were more worried compared with doctors during the A/H1N1 influenza pandemic. The overall level of distress of nurses was significantly higher than that of other medical staff (23). During the COVID-19 epidemic, nurses reported experiencing more severe mental health symptoms than those of physicians (16). However, the emotional status and trend of negative emotions at the early stage of the epidemic were not systematically investigated, which was potentially important to develop more targeted psychological support toward different types of medical staff, since they were equally treated in the current psychological intervention (23).

In terms of emotional states, personal emotions fluctuate instead of sustaining (24). As Gross (24) pointed out, an individual's emotions unfold over seconds to minutes, which suggests the dynamic changes of emotions as time goes by. The latest cross-sectional survey (12) on the COVID-19 epidemic investigating 2042 medical staff from Fujian Provincial Hospital in China revealed that about 70.6% of the medical staff suffered from a moderate to severe level of fear, and 22.6% had a mild to moderate level of anxiety. However, this investigation was carried out at very early stage of this epidemic (January 24, 2020), and did not continue to monitor the emotion change of medical staff. The trend of negative emotions of Chinese medical staff is needed to explore timely and targeted psychological support in different periods of COVID-19. In previous epidemics, studies found (19, 25) that the fear and anxiety of medical staff appeared immediately and then decreased at the early stage of the epidemic, indicating that the early epidemic stage would be a critical period to monitor the negative emotional responses of frontline medical staff, as well as to provide timely psychological assistance. We thus supposed that negative emotions might be continuously decreasing from the initial phase of the epidemic.

So far, only the negative emotion reaction under crisis has been discussed, while according to Myer's TAS model, cognitive and behavioral reactions of frontline medical staff also need to be paid attention to. Facing the COVID-19 crisis event, a full understanding of the negative emotional responses and its influential factors from cognitive and behavioral domains might help to provide comprehensive information to formulate effective psychological interventions in future.

Studies reported (26) that risk perception in the cognitive domain might induce negative emotion. One study showed (27) that the level of fear elevated when people perceived a

higher risk perception of SARS. Kushnir et al. (28) also reported that people tended to overestimate the risk of events that rarely happened while eliciting intense fears. Moreover, irrational risk perception would bring unnecessary anxiety and panic in turn (26). According to the Health Belief Model (29), risk perception could also influence individual behaviors. The high risk perception could affect medical staff's willingness to care for patients, especially when they were afraid of infecting their family members (30). Therefore, it could be assumed that the risk perception might influence the negative emotions and behavior of frontline medical staff under this epidemic.

Emotions might change behavior pattern. In terms of the relationship between negative emotion and behavioral reaction, studies revealed that fear was linked with avoidant behavior for protecting individuals from dangers (31, 32). For example, some medical staff were reluctant to work or determined to resign due to the fear of being infected or infecting their family members during the SARS epidemic (17, 33). The results suggested that negative emotions might promote the avoidant behavior tendency of medical personnel in the present epidemic, which need further evidence.

Stress would not only induce negative emotions, but also activate physical response. As mentioned above, the high level of negative emotion might cause physical function disturbance of frontline medical staff during an epidemic, such as headaches (7), anorexia (10), sleep disorders (34), and pain (35). Indeed, medical staff experienced more physical symptoms such as burnout, insomnia, and anorexia (10, 11, 13). However, the influence of negative emotions on the physical health of medical staff remains unknown under COVID-19, and we supposed that focusing on the physical response of frontline medical staff could broaden Myer's TAS theoretical system and reflect individual response toward COVID-19 more systematically.

Moreover, emotion regulation defined as the attempt to affect the way that one experiences or expresses emotions (24), can be used to help frontline medical staff deal with emotion reactions under the COVID-19 crisis. Gross and John (36) proposed that cognitive reappraisal and expressive suppression were two common emotion regulation strategies. Cognitive reappraisal, defined as the attempt to reinterpret the situation eliciting the emotion in the manner of changing its emotional impact (37, 38), could reduce negative emotions as reported (37, 39). While expressive suppression is defined as the attempt to hide, suppress, or reduce the ongoing emotion-expressive behavior (40). Cognitive reappraisal is related to healthier emotion and better wellbeing compared with expressive suppression (41). Additionally, emotional expressivity, which means expressing emotion through verbal, non-verbal, and physiological channels (42), also has an influence on negative emotions besides cognitive reappraisal and expressive suppression. Gross also pointed out that emotional expressivity as an opposite regulation strategy of expressivity suppression, might have a unique influence on emotions, correlating with negative emotion and mental health problems (43). Importantly, a study showed (44) that only expressive suppression significantly modulated fear under an epidemic, while other emotional regulation strategies did not, which suggested that different types of emotional regulation had

different effects on fear emotion. However, previous research usually observe the effect of emotion regulation strategies on emotion in total, while the effect of different types of emotional regulation strategies on different types of emotions under crisis was not systematically revealed.

In summary, our present study aims to investigate the emotional status of Chinese frontline medical staff at the early period of the COVID-19 epidemic, and further explore its trend and influential pathway. Our hypotheses were:

- 1) Chinese frontline medical staff might have a certain degree of negative emotions at the early stage of the COVID-19 epidemic;
- 2) Nurses might have a higher level of negative emotions compared with other medical professionals;
- 3) At the early stage of the COVID-19 epidemic, negative emotions of the Chinese frontline medical staff might decrease significantly;
- 4) Risk perception and emotion regulation might influence negative emotion;
- 5) Negative emotion might have a potential effect on avoidant behavior tendency and physical health;
- 6) Negative emotion might have a mediation effect between risk perception and avoidant behavior tendency and physical health.

## METHODS

### Participants

A cross-sectional online survey was used to assess the emotional responses of Chinese frontline medical staff with a convenience sampling method. Doctors, nurses, and other medical staff, who cared for COVID-19 patients in the designated hospitals during this epidemic were eligible for this online national investigation from January 27 to February 11, 2020. Participants answered the questionnaire through an online link based on their personal will. A total of 4,100 medical staff responded, and 3,025 questionnaires were completed, which were from all provinces in China. Incomplete and halfheartedly filled in questionnaires were excluded from formal analysis. As depicted in **Supplementary Table 1**, there were 1,916 (63.3%) women and 1,109 (36.7%) men, aged between 20 and 65 years old. Among them, 1,237 (40.9%) were doctors, 1,371 (45.3%) were nurses, and 417 (13.8%) were other medical staff. In addition, 1,852 (61.2%) were married, 1,067 (35.3%) were unmarried, and 106 (3.5%) were divorced or widowed. Over 96.6% of the participants had college and postgraduate or higher educational levels. The participants covered all provincial administrative regions in China, which were divided into six groups of provinces according to the number of confirmed cases (above 10,000, 1,000–9,999, 500–999, 100–499, 10–99, and 1–9).

### Instruments

**General information:** Basic information about demographic characteristics, including gender, age, degree of education, marital status, and city (number of confirmed cases above 10,000, 1,000–9,999, 500–999, 100–499, 10–99, and 1–9) were collected.

**Negative emotions:** To collect the degree of negative emotions, four questions were designed with five options (none, mild, moderate, severe, extremely severe/unbearable): How fearful (anxious, angry, sad) do you feel today? Exploratory factor analysis (EFA, principal axis factoring (PAF)) and reliability analysis were carried out and found that the KMO of this scale was 0.797, which accounted for as much as 64.931% of the total variance; the Cronbach's alpha was 0.82. Cognitive sources for negative emotions are listed in the **Supplementary Materials**.

**Risk perception:** To observe people's risk perception during the epidemic, three questions were designed (yes or no): "This is a severe outbreak," "Epidemic is close to me," "I am in danger." Exploratory factor analysis [EFA, principal axis factoring (PAF)] and reliability analysis were carried out and found that the KMO of this scale was 0.622, which accounted for as much as 57.94% of the total variance; the Cronbach's alpha was 0.635.

**Cognitive sources of public anxiety:** To explore possible sources of public anxiety, 12 questions were investigated (yes or no): Do you feel anxious about the new confirmed cases, possible infection without isolation, death number, shortage of protective supplies, new suspected cases, possible infection without protection, new foci, insufficient cooperation of patients, insufficient protection, being isolated due to the epidemic, insufficient duty of medical staff, and others?

**Cognitive sources of public anger:** To explore possible sources of public anger, 10 questions were surveyed (yes or no): Do you feel anger about irresponsible rumors, possible infection without isolation, possible infection without protection, insufficient cooperation of patients, shortage of protective supplies, insufficient attention of unit, insufficient duty of medical staff, unsupported by families, being isolated due to the epidemic, and others?

**Cognitive sources of public sadness:** To explore possible sources of public sadness, eight questions were investigated (yes or no): Do you feel sadness about innocent people, shortage of protective supplies, helpless patients, exhausted medical staff, being infected by the virus, being isolated due to the epidemic, unsupported by families, and others?

**Cognitive sources of public fear:** To explore possible sources of public fear, 14 questions were investigated (yes or no): Do you fear being infected by the virus, infection of families, possible infection without isolation, new confirmed cases, death after infection, shortage of protective supplies, possible infection without protection, death number, disrupted work or study after the epidemic, new foci, new suspected cases, insufficient cooperation of patients, being isolated due to the epidemic, and others?

**Avoidant behavior tendency:** To observe potential avoidant behavior tendency during the epidemic, three questions were designed (yes or no): "I am intending to run away if possible," "To escape isolation, I might not go to hospital if I am a suspected case," "To protect myself and families, I might quit the job if I am a medical staff member." The KMO of this scale was 0.687, which accounted for as much as 77.88% of the total variance; the Cronbach's alpha was 0.857.

**Disturbed physical function:** To observe potential disturbed physical health during the epidemic, three questions were designed (yes or no): "Within the past week, I cannot keep my

regular schedule as usual," "Within the past week, I cannot eat as well as usual," "Within the past week, I cannot sleep as well as usual." The KMO of this scale was 0.602, which accounted for as much as 56.20% of the total variance; the Cronbach's alpha was 0.607.

**Emotional regulation strategies:** The Emotion Regulation Questionnaire (ERQ) with 10 items was used in this investigation, which was designed by Gross and John (36) and translated into Chinese in 2007 (45). High scores indicate higher cognitive reappraisal and expressive suppression, respectively. The Cronbach's alpha coefficient was 0.827 for cognitive reappraisal and 0.714 for expressive suppression in this study.

The Berkeley Expressivity Questionnaire (BEQ) (43) was also used to observe personal emotional expression, which is comprised of 16 items and 3 subscales: impulse strength, negative expressivity, and positive expressivity. The Cronbach's alpha coefficient was 0.834 in this study.

## Procedures

Questions were designed and edited as an online questionnaire, which was approved by the Human Research Ethics Committee of the Army Medical University of China and Wenjuanxing online platform ([www.wjx.top](http://www.wjx.top)), a platform providing functions equivalent to Amazon Mechanical Turk. From January 27 to February 11, 2020, participants answered the questionnaire through an online link with their personal cellphone or computer based on his/her individual will; there was no adverse consequence if they refused or did not have time to fill in the online questionnaire. Each person took about 10–15 min to complete the questionnaire after they signed the electronic version of the informed consent form. All participants could get a professional psychological consultation and aid *via* the hotline at the bottom of the electronic questionnaire.

## Statistics

An independent *t*-test and one way ANOVA were conducted to observe the demographic characteristics of negative emotions. Independent *t*-test analysis was also carried out to observe the influence of risk perception on negative emotions. The Chi-squared test was carried out to observe the effect of negative emotions on avoidant behavior tendency and disturbed physical function. Pearson correlation was carried out to observe the correlation between negative emotions, risk perception, emotional regulation, avoidant behavior, and disturbed physical function. A structural equation model was carried out with AMOS 24.0 to test the interaction between variables based on the TAS theory model.

