**Table 1** shows the mean, standard deviations, and correlations among variables for both the regression outcome variables. Positive affect correlates adequately with all the other variables included in the analysis, except for the chance dimension of the locus of control (LOC\_C). Negative affect is significantly correlated with all the variables considered. The chance dimension of locus of control (LOC\_C) is not connected with the trauma focus factor of coping flexibility (CF\_TF). Other

non-correlated variables are two dimensions of locus of control: internality (LOC\_I) and chance (LOC\_C). Please see **Table 1** for detailed results of the correlation analyses.

The first stepwise multiple regression was conducted to evaluate whether the dimensions of family resilience, coping flexibility, and locus of control were necessary to predict positive affect. The analyses generated three models (please see **Table 2** for details). The final model of the regression analysis accounted for 45.4% of the variance of positive effect with three predictors (family organization and interaction of family resilience, the trauma focus subscale of coping flexibility, and internality of locus of control) with a significant improvement from previous models. Other variables – chance of locus of control (LOC\_C:  $t = -0.433, p = 0.666$ ), powerful of others of locus of control (LOC\_PO:  $t = 0.101, p = 0.902$ ), forward focus of coping flexibility (CF\_FF:  $t = 1.179, p = 0.240$ ), shared beliefs and support of family resilience (FR\_SBS:  $t = 1.007, p = 0.316$ ), and utilization of social resources of family resilience (FR\_USR:  $t = 1.417, p = 0.159$ ) – did not enter the model at any stage (refer to model 3 for values reported).

The second stepwise multiple regression was conducted to evaluate whether the same variables were necessary to predict

negative affect. Three models were calculated (please see **Table 2**). The multiple correlation coefficient for the final model was 0.57, indicating that approximately 33.1% of the variance of positive affect could be accounted for by family organization and interaction of family resilience, the powerful of others dimension of locus of control, and internality of locus of control, with a significant improvement from the other models. Internality of locus of control (LOC\_I:  $t = -0.454, p = 0.650$ ), forward focus in coping flexibility (CF\_FF:  $t = -1.090, p = 0.278$ ), trauma focus subscale of coping flexibility (CF\_TF:  $t = 1.117, p = 0.266$ ), shared beliefs and support of family resilience (FR\_SBS:  $t = -0.459, p = 0.647$ ), and utilization of social resources of family resilience (FR\_URS:  $t = 0.307, p = 0.759$ ) did not enter the model at any stage (refer to model 3 for values reported).

## DISCUSSION

The data highlights that family resilience, coping flexibility, and locus of control contribute significantly in managing the positive and negative affect in patients with cancer during the COVID-19 pandemic in Italy. Results show that one dimension of each

Regression models, beta values and collinearity statistics for the two regression analyses.

considered construct contributes to positive affect levels. Family organization and interaction (FR\_FOI) is the main predictor for positive affect, as it is possible that the pandemic required patients and their family to adapt their previous organizational and interactive patterns to cope with the mandatory and prolonged cohabitation necessitated by the lockdown and to discover new ways of managing the patient's cancer during the public health crisis, as suggested by colleagues (Killgore et al., 2020; Prime et al., 2020; Russell et al., 2020). It is noteworthy that family organization and interaction (FR\_FOI) also mitigates negative affect, as its standardized beta value is negative, which likely occurred because patients who perceive higher levels of family organization and interaction (FR\_FOI) manage the requirement

of the crisis more efficiently and, thus, experience more positive affect and less negative affect. Furthermore, family organization and interaction (FR\_FOI) serves as a protective factor from negative emotions, confirming previous findings indicating that positive and negative emotional states can happen during a crisis simultaneously (Fredrickson et al., 2003; Terraciano et al., 2003; Weber, 2010).