## RESULTS

### The Negative Emotional Status of Frontline Medical Staff

#### The Demographic Characteristics of Negative Emotions

To observe the negative emotional features of frontline medical staff, an independent two-sample *t*-test and one-way ANOVA analysis were conducted, which indicated (**Supplementary Table 1**) that women had a higher level of

fear compared with men [ $t_{(3,023)} = -3.288, p = 0.001$ , Cohen's  $d = 0.12$ ]. Medical staff aged 40–49 years old had lower levels of anxiety [ $F_{(3,3,021)} = 5.026, p = 0.002$ , partial- $\eta^2 = 0.005$ , and fear [ $F_{(3,3,021)} = 3.417, p = 0.017$ , partial- $\eta^2 = 0.003$ ]. Medical staff with postgraduate degrees or higher reported lower fear levels [ $F_{(3,3,021)} = 2.763, p = 0.041$ , partial- $\eta^2 = 0.003$ ]. Unmarried medical staff reported higher levels of anxiety [ $F_{(3,3,021)} = 3.200, p = 0.022$ , partial- $\eta^2 = 0.003$ ] and fear [ $F_{(3,3,021)} = 3.564, p = 0.014$ , partial- $\eta^2 = 0.004$ ]. As expected, medical staff from the city (over 10,000 confirmed cases) had higher levels of anxiety [ $F_{(3,3,021)} = 2.440, p = 0.004$ , partial- $\eta^2 = 0.032$ ] and anger [ $F_{(3,3,021)} = 3.412, p = 0.004$ , partial- $\eta^2 = 0.006$ ].

### The Negative Emotions of Different Medical Staff

One way ANOVA (Figure 1A) showed that among the negative emotions, anxiety was the most prominent emotion in medical staff, followed by sadness, fear, and anger [ $F_{(3,12,096)} = 174.075, p < 0.001$ , partial- $\eta^2 = 0.041$ ]. The response selection rates of anxiety, sadness, fear, and anger were 78.3, 67.5, 68, and 45.8%. And 32.8–55.2% of medical staff rated their emotion at a mild degree. Further analysis (Supplementary Table 2) showed that compared with doctors and other medical staff, nurses had higher selection rates of anxiety [ $\chi^2_{(2,3,025)} = 16.776, p < 0.001$ ], sadness [ $\chi^2_{(2,3,025)} = 11.908, p < 0.001$ ], fear [ $\chi^2_{(2,3,025)} = 49.976, p < 0.001$ ], and anger [ $\chi^2_{(2,3,025)} = 21.270, p < 0.001$ ].

Figure 1B shows that nurses also reported higher levels of anxiety [ $F_{(2,3,022)} = 8.347, p < 0.001$ , partial- $\eta^2 = 0.005$ ], sadness [ $F_{(2,3,022)} = 7.732, p < 0.001$ , partial- $\eta^2 = 0.005$ ], fear [ $F_{(2,3,022)} = 34.630, p < 0.001$ , partial- $\eta^2 = 0.022$ ], and anger [ $F_{(2,3,021)} = 9.719, p < 0.001$ , partial- $\eta^2 = 0.006$ ]. The results indicated that nurses experienced stronger negative emotions compared with other medical staff.

### The Trend of Negative Emotions Over Time

Figure 2A shows that the levels of negative emotions gradually declined over time during the early stage of the epidemic [anxiety:  $F_{(15,3,009)} = 3.199, p < 0.001$ , partial- $\eta^2 = 0.016$ , sadness:  $F_{(15,3,009)} = 2.016, p = 0.011$ , partial- $\eta^2 = 0.010$ , fear:  $F_{(15,3,009)} = 2.577, p = 0.001$ , partial- $\eta^2 = 0.013$ , and anger:  $F_{(15,3,009)} = 2.067, p = 0.009$ , partial- $\eta^2 = 0.010$ ]. Further analysis indicated (Figure 2B) that different medical professionals had a similar downward trend of sadness, fear, and anger over time without significant difference.

## Relationship Between Negative Emotions and Risk Factors, Emotional Regulation, Avoidant Behavior Tendency, and Disturbed Physical Function

### The Sources of Negative Emotions

Supplementary Figure 1 shows that the shortage of protective supplies was the leading cause for all negative emotions. Specifically, the main sources for anxiety were possible infection without isolation, new confirmed cases, and possible infection without protection. The main sources for sadness were exhausted medical staff, helpless patients, and innocent people. The main sources for fear were possible infection without isolation, possible

infection without protection, and being infected by the virus. The main sources for anger were possible infection without isolation, possible infection without protection, and irresponsible rumors.

The Chi-squared test was conducted to compare the percentage of sources between different medical professionals, which (Supplementary Table 3) indicated that compared with doctors, nurses had higher rates of “shortage of protective supplies” [ $\chi^2_{(2,3,025)} = 10.121, p = 0.006$ ] and “new confirmed cases” [ $\chi^2_{(2,3,025)} = 39.266, p < 0.001$ ], which were sources of anxiety, as well as a higher percentage of “being infected by the virus” [ $\chi^2_{(2,3,025)} = 17.980, p < 0.001$ ], which was a main source of fear.

### The Impact of Risk Perception and Emotional Regulation Strategy on Negative Emotion

Figure 3 shows that medical staff answered “yes” for “this is a severe outbreak,” and had higher levels of anxiety [ $t_{(3,023)} = 2.980, p = 0.003$ , Cohen's  $d = 0.46$ ], sadness [ $t_{(3,023)} = 2.677, p = 0.007$ , Cohen's  $d = 0.42$ ], and fear [ $t_{(3,023)} = 4.455, p < 0.001$ , Cohen's  $d = 0.73$ ] compared with those medical staff who had no risk perception. Similarly, medical staff answered “yes” for “the epidemic is close to me,” and reported higher levels of anxiety [ $t_{(3,023)} = 2.945, p = 0.003$ , Cohen's  $d = 0.31$ ], sadness [ $t_{(3,023)} = 2.375, p = 0.018$ , Cohen's  $d = 0.26$ ], and fear [ $t_{(3,023)} = 4.073, p < 0.001$ , Cohen's  $d = 0.47$ ]. Moreover, medical staff answered “yes” for “I am in danger,” and reported higher levels of anxiety [ $t_{(3,023)} = 12.602, p < 0.001$ , Cohen's  $d = 0.70$ ], sadness [ $t_{(3,023)} = 8.536, p < 0.001$ , Cohen's  $d = 0.47$ ], fear [ $t_{(3,023)} = 13.567, p < 0.001$ , Cohen's  $d = 0.77$ ], and anger [ $t_{(3,023)} = 7.061, p < 0.001$ , Cohen's  $d = 0.41$ ].

Pearson correlation showed that (Table 1) cognitive reappraisal and expression suppression were negatively related to the levels of anxiety, fear, anger, and sadness ( $r = -0.049 \sim -0.137, p < 0.01$ ), while positive emotion expression, negative emotion expression, and impulse strength were positively correlated with negative emotions ( $r = 0.041 \sim 0.166, p < 0.05$ ).

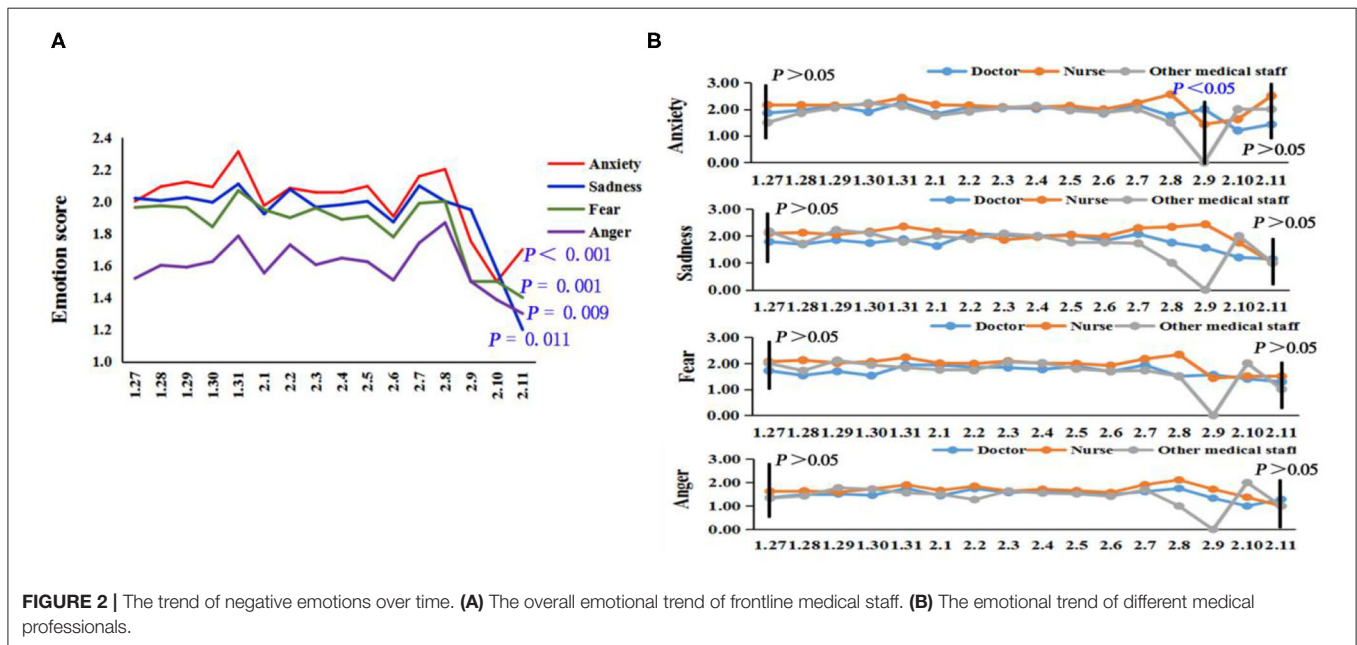

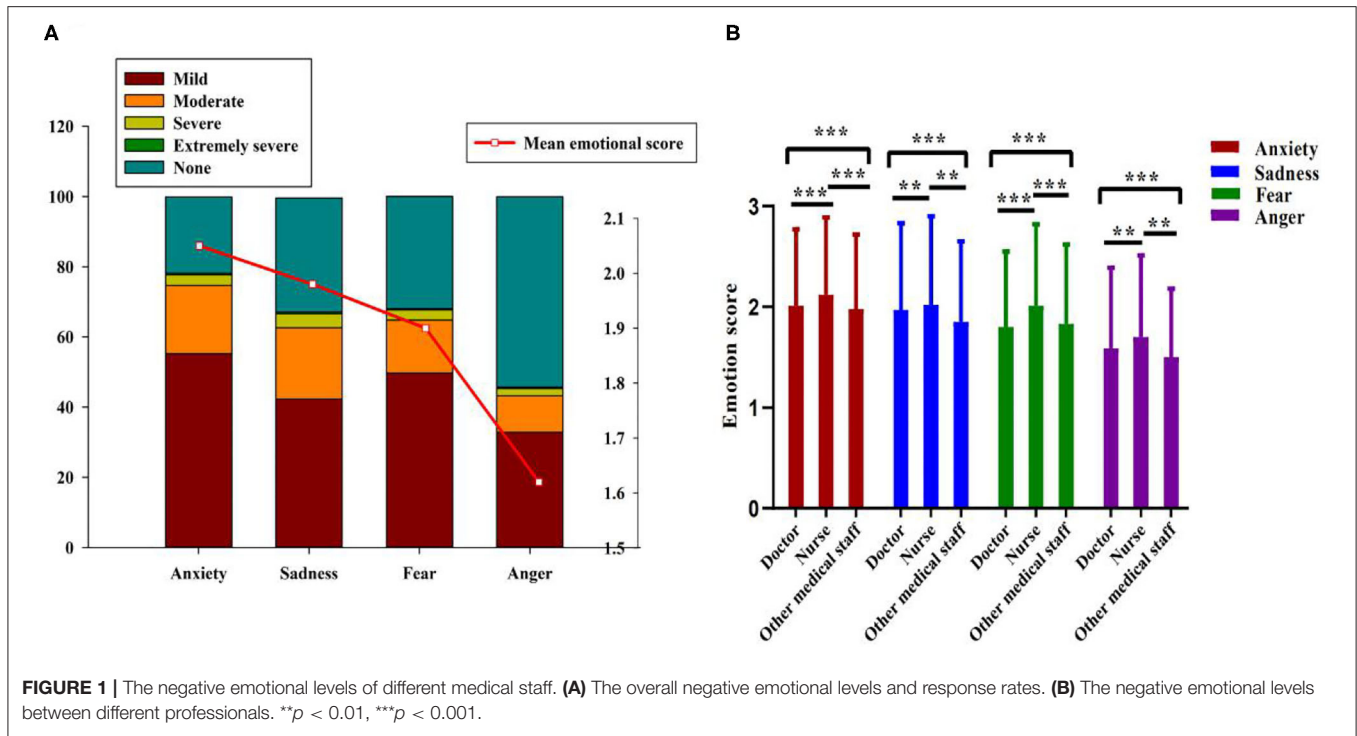

### The Effects of Negative Emotions on Avoidant Behavior Tendency and Disturbed Physical Function

Figure 4 indicates that negative emotions increased avoidant behavior tendency [ $\chi^2_{(4,3,025)} = 12.530 \sim 145.929$ , all  $p < 0.01$ ] and disturbed physical function [ $\chi^2_{(4,3,025)} = 46.331 \sim 319.721$ , all  $p < 0.001$ ] with increasing tendency as the enhancement of negative emotions (Supplementary Table 4).

## Emotional Models of Frontline Medical Staff

### Confirmatory Factor Analysis (CFA) Results

Supplementary Figure 2 shows that the CFA analysis on risk perception, disturbed physical function, and avoidant behavior tendency indicated an ideal model fit (46) ( $\chi^2 = 0$ ,  $df = 0$ , NFI = 1.000, IFI = 1.000, CFI = 1.000, RMSEA = 0.012  $\sim$  0.052), whereas the CFA coefficients of negative emotions also showed a satisfied model fit ( $\chi^2 = 4.998$ ,  $df = 1$ ,  $\chi^2/df = 4.998$ , NFI = 0.999, IFI = 0.999, CFI = 0.999, RMSEA = 0.005).

### Interaction Pathway Between Negative Emotions and Their Influential Factors

To further explore the interaction between negative emotions and risk perception, emotional regulation, avoidant behavior tendency, and disturbed physical function, a hypothesis-driven model test was carried out ( $\chi^2 = 57.986$ ,  $df = 9$ ,  $\chi^2/df = 6.443$ ,  $RMSEA = 0.042$ ,  $GFI = 0.995$ ,  $AGFI = 0.983$ ,  $NFI = 0.973$ ,  $IFI = 0.977$ ,  $TLI = 0.946$ ,  $CFI = 0.977$ ).

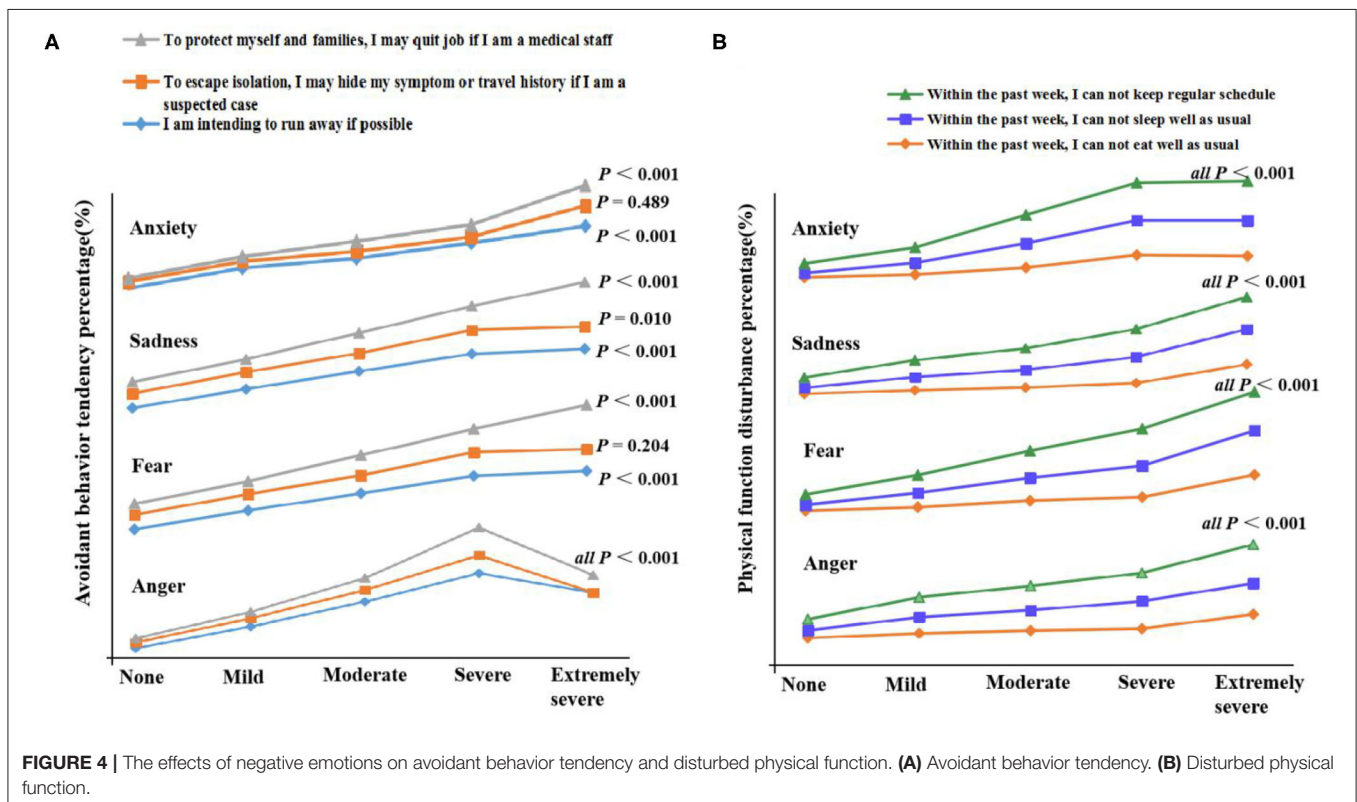

Figure 5 indicates that risk perception had a positive direct effect on negative emotion and avoidant behavior tendency, and an indirect effect on avoidant behavior tendency (0.029–0.048). Cognitive reappraisal had a negative effect while emotional expressivity had a positive effect on negative emotion. Negative emotion had a positive direct effect on avoidant behavior tendency and disturbed physical function, and an indirect effect on disturbed physical

**TABLE 1 |** Correlation between negative emotion and emotion regulation strategy.

	Cognitive reappraisal	Expressive suppression	Positive expressivity	Negative expressivity	Impulse strength
Anxiety	-0.076**	-0.049**	0.078**	0.139**	0.142**
Anger	-0.137**	-0.059**	0.084**	0.094**	0.151**
Sadness	-0.057**	-0.026	0.069**	0.132**	0.124**
Fear	-0.094**	-0.051**	0.096**	0.166**	0.148**

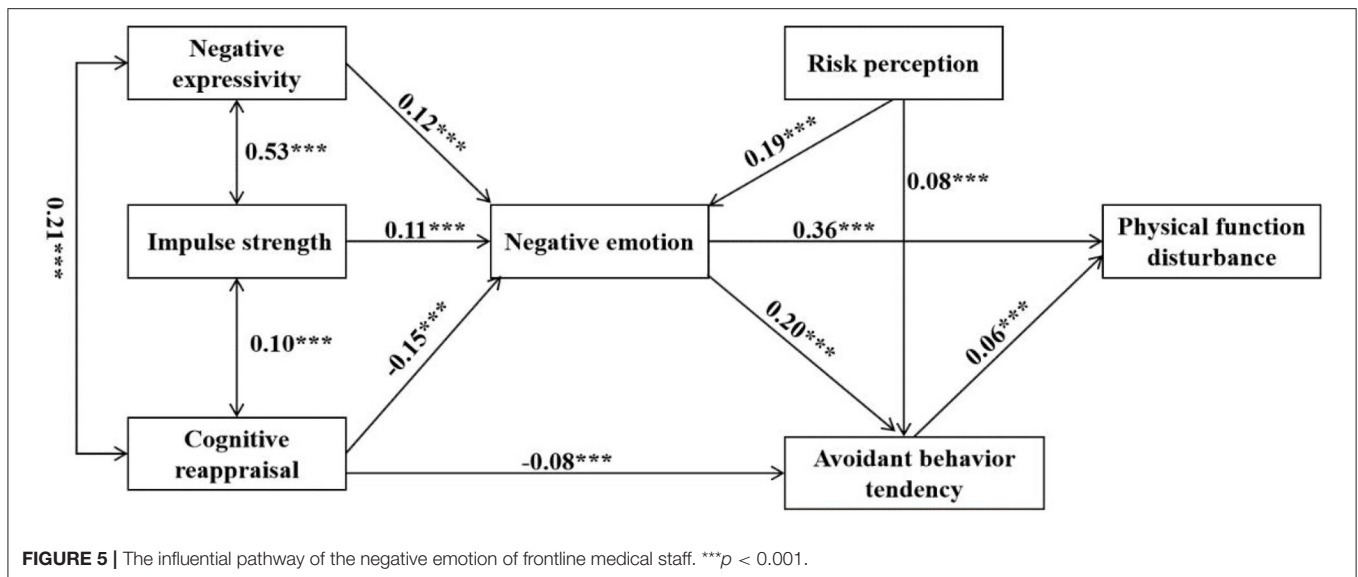

\*\* $p < 0.01$ .

function (0.005–0.02). The results indicated a positive effect between negative emotion and risk perception, avoidant behavior tendency, and disturbed physical function, in which negative emotion and avoidant behavior tendency played a mediation role.

Moreover, cognitive reappraisal reduced negative emotion ( $\beta = -0.15, p < 0.001$ ), and avoidant behavior tendency ( $\beta = -0.08, p < 0.001$ ), while impulse strength and negative expressivity increased negative emotion ( $\beta = 0.11, 0.12, p < 0.001$ ).

Multi-group analysis was conducted to verify the differences of models in three groups (doctors, nurses, and other medical staff). The result showed that there was no statistical difference in group comparisons ( $p = 0.367$ ), which indicated that the different roles of medical staff did not affect this model.

## DISCUSSION

In the current study, we explored the status, trend, and influential pattern of negative emotions in the Chinese frontline medical staff at the early stage of the COVID-19 epidemic *via* a nationwide investigation. Overall, we found that Chinese frontline medical staff experienced a mild level of negative emotions (i.e., fear, anxiety, anger, and sadness) in the early period of COVID-19, the trend of which decreased gradually over time. Additionally, nurses experienced a higher level of negative emotions, as well as women, younger, and unmarried medical staff. Risk perception and emotional expressivity increased negative emotions, cognitive reappraisal and expressive suppression reduced negative emotion, while negative emotions led to more avoidant behavior and more physical health disturbances, in which negative emotions mediated the effect of risk perception on avoidant behavior tendency and physical health disturbance of Chinese frontline medical staff.