Positive states are also enhanced by the Trauma Focus Scale of PACT, which provides that the perceived ability to focus on processing the trauma focus subscale of coping flexibility (CF\_TF) is associated with positive states. The ability to focus on trauma helps personal reorganization (Comer et al., 2014; Sahar and Muzaffar, 2017), demonstrating that this result appears

to confirm that the focus on elaborating traumatic events, both individually on the trauma focus subscale of coping flexibility (CF\_TF) and as a family about organization and interaction (FR\_FOI), helps activate a more positive outlook and think realistically about COVID-19 without using strategies of denial and avoidance or feeling overwhelmed. Experiencing positive emotions in the wake of a traumatic event is particularly important, as it allows individuals to evoke powerful changes in their emotional trajectory (Fredrickson, 1998, 2000). The literature highlights how this type of coping can moderate the impact of heightened trauma exposure (Romero et al., 2015; Juanjuan et al., 2020).

As previously mentioned, family organization and interaction (FR\_FOI) is also responsible for mitigating the negative affect generated by the pandemic, which is instead enhanced by two dimensions of external locus of control: chance of locus of control (LOC\_C) and powerful of others of locus of control (LOC\_PO). When persons believe they have no control over a situation and rely on chance or others to decide how to act, they show higher levels of negative emotions. This potentially results from the perceived lack of agency in the course of their lives and could be related to a “learned helplessness condition.” Literature supports that learned helplessness affects personal resilience and distress management (Mikulincer, 1989; Smallheer et al., 2018). Learned helplessness is a consequence of a perception of scarce personal power over the situation and may result in anxiety, depression, and PTSD (Klein and Seligman, 1976; Akca, 2011; Hammack et al., 2012). This is particularly relevant since coping flexibility does not enter the model with negative affect as an outcome. Additionally, a negative locus of control may affect the ability to access personal coping abilities, which allow persons to activate strategies and tactics (Fresco et al., 2006) to individually deal with the negative event and associated negative affect. The perception of good family support and the family’s ability to autoregulate its resources may compensate for these processes of learned helplessness and aid patients through the crisis.

## CONCLUSION

These considerations are limited. The models explain 44% of the variance of positive affect and 33% of negative affect produced by the pandemic. There may be other variables that moderate or mediate positive and negative affect, such as health locus of control, dyadic support, relationship closeness, emotional carrying capacity, personality traits, and self-efficacy (Cheng, 2003; Fresco et al., 2006).

Another limitation is that affect is a time-limited outcome. It refers to an affective state that may resolve itself in a short time, and requires constant monitoring of patients to verify if especially negative affective states become more persistent as the COVID-19 crisis continues and transform into more stable psychological conditions such as distress, depression, and anxiety or into optimism and positive outlooks. For example, acute stress disorder (ASD) can occur immediately after the traumatic event and last for less than a month (Weber, 2010). Essentially, a person with ASD can present with stress reactions between 2 days and 4 weeks after experiencing a traumatic event (Smith et al., 1999).

One more limitation regarding the affect is that in this study it was not possible to measure the emotional effects of cancer alone (e.g., a baseline before the pandemic). It is not possible to clearly differentiate the emotional effects of the pandemic and of the patient’s cancer, even though the participants were asked to refer to their experience about the pandemic in the previous 15 days. Results are therefore to be taken with caution.

Future studies should also consider the contribution of demographic variables (e.g., parental and relationship status) to the emotional well-being of the patients during critical times, such as the present pandemic.

While this evidence is limited, it can be applied to structuring clinical interventions for both the present and near future as well as for avoiding more serious psychological consequences, as suggested by colleagues from Wuhan (Mei et al., 2020). Clinical psychologists should develop and propose programs to support oncology patients’ adjustment and empowerment (Bryant et al., 1999; Bailo et al., 2019), not only during stressful events but also during follow-ups for further monitoring, as suggested by an emergency psychology approach. Interventions, in particular, should address the “patients’ strategies” (Arnaboldi et al., 2020) to organize and regulate their family organization and interactions; to stay in the moment and think concretely about their choices, behaviors, and emotions during the crisis, and to make them feel more pro-active during the crisis in relation to their cancer and the crisis itself (Stephens et al., 2013; Ramezani and Gholtash, 2015; Oliveri et al., 2019b). These foci of attention could result in patients that are less prone to negative affect and are able to make more effective decisions about their cancer effectively during this pandemic.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The study was reviewed and approved by the IEO (Istituto Europeo di Oncologia) Ethics Committee (ID 2612). The patients/participants provided their informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