### The Emotional Status of Frontline Medical Staff

The study revealed that Chinese frontline medical staff did experience different negative emotions, such as anxiety, sadness, fear, and anger. Among all the negative emotions, anxiety was the most common one for Chinese medical staff at the early stage of COVID-19. At the initial stage of COVID-19, it was normal for the public including frontline medical staff to experience negative emotions with the increasing

number of confirmed cases and deaths. Our finding was consistent with other studies (48, 49), which also revealed that medical staff experienced a higher level of anxiety during epidemics. For example, a multicenter survey (50) reported that the prevalence of anxiety was 44.7% in 1,563 Chinese medical workers fighting against COVID-19. Another study (20) also showed that frontline health professionals were highly vulnerable to experiencing physical exhaustion, fear, and emotion disturbance. Notably, in this study, four negative emotions were measured based on the TAS theory, while previous studies (5, 47) rarely investigated all the four negative emotions in one research. Thus, the findings suggested that psychological interventions and support should focus on relieving these primary negative emotions under crisis for frontline medical staff.

As to the degree of those negative emotions, medical staff only suffered from a mild degree even in the toughest period of fighting COVID-19, while the degree of negative emotions was rarely reported in other research. This might be due to the fact that Chinese medical staff had experienced the SARS epidemic in 2003 and they had been well prepared for the challenge of future epidemics ever since.

Among all the frontline medical staff, nurses reported the highest level of negative emotions compared with other medical professionals in our investigation, which was consistent with previous studies (22, 23). Nurses were more worried than doctors during the A/H1N1 influenza pandemic (22), and the overall level of distress was significantly higher than that of other medical staff during SARS (23). Nurses were regarded as the most vulnerable group among frontline medical staff due to their high exposure risk to the novel coronavirus compared with other medical professionals. For example, nurses were always at the frontline to screen suspected patients (51) and had close contacts with patients (52). Besides nurses, women, younger, and unmarried frontline medical staff also reported a higher level of negative emotions. Therefore, more attention should be

paid to maintain their psychological health under the current epidemic, and it is essential to support different kinds of medical staff differently.

### The Trend of Negative Emotions Over Time

The trend of negative emotions of Chinese frontline medical staff declined gradually as time went by, which was consistent with our hypothesis and previous findings (19, 25). However, according to one study conducted in Hong Kong in June 2003, researchers reported a relatively low level of distress in medical staff at the first stage of the epidemic, and they assumed that the level would be higher at the peak of the epidemic (23). Our result was inconsistent with their assumption. Two possible explanations for this finding: Firstly, the Chinese government played an active and productive role in the response to fighting against the epidemic, which enhanced medical staff's confidence toward the epidemic, and reduced their negative emotions effectively. Secondly, Chinese mental healthcare professionals provided psychological support for frontline medical staff in a timely and convenient manner (23), which guaranteed their mood effectively. The results suggested that along with the powerful executions of the government and epidemic control in China, medical staff's negative emotion decreased in a sense, which confirmed the effect of national epidemic control on public emotion. The finding also showed that psychological experts could provide psychological support at the beginning of an epidemic, which would be an important preventive measure to deal with the mental health problems of frontline medical staff.

### The Sources of Negative Emotions of Frontline Medical Staff

In this study, we found that the shortage of personal protective equipment (PPE) was the leading source of all negative emotions (i.e., fear, anxiety, anger, and sadness) of frontline medical staff at the early stage of the COVID-19 epidemic, which was also consistent with previous findings (13). Without standardized PPE, frontline medical staff were exposed to the higher risk of being infected with the virus. Besides, the potential infected individuals without quarantine and the suspected cases without protection were the main causes of anxiety, fear, and anger of frontline medical staff in this study, which was not previously reported. The results indicated that the quarantine and protection of suspected patients should be implemented strictly and effectively to reduce medical staff's psychological stress. Moreover, being infected by COVID-19 was also a primary source of fear among frontline medical staff. Thus, self-protection is of vital significance and much attention should be paid to train medical staff on how to use PPE before contacting patients (50). Our findings also showed that frontline medical staff felt sad about the existence of exhausted medical staff and severely infected patients. Together, results suggested that to reduce negative emotions of medical staff effectively, strategies should ensure PPE and implement protective procedures strictly and enhance therapeutic efficacy so that it might be most effective, which offers valuable evidence for the government.

### The Influential Effects Between Negative Emotions and Risk Perception, Avoidant Behavior, Physical Dysfunction, and Emotion Regulation

The findings confirmed that risk perception induced negative emotions of frontline medical staff significantly, which was consistent with the study (27) conducted during SARS. It showed that the level of fear elevated when people perceived a higher risk perception of the infectious disease (27). Therefore, reducing the risk perception of the epidemic may help healthcare workers reduce negative emotions. One systematic review of healthcare workers' perceptions of risk suggests that institutions need to ensure that appropriate infection control safeguards are in place to protect workers and their families (30). By doing so, negative emotions of medical staff are reduced effectively with lower risk perception.

Additionally, our findings showed the potential effect of negative emotion on personal avoidant behavior tendency, with the evidence of higher avoidant behavior tendency in medical staff with stronger negative emotion. Previous studies also found that some medical staff were reluctant to work or wanted to resign due to the fear of being infected or infecting their family members during the SARS epidemic (17, 33). The results suggested that reducing negative emotions may decrease the avoidant behavior tendency accordingly.

Besides, the findings also revealed the effect of negative emotion on personal disturbed physical function, with the evidence that a higher level of disturbed physical function in medical staff was related with a stronger level of negative emotion. The findings filled in the blank of previous empirical research between negative emotion and personal disturbed physical function, which also suggested that reducing negative emotions might decrease the physical function disturbance of frontline medical staff accordingly.

Moreover, the study innovatively verified the effect of emotion regulation strategy on negative emotion in the group of frontline medical staff during the early period of the COVID-19 epidemic. The findings showed that higher cognitive reappraisal and expressive suppression reduced the degree of negative emotions, while emotional expressivity increased negative emotions. The results indicate that the application of cognitive reappraisal and expressive suppression and less utilization of emotional expressivity may reduce negative emotions of frontline medical staff.

Together, risk perception induced negative emotions of frontline medical staff, emotion regulation strategies modulated negative emotions, and negative emotion had an effect on avoidant behavior tendency and disturbed physical function. The findings confirmed the TAS theory and further suggested the interaction between cognition, emotion, and behavior.

### The Pathway Between Negative Emotions and Their Influential Factors

The model test confirmed that risk perception increased negative emotion, which has been illustrated in a previous study (27). Moreover, emotional expressivity increased negative emotion,

cognitive reappraisal and expressive suppression decreased negative emotion, and negative emotion increased disturbed physical health, which were first verified in this study. Among which, negative emotion played an important mediation role between risk perception and avoidant behavior and disturbed physical function. Therefore, measures to reduce risk perception of frontline medical staff should be taken in a timely manner to decrease negative emotion and avoidant behavior at the early period of the COVID-19 epidemic. For example, training courses about the disease and treatment might be an effective way to minimize risk perception (53, 54). Meanwhile, to better maintain normal psychological and physical function under crisis, intervention and guidance on fear emotion are critical. We also found that avoidant behavior could directly influence disturbed physical function, filling the gap of existing knowledge. Thus, we can reduce negative emotions and avoidant behavior of frontline medical staff to promote their physical function by adopting interventions like cognitive-behavioral therapy (CBT) (55, 56). This knowledge helps to reveal an influential pattern between negative emotion and risk perception, emotion regulation strategy, avoidant behavior tendency, and physical function.

Importantly, negative emotions could be reduced through cognitive reappraisal and reduced risk perception, followed by decreased avoidance behavior and physical impairment. The findings provide a guide for psychologists to promote crisis intervention in the group of frontline medical staff during the COVID-19 epidemic, which further broadens the application of the TAS model.

The strengths of our study are as follows: firstly, the current study was one of the earliest nationwide and large population-based online surveys targeted at Chinese frontline medical staff fighting against COVID-19 from January 27 to February 11, 2020, which covered all 32 provincial administrative regions of China. Secondly, our study was a continuous trend survey of negative emotions of frontline medical staff at the early COVID-19 stage. We also explored the emotion status of different medical professionals, which might be potentially important to draw up psychological interventions for the targeted population under a public health crisis. Thirdly, we also explored the influential effects between negative emotions and risk perception, avoidant behavior, physical dysfunction, and emotion regulation among Chinese frontline medical staff, which could help provide emotion support more precisely and scientifically in the future.

Several limitations also exist in the study. First, only one question was designed to evaluate each kind of the four common negative emotions, and the study lacked more details about negative emotions of Chinese frontline medical staff fighting. Second, the data of other influential factors of emotions, such as coping styles and resilience, were not collected in the present study, and thus future research can explore more variables interacting with the emotions of frontline medical staff during epidemics. Moreover, despite the fact that numerous statistically significant results were found in the study, the effect sizes were rather weak. Some bias might exist due to the online data collection though it was a very convenient and effective way to do the online survey during COVID-19.

## CONCLUSION

In conclusion, Chinese frontline medical staff experience a mild level of negative emotions (i.e., fear, anxiety, anger, and sadness) at the early stage of COVID-19, which decreases gradually over time. Nurses report a higher level of negative emotions, as well as women, younger, and unmarried healthcare professionals. To better ensure the mental health of medical staff, reducing risk perception and improving cognitive reappraisal might be important, which would be potentially valuable to form targeted psychological intervention and emotional guidance under crisis in the future.

## DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Material**, further inquiries can be directed to the corresponding author.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Human Research Ethics Committee of the Army Medical University of China. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

QD: research design, review, and supervision. XS: making questionnaires, data analysis, and writing original draft preparation. FX: review and editing. BC, PS, SS, ZC, YY, MZ, XQ, YL, and YW: data collection. All authors have read and agreed to the published version of the manuscript.

## FUNDING

QD claims that this study was supported by the Key Project of Natural Science Foundation of Chongqing (cstc2020jcyj-zdxmX0009), the Medical Innovation Project of Army Medical University (2019ZLX003), and the Key Project and Innovation Project of People's Liberation Army of China (18CXZ005).

## ACKNOWLEDGMENTS

The authors thank the Wenjuanxing platform and Mr. Li of Weirenren psychological consultation center for their support and endeavor on questionnaire investigation. We also thank all participants who took part in this online investigation. We appreciate the hard work of all graduate students who took part in this study as research assistants.

This article investigates the role of Big Data in situations of psychological stress such as during the recent pandemic caused by the COVID-19 health crisis. Quarantine measures, which are necessary to mitigate pandemic risk, are causing severe stress symptoms to the human body including mental health. We highlight the most common impact factors and the uncertainty connected with COVID-19, quarantine measures, and the role of Big Data, namely, how Big Data can help alleviate or mitigate these effects by comparing the *status quo* of current technology capabilities with the potential effects of an increase of digitalization on mental health. We find that, while Big Data helps in the pre-assessment of potentially endangered persons, it also proves to be an efficient tool in alleviating the negative psychological effects of quarantine. We find evidence of the positive effects of Big Data on human health conditions by assessing the effect of internet use on mental health in 173 countries. We found positive effects in 110 countries with 90 significant results. However, increased use of digital media and exclusive exposure to digital connectivity causes negative long-term effects such as a decline in social empathy, which creates a form of psychological isolation, causing symptoms of acute stress disorder.

**Keywords:** big data, psychological stress, quarantine, COVID-19, mental health, 5G

## INTRODUCTION

During the ongoing COVID-19 pandemic many countries have introduced measures to manage and mitigate the risk of the virus spreading. People have been exposed to conditions of severe uncertainty in relation to case fatality rates, the spread of the virus, and the costs of risk mitigation measures. The impact of this uncertainty is connected to morbidity, mortality, and risk, and has resulted in increased levels of panic and anxiety across almost all societies.

Previous disease outbreaks such as SARS or Ebola have shown that anxiety can appear in a community as the result of many factors such as death and the number of new cases reported frequently by media (Rubin and Wessely, 2020). However, the recent COVID-19 outbreak caused drastic measures to be taken by governments globally, e.g., imposing stay-at-home orders. These dramatic measures increased the level of anxiety because they interfered with the natural desire

and necessity of people to socially interact with other people. Generally, quarantine implies a lack of control and a sense of being trapped, which is intensified when families are isolated (Rubin and Wessely, 2020). There is sufficient evidence that quarantine can cause substantial psychological, emotional, and financial challenges. To be more effective, quarantine requires the person at risk to be isolated and follow proper infection-control steps within the quarantine area (Hawryluck et al., 2004). Moreover, self-isolation can lead to severe symptoms of acute stress disorder (ASD) (Brooks et al., 2020).

The impact of quarantine measures was studied extensively in relation to pandemics such as SARS or Ebola. Various interviews and surveys among those who experienced the quarantine measures revealed that the impact on mental and psychological health can be enormous including isolation and separation, post-traumatic stress, depression, avoidance behavior, irritation, sadness, annoyance, anxiety, frustration, guilt, helplessness, loneliness, and nervousness. The quarantine measures can also lead to symptoms of ASD, which is characterized by panic and anxiety, and stigmatization, even following social isolation. The major difference of the current situation in comparison to the SARS or Ebola pandemics is the role of social media. Through social media various fake news, rumors and misinformation was spread which further increased the negative impact and the levels of anxiety. This is also defined as digital stress, caused by a huge variety of communication channels and contradictory information. The COVID-19 crisis showed a correlation between psychological consequences and the utilization of digital media.

Big Data is a comparatively new discipline of data science that investigates how massive data sets can be interpreted to harvest significant insights and information. It is worth mentioning that traditional data processing methods/approaches are not suitable for gathering, warehousing, and the analysis of big data. The five V's of big data (velocity, volume, value, variety, and veracity) are the five primary and innate characteristics of Big Data (for more information, see, for example, Hassani et al. (2019a,b, 2020, 2021).

So-called "Big Data" have significant potentials for the health sector as it can help monitor the spread of disease. They can also help to increase the quality of medical services. Big Data can also help to create transparent information for people, and this helps to alleviate some of the most negative impacts on mental health such as anxiety and uncertainty, which leads to additional stress.

The deployment of Big Data will benefit from the introduction of 5G technology, which will connect more than 50 billion people and will allow the analysis of a much larger percentage of digital data than before. The 5G network also enables the transmission of Big Data in real time, including up-to-date diagnostics. The health sector welcomes the deployment of 5G, as this technology will benefit from the features of high-speed networks by reducing the time required to analyze large amounts of data.

Influenced by mobility restrictions, people in quarantine use digital channels of communication much more frequently to compensate for the restricted mobility. During the pandemic, this resulted in a greater volume of Big Data being generated during quarantine. This is on the one hand a chance for further

data analysis, but on the other, personal data protection, and the appropriate storage of data should be considered.

The usage of the Big Data approach in health systems is still minimal. This paper discusses the sustainable use of Big Data with the application of 5G technology, concerning data protection issues. Such usage can be beneficial in the health sector and could help to address the negative impacts on mental health that have arisen after quarantine measures. The paper discusses the benefits of 5G technology, such as increased speeds of data transmission and how they can be beneficial for the health sector and calls for further research in this area to understand all consequences of the implementation of 5G technology.

## COMMON SYMPTOMS CAUSED BY QUARANTINE

Quarantine is critical for managing infectious diseases, and may be successful from an epidemiological perspective to control exposure to infection. However, it has some side effects. It has a dramatic effect on the finances, emotions, and psychology of the people who have had to stay at home completely (Brooks et al., 2020). A review of related articles shows that psychological stress is one of the critical negative consequences of quarantine. Emotional disturbance, depression, low mood, irritability, and insomnia have been seen repetitively (Hawryluck et al., 2004; Brooks et al., 2020). It has been confirmed that the increased duration of quarantine is associated with growing post-traumatic stress disorder (PTSD) and ASD. PTSD and ASD are anxiety disorders with long-term psychiatric morbidity. From a psychological point of view, PTSD is developed by someone who experienced a life-threatening event. It can be recognized by some criteria, such as increased vigilance and heart beating (Bryant, 2017). Some evidence indicates that post-traumatic stress can increase significantly in more than a 10-day quarantine. Moreover, ASD is identified by PTSD symptoms, which occur early after trauma. It could be a short-term side effect of staying completely at home. ASD can lead to anxiety, insomnia, poor concentration, and exhaustion. As a result of this problem, the number of people who changed careers, relocated for work, and/or considered resigning has increased (Brooks et al., 2020). In one study, 87.4 percent of people who stayed at home reported psychological and corporeal distress after the outbreak (Lee et al., 2005).

Fear is a common emotion experienced by most people in quarantine, fear for their health, or fear of infecting others. People quarantined often experienced a lack of communication, even with their family members. As a result, depression and low mood have been reported in some studies. One qualified study about the psychological effect of SARS quarantine in Toronto showed that symptoms of depression were observed in about 31.2 percent and in this study, the presence of depressive symptoms was highly correlated with PTSD symptoms (Hawryluck et al., 2004). In the December 2019 outbreak, most of the countries around the world applied quarantine once again for reducing the spread of the disease managing better of the COVID-19 pandemic.

According to WHO technical guidance notes about COVID-19 “the main psychological impact to date is elevated rates of stress or anxiety, as new measures and impacts are introduced (especially quarantine and its effects on many people’s usual activities, routines or livelihoods) levels of loneliness, depression, harmful alcohol, and drug use, and self-harm or suicidal behavior are also expected to rise” (CDC Covid-19 Response Team, 2020). Some other articles provide scientific evidence about similar negative consequences caused by quarantine. These articles outline a tremendous increase in frustration, boredom, and distress reactions such as rage and rigid fear of getting illness even in those not exposed (Caleo et al., 2018) and lasting impact on health-risk behaviors, for instance, overuse of tobacco and alcohol. With increased numbers of people experiencing social isolation, people may experience stigmatization (Pan et al., 2005; Ćosić et al., 2020).

A significant number of scientific works exist about the impact of quarantine on mental and psychological health. These studies focused on the impacts of Ebola, SARS, and other diseases. There were also various studies on the impact of quarantine, mainly because of SARS, on the mental health of inhabitants in different countries such as Taiwan (Bai et al., 2004), China (Mihashi et al., 2009), Hong Kong (Lee et al., 2005), and South Korea (Jeong et al., 2016), but also the United States (Sprang and Silman, 2013), Canada (Blendon et al., 2004), and Australia (Braunack-Mayer et al., 2013). Many studies have identified the impact of quarantine measures on mental health, because of the Ebola pandemic in Liberia (Pellecchia et al., 2015) and Sierra Leone (Caleo et al., 2018).

Many of these studies examine the impact of quarantine measures on various social groups. For instance, a study that compared post-traumatic stress symptoms among parents and children found that children who were in quarantine had four times more frequent post-traumatic stress symptoms than children who were not in quarantine. A significant share of parents (28%) showed symptoms of trauma-related mental health disorders in comparison to a less significant (6%) share of parents who were not in quarantine (Sprang and Silman, 2013). Another study identified the impact of quarantine measures on hospital workers. It found that a significant share of workers showed symptoms of depression even 3 years after the event. In total, 60% of workers who showed depressive symptoms also experienced quarantine measures (Liu et al., 2012). Another study found that people who were quarantined because they were in close contact with people who had infectious diseases experienced fear (20%), nervousness (18%), sadness (18%), and guilt (10%). Positive feelings such as happiness (5%) or feelings of relief (4%) were reported in fewer studies (Reynolds et al., 2008).

Only a few studies have conducted correlation analysis of the impact of quarantine measures on mental health dependent on demographic variables such as marital status, age, education, living with other adults, or having children. However, no significant evidence of the correlations between these variables was found (Hawryluck et al., 2004). Two variables had a significant influence on mental health, such as professional occupation and previous psychological

sicknesses (Jeong et al., 2016). For instance, among those who have been quarantined, health workers have more severe symptoms of post-traumatic stress syndrome than the general public. Furthermore, quarantined workers feel more anger, annoyance, fear, frustration, guilt, helplessness, isolation, loneliness, and nervousness. They are also more likely to think that they have an infection and that they will infect others (Robertson et al., 2004).

A number of studies have identified correlations between a negative impact on mental health and factors such as the duration of quarantine, fear of infection, frustration and boredom, and inadequate supply and information. Longer durations of quarantine resulted in more frequent post-traumatic syndromes, avoidance behavior, and anger (Marjanovic et al., 2007). The negative impacts of quarantine were significantly higher if the duration of the measures was longer than 10 days (Hawryluck et al., 2004). Some studies found correlations between fears and factors such as having young children or expecting children or being physically vulnerable physically (Desclaux et al., 2017). There was also a correlation between how strongly the daily routine was affected, the reduction of social contact, and feelings of boredom and frustration (Blendon et al., 2004). The inadequate supply during quarantine, such as the delivery of medical items, food, water, or groceries, was strongly connected with feelings of anxiety and anger, which were present even several months after the release of quarantine measures (Wilken et al., 2017). Inadequate, confusing, or contradictory information about the pandemic or necessary actions was cited as one of the main stress factors (Braunack-Mayer et al., 2013). Often the various messages, differences in style, approaches, and content used by various public institutions were perceived as stress factors (DiGiovanni et al., 2004). Lack of clarity about the risk and its seriousness significantly influenced risk perceptions (Desclaux et al., 2017). Perceived lack of transparency from public authorities about the severity of pandemics also influenced risk perceptions (Braunack-Mayer et al., 2013). Lack of clear guidelines and perceived difficulties in coping with quarantine measures contributed significantly to the development of post-traumatic stress symptoms (Reynolds et al., 2008).

The main difference to the situation of today is that the role of social media during the earlier Ebola and other pandemics was not as significant. Social media make the spread of information much faster and almost universal as almost everybody has access to social media. Together with various kinds of messages and news, social media are also spreading misinformation or in some cases even disinformation. Existing widespread information, a great number of rumors, fake news, and conspiracy stories in conditions of high uncertainty and high impact on human life is creating further negative impacts on mental and psychological health, in addition to the already stressful situation. This situation also adds to the effects described above, including anxiety and various psychological disorders. Negative perceptions of quarantine measures can also be influenced by social media and are connected with factors such as perceived loss of freedom, uncertainty over disease status, and boredom. These factors can lead to feelings including irritation or depression or even to dramatic consequences such as suicide.

## HOW BIG DATA CAN HELP ALLEVIATING STRESS SYMPTOMS

We are now living in an era of “Big Data” marked by significant growth and an exponential rate of data generation. This fact creates a huge opportunity for public health in finding possible patterns and trends across populations and possibly foretelling disease outbreaks based on powerful search engine results combined with a huge data warehouse and analytics. For instance, using API information, and geographic location to identify disease transmission, combined with other auxiliary information such as analyzing posts on Twitter could lead to promising results (Rosen et al., 2020). By analyzing people’s data in quarantine, we can recognize the main problems, and possibly find a solution. Improving the level of public health is a vital aim for all countries, so by using data, we can achieve this aim. People in quarantine have used digital media more than usual. They have tried to catch more information about their worries. Lack of education and having false information leads to increased psychological problems.

An important factor is the availability of a standard instrument. For instance, based on collected data, this could be a survey that reflects the full spectrum of psychological aspects of quarantine and useful approaches to overcoming many related issues. Such an instrument would be extremely useful for possible outbreaks in the future. A standardized instrument facilitates a connection and probable correlation between the psychological responses to outbreaks for various infectious causes and also could be utilized to control symptoms over time (Hawryluck et al., 2004). Categorizing these data would provide a guideline for managing public health problems as well as alleviating stress symptoms during the quarantine. It should be noted that although employing the Big Data approach for public health intervention is still very minimal, with growing data convergence, impressive analytic power, and the broad range of applications and its success, one expects Big Data and smart techniques to become one of the increasingly common prime choices (Rosen et al., 2020).

Belle et al. (2015) indicated two devices that are available everywhere and continuously generated data and information; telemetry and physiological signal monitoring devices. However, data and information generated from these devices have not been deposited, as would be expected during this age of technology. Nevertheless, there have been some efforts toward collecting, depositing, employing, and analyzing telemetry and continuous physiological extracted signals and data from monitoring to improving patient care and management (see, for example, Mackenzie et al., 2008; Apiletti et al., 2009; Bodo et al., 2013; Hu et al., 2014).

The computational aspect of Big Data aids the health care system and organizations across the globe to have real-time decision-making. This enables them to enhance and advance the quality of healthcare services as well as cost reduction (Ta et al., 2016).

It is important to consider the compatibility of front-end as well as back-end systems. While certain environments run on different operating systems, the devices that gather the data and

send it to be stored (i.e., on clouds) might run on different systems. This incompatibility might cause delays or inefficiencies in the transmission process. It might also lead to misleading analytics or even system crashes.

There are various applications of Big Data and its related techniques for tackling fundamental issues and trends in healthcare analytics research, with various applications ranging from text mining and predictive modeling to pattern and face recognition (Sun and Reddy, 2013).

One psychological factor of how Big Data can help alleviate stress symptoms during a pandemic is through the creation of transparent information for affected people. A very significant factor adding to stress is uncertainty. During a pandemic, quarantined people have a lot of time due to the imposed restrictions. However, this suddenly gained time might turn into stress when people are confronted with an indefinite course of the measures taken by authorities, as well as contradictions in the health statistics published. The data generated through surveillance tracing, health statistics, and reports can help people to alleviate these kinds of stress symptoms, enabling them to stay informed.

As well as creating more accurate information on the current status of the pandemic, Big Data can create better predictions about the future of the outbreak (Bansal et al., 2016).

To test how Big Data can help to improve health conditions we first want to give an overview of the existing literature in this area. As a proxy for Big Data, we relate general internet usage to the generation and use of Big Data. It, therefore, makes sense to take a closer look at health studies conducted since the emergence of the internet, since this time frame covers a regime change that potentially reveals changes in health-related conditions. An obvious way in which Big Data and the internet were and continue to be used was to look up potential diagnoses and treatments for certain health problems. Trotter and Morgan (2008) study internet usage in 2000 and 2006 for health related information. Through a survey, they found a significant increase in looking up health related information on the internet.

Several studies have been conducted to investigate the introduction of 5G and data provision. A recent study by Rizzato (2020) estimates that 5G users on average consume up to 2.7 times more mobile data compared to 4G users. The study comprised six countries: South Korea, United Kingdom, Japan, United States, Australia, and Germany, and found an average consumption of 15GB of mobile data for 5G users. By estimating the effect of regular internet usage, which is assumed to be mainly based on 4G, on mental health, we can therefore deduct the potential effect of the introduction of 5G on improving health conditions.

A white paper by Cisco (2020) indicates that nearly two-thirds of the global population will have internet access by 2023. They also outline that over 70 percent of the global population will have mobile connectivity by 2023 and that 5G devices and these connections will account for over 10 percent of global mobile devices and connections by 2023. Another study by Cisco (2016) found that more than 500 billion Internet of Things (IoT) devices, from sensors to actuators, to medical devices, will be connected to the internet by 2030.

In a survey, Pew Research Center (2018) found that 95 percent of Americans own a cell phone and 77 percent have smartphones, whereas, for low-income segments of the population, including those in African-American and Hispanic communities, wireless connectivity is most likely their only online access (Turner Lee, 2019).

Turner Lee (2019) also mentions the importance of 5G for health care services. This is because 5G and IoT are broadly applied to life-saving devices and other applications in health care where it is “*imperative that they operate as anticipated, without fail, every time.*” Lee further mentions significant examples of the importance of the 5G applications for health such as home health sensing, which is a critical intervention for chronic disease patients that uses microphones in smartphones to replicate spirometers, which measure the airflow in and out of lungs for patients with chronic obstructive pulmonary disease (COPD). The data collected is used by doctors to monitor the disease’s progression in patients in real-time (Turner Lee, 2019).

Another important application of 5G, and internet usage, is among pregnant women seeking health information. Javanmardi et al. (2018) conducted a review study of 16 articles and found that the use of the internet by pregnant women was driven by information needs, ease, and speed of access, and finding people with the same situation. The article shows the importance of accessibility and speed provided by 5G.

Ducrot et al. (2021) analyze and describe the evolution of internet use as a source of health information between 2010 and 2017 and found that the use of the internet as a source of health information rose between 2010 and 2014 (from 37.3 to 67.9%,  $P < 0.001$ ) but decreased significantly in 2017 (60.3%,  $P < 0.001$ ). They outline that the reason for the recent decrease in internet usage was the parallel decrease in trust in the quality and reliability of information found online. The authors stress the need for public health authorities to increase citizens’ eHealth literacy and to provide alternative trustworthy sources combining the popularity and accessibility of general health information websites. Their results highlight the importance of 5G to enable patients a quicker verification of health information found online.

## DATA AND POTENTIAL ANALYSIS

To show the potential of 5G to alleviate stress symptoms, and thus, to improve mental health conditions we tested the impact of global internet usage in each country on its population health condition. For this purpose, we took telecommunication network usage as a proxy and individuals using the internet in % of the population (Worldbank, 2021) and for the measurement of mental health the Disability-Adjusted Life Years (DALYs), which considers not only the mortality associated with a disorder but also years lived with disability or health burden (Ourworldindata, 2021).

Our sample size comprises 173 countries for which we found available data from Worldbank. We took yearly data from 1990 to 2019 for each country,  $k$ , and regress the annual changes of DALYs on the percentage of the population of country  $k$  using

the internet,  $INT$ ,

$$DALY_k(t) = \alpha_k + \beta_k INT_k(t) + \epsilon_t, \quad (1)$$

for all countries,  $k = 1, \dots, 173$ . We assume that, as discussed above, broader usage of the internet leads to an alleviation effect of stress symptoms, causing an improvement of mental health in the long-run.

By estimating these parameters we are able to deduct what impact the average increase in internet usage will have on the mental health of a population.

## RESULTS

The results show that a significant amount of countries exhibit a negative beta, which means that an increase in internet usage improves mental health conditions. For most of the countries, we found a significant reduction of a population’s share of the total disease burden. In detail, as reported in **Supplementary material Appendix**, out of 173 countries we found that 90 have significant results ( $P < 0.10$ ), 73 countries highly significant ( $P < 0.05$ ), and 110 countries had a negative beta, meaning that 63.58% of the analyzed countries show a positive impact of increased internet usage on mental health.

When looking at continents, we classify the countries into 6 regions: North America, South America, Arabia, Asia/South Pacific, Europe, and Africa. When analyzing the relative share of countries with a negative beta to the total number of countries in the region, and the level of significance, we found the following results.

**Table 1** provides an overview of the relative amount of countries that exhibit a negative beta, compared to the total number of countries in that region. We can see that North America leads by far in terms of the positive effect of internet usage on mental health, followed by South America, the Arabic region, Asia/South Pacific, Europe, and Africa. The reason for Africa coming last might be under-developed internet access and infrastructure, respectively, and awareness of the population of the positive effect of internet usage on their health condition.

The results also indicate the relative share of countries for which we found the negative beta to be significant ( $P < 0.05$ ). We found that the Arabic region yielded the most significant results, followed by the African continent, South and North America, Asia/South Pacific, and finally Europe. The reason for Arabia and Africa having the majority of significant results might

**TABLE 1** | Relative share of countries with a negative beta to the total number of countries in each region, ranked, including the relative amount of significant results in each region.

Negative Beta			Significant ( $P < 0.05$ )		
1.	100%	North America	1.	63.64%	Arabia
2.	89.29%	South America	2.	53.85%	Africa
3.	81.82%	Arabia	3.	53.57%	South America
4.	78.95%	Asia/South Pacific	4.	50.00%	North America
5.	72.50%	Europe	5.	31.58%	Asia/South Pacific
6.	30.77%	Africa	6.	25.00%	Europe

lie in the growth rates of internet usage in these countries. The average internet usage growth rate per year of 56% in Arabic countries, and the average yearly growth rate in Europe is less, at around 40%.

To illustrate these results we further analyzed 20 countries and found that 13 out of 20 showed significant results.

**Table 2** shows the test results for the G20 countries, analyzing the impact of internet usage per population on the mental health condition of the corresponding country. Out of the 20 countries, we found that 17 countries had a negative beta. The only exceptions are Japan, Italy, and Russia, which exhibit a negative intercept, implying an already high degree of internet usage for these populations in general. However, the test results of these countries are not significant and exhibit a very low R<sup>2</sup>.

The test result shows that an extension of the internet and data transmission capacity, i.e., through the upgrade from 4G to 5G, has the potential to improve the mental health conditions of the populations in the countries where better accessibility and faster broadband is being established. This article will next discuss the potential role of 5G in a mental health crisis in detail.

## THE POTENTIAL ROLE OF 5G IN A MENTAL HEALTH CRISIS

In telecommunication terminology, 5G is defined as the fifth-generation technology standard for cellular networks and is considered as the next generation of 4G networks (which currently provide connectivity to most cellphones). One of the notable advantages of 5G networks is that they provide greater bandwidth and faster download speeds.

It is worth mentioning that 5G is not just an extension of 3G and 4G, rather, it involves a mixed network combining 4G, Wi-Fi, millimeter-wave, as well as many other wireless access technologies. It explores and derives a deeper aspect from the data/information/signal extracted by a significant number of devices by integrating cloud infrastructure, a virtualized network core, intelligent edge services, and a distributed computing model. In terms of frequency bands, 5G utilizes high-frequency bands around and higher than 60,000 MHz whilst the majority of current mobile (cellular) communications utilize below the 3.5 MHz range. Generally, four factors can be considered as main factors to distinguish 5G from its predecessors: connected devices, fast and intelligent networks, back-end services, and extremely low latency. As such enhanced mobile broadband, machine-to-machine communications, artificial intelligence, and advanced digital services of 5G are increasingly employed in the medical sector (West, 2016).

It is expected that the 5G network will be deployed to connect 50 billion devices and 212 billion sensors in 2020. This will include smartphones, tablets, smartwatches, cars, machinery, appliances, and remote monitoring devices, and many others (King, 2016). Accordingly, a huge amount of valuable data will be generated and provide a golden opportunity to extract useful information. It is expected that 5G as a connected ecosystem empowers us to use a more substantial percentage of digital data (35%) than previously (5%) (Davis, 2017).

During a quarantine, symptoms of ASD are likely to occur. It is characterized by anxiety and panic, particularly stigmatization and social isolation of confirmed cases, survivors, and relations, which may escalate into further negative psychological reactions, including adjustment disorder and depression (Kinsman, 2012). During the epidemic, rapid, integration can maximize effective management of the psychological crisis. Psychological crisis intervention should be dynamic, adapted to setting different stages of the epidemic, i.e., during and after the outbreak. During the outbreak, mental health professionals should actively participate in the overall intervention process in the disease, so that the mental health and psychosocial response can be mobilized in a timely fashion (Mohammed et al., 2015). With the support for remote psychological intervention provided by the development of internet technology, especially the widespread application of 4G or 5G networks and smartphones, the new intervention model was developed to handle the present COVID-19 public health event (Zhang et al., 2020). Nevertheless, some evidence suggests that there is a correlation between psychological consequences and the utilization of digital media. Digital stress, which is defined as stress caused by negative interactions in emails, texts, social media, chat rooms, and forums, is an essential intervening factor (Steele et al., 2020).

There is an indication that digital media increase the perception of our communities and activities (**Table 3**). The association between digital media and stress is indirect. The increase in digital media usage is undoubtedly related to alterations in the structure of humans' life (Hampton et al., 2016).

To analyze the potential role of 5G in a mental health crisis, one first needs to distinguish between the role of 5G in diagnostics and treatment. For instance, EMC in the context of 5G offers

**TABLE 3 |** 4G download speed reduction during COVID-19 pandemic across Asia, Europe, the Middle East, Africa, South, and Central America, and North America on a weekly basis between the last week of January and the fourth week of March (January 27 to March 29), (Opensignal, 2020).

**Mobile Experience during the COVID-19 pandemic: 4G Download Speed (Mbps)**

personalized emotion-aware services with the aid of mobile cloud computing and affective computing (Yu et al., 2015). As 5G allows to transmit Big Data in real time, real time diagnostics, as well as treatment, is possible. The speed factor is the fundamental reason that the 5G network could be successful in a mental health crisis. To date, cell phone applications have been used to collect data about patients that allow them to reach health professionals with just one text message. It is claimed that this system is to be effective as it represents a mobile crisis center (National Institute of Mental Health, 2020). The three times faster speeds of a 5G network provide a real time, no interruptions response to a patient's need, which is what distinguishes this technology from the older ones and why it is beneficial. Data collection can reveal information such as location, movement, and whether the patient will receive immediate care.

Another benefit of the increased speed is that it will allow experts to reach patients that reside in rural areas, where other forms of connectivity are lacking. A survey revealed that 60% of rural citizens in the United States face shortages in access to mental health professionals (National Institute of Mental Health, 2020). The medical industry is also able to use the features of high-speed networks by greatly reducing the time required to read large amounts of data from patients, whether it is personal information, clinical research, or high-resolution MRI and CT imaging information.

5G also enables remote monitoring devices, such as wearable technology, to send patient health data to doctors instantly, while also being able to know what kind of space the patient is currently working through the sensor to achieve more comprehensive and adaptive sexual medical or nursing methods.

The interconnectivity of medical devices enables instant remote monitoring of the mental health of patients that show symptoms of ASD caused by quarantine measures. A reliable way to achieve direct monitoring would be by invasive deep brain stimulation (DBS) as is already performed by neurosurgeons to treat obsessive compulsive disorder, which is characterized by an obsessive behavior in which the patient cannot stop what they are doing, e.g., washing hands or cleaning their surroundings. It is well documented that by employing advanced technology, biomedical sensors can provide an impressive possibility to measure human physiologic parameters in a continuous, real-time, and non-intrusive manner (Seshadri et al., 2019).

In the case of Big Data, devices monitoring the mental health of quarantined people could be placed in or on the body to track the mental and physiological status, such as the emotional and vital functions of the person and send them in real time *via* the IoT to medical cloud centers. There, artificial intelligence backed systems could analyze data in real time and alert alarm medical response teams. They could even initiate emergency measures in cases where the condition of the person is deteriorating, which could lead e.g., to self-harming behavior. On the one hand, this means that immediate intervention is made possible through the utilization of 5G's instantaneous connectivity. On the other, the long-term implications of quarantine measures could be analyzed using real-time data over a prolonged period of time, and thus reveal important insights to prevent symptoms of ASD.

These types of procedure would, of course, be highly questionable ethically but nevertheless, show the power and capabilities of 5G technology. Since neurostimulators are already widely used, e.g., to listen to and stimulate electric current in the brain at the same time, 5G could help to understand the symptoms of ASD caused by quarantine measures and even serve for instant diagnostics and treatment for vulnerable people (Manke, 2018). Combining the potential of 5G with the power of brain pacemakers or any other body-attached devices opens a huge potential for suicidal or depression treatment, or any other negative effects caused by long-term lockdowns.

We will next show the potential of 5G in medical applications by simulating the download speed of 5G compared to the 4G download speed (in Mbps) during the COVID-19 pandemic. The potential time saved indicates that the higher capacity enabled by 5G would allow medical response teams to react faster and thus save more lives when it comes to life-threatening mental conditions caused by symptoms of ASD caused by quarantine measures. It is important to note that the reduction in download speed took place in the absence of any real time health data monitoring, simply due to increased use of the internet. This means that in the presence of health data monitoring, the potential reduction in download speed, and transferrable data, would be even more significant. For our analysis we focused on the relation of data being not able to be transmitted due to reduction in download speed, compared to a 5G framework.

**Table 2** provides data on the 4G download speed reduction across Asia, Europe, the Middle East, Africa, South, and Central America, and North America on a weekly basis between the last week of January and the fourth week of March (January 27 to March 29) (for more information regarding the data collection and source of the data, refer to <https://www.opensignal.com>).

Based on this data we compare a regular 5G transmission speed of 10 *gigabits* per second (Gbps). Regular data transmission channels *via* 4G face problems like Large Volume of Data, Bandwidth Fluctuations, and High Channel Error Rates. E.g., the amount of uncompressed data is large, even for a single patient. Transmitting a large amount of generated data over a wireless link in a real time fashion is a considerable challenge (Kang, 2014). Given a world population size of almost 7.79 billion globally, this means that a day worth of digital mental and physiological data would encompass 3.795 billion GB of data each day, or 43,923 GBps, additional on currently transmitted data.

Since our data set comprises 40 nations, totaling 62 billion people, a day worth of digital mental and physiological data would encompass 1, 31 billion GB of data each day, or 15,179 GBps. The total Mbps transferred over the 9 weeks across all 40 nations was 10,380 Mbps. Considering the average reduction over 9 weeks of  $-1.2\%$  of data transfer speed across all 40 nations, this would result in an average loss of deliverable data of  $-0.28$  Mbps/week, totaling  $-95.83$  Mbps/week.

In total, this means that under the current 4G network capacities, the total pro-rata loss would be  $-0.92\%$  or  $-140.15$  Gbps across the 40 nations. Considering that a day of data potentially encompasses 500MB per person, the equivalent of a loss of  $-140.15$  Gbps would be an uncovered amount of 500 people per second or 43.25 million people per day. Given

the transmission speed of 10 Gbps, 5G would enable coverage of these 43.25 million people who might not be covered under the regular 4G network speed as these people might potentially need medical aid throughout a day due to ASD symptoms. The results of this study are in line with recent findings. For instance, Thomas et al. (2021) discuss “how” and how “effective” modern technologies are in controlling the COVID-19 outbreak. They also discussed the pros and cons of social media and television in ensuring global connectivity and awareness.

## CONCLUSION

Big Data can be useful for public health interventions, especially in crisis times like the COVID-19 pandemic. Even though quarantine is a critical method for managing infection and the spread of disease, it has side effects such as increasing the number of people who suffer from ASD and PTSD. A new intervention model that adopts digital media could alleviate this problem.

The development and rollout of the 5G network enables interconnectivity among devices at an incredible speed. While real time data about the physiological and emotional well-being of humans during a lockdown has not been generated yet, 5G opens the possibility of gathering data about not only the psychological status of quarantined people but also provides the possibility for instantaneous intervention by medical response teams in cases of deteriorating psychological and physiological conditions through real-time connection, e.g., AI-backed mental health monitoring systems. The IoT is therefore a useful tool for the 5G infrastructure to work on a comprehensive real-time health monitoring system that could benefit not only the affected people but also policymakers, enabling them to better understand the long-term health effects of quarantine and lockdown measures.

The present study took internet usage as a proxy for Big Data utilization and tested the effect of internet usage per population in 173 countries on the mental health conditions in the corresponding population, measured by the DALYs, which measures the years lived with disability or health burden. We

found the positive effect of internet usage on mental health in 110 countries, out of 173, by looking at yearly changes in internet usage and the reduction in DALYs. The results show geographically interesting distributions as the effect seems to be biggest in North and South America, followed by the Arabic region, Asia and the South/Pacific, and then Europe and Africa. The distribution reveals certain conclusions, such as a higher awareness in populations in North and South America about the positive effect of using digital information on health conditions. Poor results in Europe indicate hesitation in the population about the digital information provided in improving health conditions, while the poor results in Africa might be caused by lack of infrastructure and accessibility to online sources as well as affordability.

Taking historical 4G download speed reductions during the COVID-19 pandemic, we calculate that given the transmission speed of 10 Gbps, 5G would enable the real time transmission of digital mental and physiological data of 43.25 million more people who suffer from ASD symptoms caused by quarantine measures per day to remote medical response teams, than under the current 4G capacities.

The COVID-19 pandemic has far reaching potential public mental health impacts and is linked to higher levels of depression and anxiety. To address these in part, online information resources acted as mass interventions. It is vital to explore the content of these interventions, to consider the framing of the pandemic and to examine the extent to which their content is relevant. In March 2020, a qualitative content analysis was undertaken of 39 easily accessible online resources that offered advice, tips or guidance relating to mental health or mental wellbeing and COVID-19. Their content was compared to subsequent reports of the mental health impact of the pandemic. Resources frequently focused on anxiety. The content of intervention was typically of a cognitive-behavioral nature, with a significant focus on maintaining social contact. Typically, distress related to the situation was normalized and stigmatizing language was not seen. Data revealed a significant impact of the pandemic on depression as well as anxiety measures in the general UK population. A key recommendation is to ensure both depression and anxiety are addressed in these public mental health resources.

**Keywords:** information quality, online intervention, qualitative, mental health, COVID-19, mass intervention, online health information

## INTRODUCTION

The COVID-19 pandemic presented a major public health and public mental health challenge. At the start of the pandemic in March 2020, reviews of the impact of restrictions such as quarantine and COVID-19 itself pointed to an understandable effect on psychological wellbeing and mental health. Prior to COVID-19, research on the psychological impacts of epidemics and quarantine suggested high risk of potential distress including confusion, loss, anger, frustration, low mood, fear, stress, insomnia and boredom, with a minority of participants reporting high levels of depressive symptoms and anxiety (1–7). Given the impact on entire populations, often under protective measures that restrict their movement and interaction with others, even a minority of the population represents a significant number of people in distress and a significant challenge to the mental health services. UK data suggest that anxiety and depression levels “spiked” at the point at which the lockdown strategy was announced (8), prompting online public mental health information.

“Lockdown” and threat of illness are stressful. Stopping work, loss of routine, reduced physical social contact, a sense of isolation and loss of day-to-day activities are all identified as stressors, which can be addressed with coping and stress management techniques, problem solving, self-care,

alleviation boredom, use of social networks, engagement with reliable information and re-iterating the purpose of isolation is to keep others safe (1, 2, 9). Sharing basic strategies to manage this distress has been recommended (10), alongside a need for online psychoeducation and self-management support, with self-directed interventions (7, 11–13).

Numerous online resources offering support and guidance on how to manage one's mental health were published in March 2020, in the period where the pandemic rose to the public's awareness and protective measures were enacted in many nations. These were effectively mass interventions, to attempt to maintain psychological wellbeing or minimize adverse impact on mental health. Many online resources were produced, however for these to be useful, their content must be optimized. Some would argue that anxiety and distress in the face of this global health threat is entirely normal. However, it is also important to offer support and strategies to maintain wellbeing, and further intervention where people require more specialist mental health support.

The content of online resources intending to address mental health needs to be explored, to highlight any areas of omission in particular. This is important both at the time of the protective measures being put into place and subsequently, to learn from this pandemic and plan for the next. Indeed, future pandemics are thought to be “inevitable” (14). Mental health is key in their management: avoiding or treating depression and anxiety is important in its own right, but also as they may be linked to lower engagement in adaptive health-behaviors needed for COVID-19, as they are for many other health behaviors (15). The way in which these resources frame both COVID-19 and mental health is also important to understand and potentially improve. Excessive fear arousal or global descriptions of lack of personal control are likely to risk both mental health and adherence to public health infection reduction measures (16, 17). Stigmatizing messages must be avoided, for both mental health and COVID-19 (1). This study aimed to complete a rapid content analysis of the easily accessible, online resources to elucidate their content, comparing these to subsequent data on the mental health impact of the pandemic.

## METHOD

### Sampling of Resources

Google search for “COVID-19 mental health” was conducted (29/03/2020). The first twenty results that included guidance and advice were selected for analysis. An additional 10 novel results (i.e. disregarding duplicates from previous search) from a search for “COVID-19 mental wellbeing” were also selected. The searches were limited to results in English and was conducted from google.co.uk. This was augmented by Twitter searches using the same terms, selecting results not duplicating those from the Google searches. Snowballing was used to identify further resources from links within the online documentation. Links to other resources were all noted and these resources then analyzed.

Analysis began immediately with the Google search results, then Twitter results and snowballed results. Sampling was ceased when saturation was reached.

## Evidence of the Mental Health Impact of COVID-19

The sampling of resources relating to the pandemic focused was conducted in the UK, and was limited to results in English. As such, the evidence we use to compare the impact of the pandemic on mental health uses UK focused data. The Office of National Statistics (ONS) is a UK government organization that collects, analyses and reports on relevant health, wellbeing, economic and population data. During the COVID-19 pandemic, they have collected and reported data relating to anxiety and depression symptom experience in adults. Data were collected using common measures—the Patient Health Questionnaire for depression (18) and the Generalized Anxiety Disorder assessment for anxiety (19). The measures provide an indication of those with probable clinical levels of depression or anxiety. These data were used to identify the estimated actual impact on the pandemic on mental health. An ONS report on depression provides data from pre-pandemic, 2020 and January-March 2021 (20). The report on anxiety uses data from the early pandemic—from April to May 2020 (21). These are supplemented by a report presenting data from July-August 2021 (22).

## Data Analysis

The content from each resource was downloaded. Qualitative content analysis was used inductively to code the data, as this approach allows analysis of both the explicit content and the latent meaning (23). Descriptions of the (a) type of data source, (b) type of resource, and (c) focus/topics were analyzed to create discrete categories addressing each factor. The details of the guidance itself were initially described with open-ended, descriptive responses. These were inspected to form inductive categories relating to each of the six areas outlined in the data collection (key message, diagnostic categories, responsibility, mechanism for change, normalization, claims). After analysis of 10 resources, initial categories were created and each resource re-checked for the presence of all categories. As analysis continued, with each new category, the previous resources were re-checked to explore whether this category was present. All data were first analyzed by one researcher, and then second coded by the other.

Coding continued until all the initially identified resources had been analyzed. During this process, it was noted whether each new resource was adding any new data. Saturation was used as the criterion as to whether it was necessary to seek further resources. Saturation was defined as resources being redundant, in that no new data advanced the conceptual categories (24, 25). Forty percentage of the resource data were second coded, and inter-rater reliability was calculated (26), with the protocol that a kappa <0.90 would lead to second coding of all data.

## RESULTS

The 30 resources identified from Google were supplemented with a further 19 identified from Twitter or snowballing. These included the resources published by Public Health England, UK National Health Service, World Health Organization, United States Center for Disease Control and several mental

**TABLE 1** | Lists the organizations that produced the resources.

Attending to physical environment		4 (10)

resources, therefore no further sampling was conducted. Inter-rated reliability of kappa 0.94 was achieved for second coding of 40% of the resources.

**Table 2** provides a summary of the results, which are described in further detail below.

## Framing of the Situation, Impact, and Resource

The COVID-19 pandemic was mostly referred to as “COVID-19 outbreak” or simply as “COVID-19” or “coronavirus.” Almost all resources specifically named the situation, with the language of outbreak, virus name, pandemic or epidemic used. Just four resources did not use this language, instead referring to “lockdown,” “crisis,” or “social isolation.” Potentially stigmatizing language of “Wuhan virus” or “Chinese virus” were not seen.

The impact of the situation on psychological wellbeing and mental health typically included significant attempts to normalize. Resources described the situation as having an impact on everyone, emphasizing universality. Worry and stress were

described as “natural,” “normal” and “understandable.” Many described that everyone would react differently. Some described examples of specific people’s experiences, to exemplify potential reactions. Of the 39 inspected resources, nine did not offer normalization of psychological distress. Some of these were very brief resources, however four were resources, longer than a list of tips, from mental health charities. Most resources did not use diagnostic labels to describe people’s experiences, and offer normalization of distress. Where diagnostic categories were used and where symptoms or difficulties were described, the focus was on anxiety.

Whilst resources described a range of potential emotional and psychological impacts, the majority focused on anxiety and its management, focusing on “worry,” “stress,” “anxiety,” “fear” and “uncertainty”.

The resources were published by a range of organizations, as show in **Table 1**. The results reflect to some extent the geographical location of the authors, and cover international, national, and local sources, from governments, charities, businesses, and individuals. They are mostly lists of instructions, sometimes with text preceding these instructions. The intended aims or claims of what the resources could offer were commonly to “look after,” “help,” “support,” “take care,” “manage” and “protect.” No resource made claims to remove distress or treat.

## Content of Resources

The resources offered a range of strategies, detailed in **Table 2**. The majority of resources offered a list of tips or strategies. The resources then were frequently very brief, offering little detail on how to implement the suggested tips or strategies.

It was rare to see the likelihood of achieving these acknowledged, with just one resource explicitly suggesting “cut yourself some slack.” Managing expectations of oneself was rarely acknowledged. The majority of advice did not acknowledge the other challenges that people may be facing, including lack of time owing to caring responsibilities, ongoing work expectations and challenges, potential ill-health, financial stressors, and difficulties in managing how to obtain everyday items such as food.

Social support was most commonly suggested. Self-care, management of media usage, maintenance of activities, and use of cognitive strategies were all advised. Several resources included content on focusing on what one can control as a cognitive strategy. Arousal reduction and emotional expression were also offered. Less commonly offered were advice relating to managing personal relationships and maintaining or altering one’s physical environment. Within the cognitive focused advice, several resources offer prompts to consider the positives or solve problems, without offering further guidance on how this can be achieved. Some suggested the situation be reframed as an opportunity. An emphasis on kindness and gratitude was also seen.

## Comparison of Resource Coverage to Mental Health Impact

Data from the ONS observed an increase in depression in the general population from pre-pandemic levels of around 10 to 19% in June and November 2020, and 21% in January-March 2021 (20). These data relate to those aged 16 or more.

Interestingly, depression was most common at 34% in the 16–29 year old age range (compared to just 10% in people aged at least 70 years). This age group are of course highly internet literate. For anxiety, in March-April 2020, at the very start of the pandemic in the UK and during a period of extreme uncertainty, 49.6% of people reported high anxiety (21). The mean score of the anxiety measure was 5.2/10, up from 3.0/10 at the end of 2019. Data from July-August 2021 show on ongoing higher than pre-pandemic level of depression, being 17% (compared to pre-pandemic levels of 10%) (22).

## DISCUSSION

Analysis examined the framing and content of a variety of online resources aiming to support psychological wellbeing. The epidemic was referred to without using stigmatizing language for either the virus or the impact on mental wellbeing. Normalizing and contextualizing distress during a distressing situation is vital, as it can offer a sense of universality and not stigmatize what is understandable during this time of threat. Resources were found to be stating aims to help support mental wellbeing, which is an appropriate aim as these mass, online resources are not to replace therapy or interventions to treat mental health problems.

Overall the content of interventions could be broadly construed as including elements of cognitive-behavioral therapies, including elements of mindfulness and acceptance commitment approaches, such as thought defusion (27). The focus on maintaining activity and social contact address likely stressors of the situation. Practical strategies are frequently offered. These strategies can address both low mood and anxiety related difficulties as they form elements of behavioral activation (28). Cognitive intervention is overall less frequently offered, and again tends to focus on anxious thinking, however could be equally well applied to depressive rumination, for example techniques of reframing and defusing from thoughts may be useful for both types of difficulties (29). Control is a theme in nearly half the resources, typically with advice to focus on what you can control. This is highly relevant as appropriate control beliefs are linked to reduced anxiety (16). This is particularly important messaging to avoid fatalism, which may reduce protective health behaviors of handwashing and social distancing (15).

The data concerning the impact of the pandemic show a large increase in both depression and anxiety. A clear recommendation results from comparing this to the content of the resources. The majority of resources focused on anxiety related symptoms and strategies. It is vital ensure impact on depressive symptoms is also acknowledged, given preliminary findings of increased depression (8).

A number of additional recommendations arise from the findings. First, most resources were didactic information giving. These could usefully be augmented with guided activities, to increase engagement with the resources’ advice. This could include links to activities to support people to problem solve, cognitively reframe, set goals and so on. Most people are likely to be able to spontaneously do these activities, however some may

require further support. Second, the pandemic events are outside of personal control, potentially leading feelings of helplessness, which are linked to low mood and depression (30). More attention should be given in resources to reducing rumination, replacing both anxious and low-mood related thoughts with alternatives or defusing from thoughts. Third, the resources' content could potentially feel overwhelming itself: a single parent, struggling to manage a toddler at home and continue to work, experiencing financial difficulties and stress when trying to acquire food shopping may find a list suggesting great social contact and doing creative activities somewhat at odds with their personal experience. Noting the context is vital and recognizing this may be having a very significant impact may help some to feel more understood and the resources to feel more relevant. Fourth, and related to the previous recommendation, it may be important to include guidance on adapting ones' expectations of oneself. The current challenges may activate core beliefs about being not good enough, which may be further triggered by lists of activities to do. This could be simply acknowledging a need to shift one's expectations from normal level of achievement or activity to abnormal ones, given the abnormal situation. Fifth, resources could continue to emphasize the rationale of the restrictions to movement, emphasizing the shared experience; social cohesion and resilience; and collective responsibility to act, in the collective good (31, 32).

Finally, two areas were commonly omitted. First, the importance of managing personal relationships was rarely mentioned. It is important to note that loneliness was observed in 27% of a UK sample in March-April 2020 (33). Addressing the maintenance of relationships during times of protective measures that restrict social interaction is then vital. In addition to the significant risk of increased domestic violence, the stress of confinement may affect many relationships within the home. Raising this issue and inclusion of basic guidance on communication skills may be beneficial (34). Second, greater awareness raising of the potential impact on mental wellbeing of home environment may be beneficial, particularly as this is an area over which many people will have some control (35).

## Limitations

This study is limited by its sampling. Only resources written in English were included, limiting its coverage and generalisability, however resources from a range of sources were included. The limitation to resources written in English does also limit the underlying cultural assumptions and approaches offered. Only resources relating to a general population were included, advice for health-workers and children must also be made available to the highest standard. It is not possible to review the resources against existing evidence standards, as no such standards exist; rather we sought to summarize the content, consider its empirical basis, and highlight areas of omission.

## CONCLUSION

In conclusion, the resources relating to public mental health addressed important topics. Supportive, comprehensive, empirically grounded resources can help maintain mental wellbeing for many, thus reducing future impact on mental health services, allowing them to focus on those with existing difficulties and high levels of distress. Such resources must address not only anxiety, but also depression. Given the high risk of future pandemics, the recommendations may inform future mass mental health support interventions.