EB and PG run the analyses. EB, PG, and LS wrote the first draft of the manuscript. EB, PG, LS, AVG, DB, FD, and GPe contributed to the literature search. LS, AVG, DB, FD, and GPe handled the data collection. KM and GPr supervised the research. EB acted as corresponding author. All authors contributed to the ideation and design of the research and to the revisions of the manuscript.

## FUNDING

EB was supported by a grant from the Fondazione Umberto Veronesi.

**Background:** In Italy, the COVID-19 pandemic has caused a collective trauma. Post-traumatic growth (PTG) has been defined as the subjective experience of positive psychological changes as a result of a traumatic event. PTG can involve changes in five psychological main dimensions: relating to others, new possibilities, personal strength, spiritual change, and appreciation of life. In the context of national emergencies, those PTG dimensions encompassing changes at the social level (e.g., relating to others) can play a role in coping strategies that involve a renewed sense of self and one's social identities, including national identities, and in turn, foster a stronger sense of trust and connection to others.

**Aim:** To investigate how each of the five PTG dimensions mediates the association between the salience of national identity and interpersonal trust in a sample of Italian young adults. Trust in national and European institutions were expected to positively predict the strength of the Italian national identity which in turn was expected to be positively associated with interpersonal trust, and the PTG relating to others dimension to mediate this association.

**Method:** This study involves the secondary analysis of data from a representative sample of 2,000 Italian young adults (age range 18–34 years). Participants completed a web survey during the peak of the COVID-19 crisis in Italy with measures of trust in EU and national institutions, national identity, interpersonal trust, and the PTG Inventory. Structural equation modeling procedures were employed for key hypotheses tests.

**Results:** Trust in national institutions positively predicted national identity, which in turn was positively associated with interpersonal trust. Evidence of a full mediation effect of the PTG relating to others dimension on the association between national identity and interpersonal trust was found.

**Discussion:** Findings contribute to clarify the psychological responses to collective traumas. In the context of Italy's COVID-19 crisis, trust in national institutions reinforced

Italian national identity, which was in turn associated with greater interpersonal trust, but only when psychological responses to the trauma involved changes in how individuals perceived and related to others, and not merely a focus on the self. Theoretical and practical implications are discussed.

**Keywords:** COVID-19, collective trauma, social identity, national identity, post-traumatic growth, interpersonal relationships

## INTRODUCTION

Italy was among the most heavily affected countries by the COVID-19 pandemic. Since February 21, 2020, when the first case of the virus contracted by a person not coming from China was registered, the government has taken a series of increasingly restrictive measures to contain the spread of the virus. At first, restrictions were limited to specific areas but were soon extended to the whole country on March 8 when a lockdown was imposed at the national level (Governo Italiano, 2020). It was mandatory to stay at home, unless there were proven reasons of necessity. Italy was the first European country to issue such a nationwide stay-at-home order.

As of April 30, 2020, 101,551 positive cases were documented out of the 205,463 people tested positive from the beginning including 19,843 admitted to the hospital and 1,694 of which were receiving intensive care, and the death toll reached 27,967. In the provinces most affected by the pandemic, such as Bergamo and Brescia, March and April monthly mortality rates raised up to 500% as compared with the previous year. The whole country was shocked by the images from Bergamo where army trucks were moving coffins of COVID-19 victims to other regions who could no longer be accommodated into local cemeteries. All this happened in a context of isolation, fear of an unknown invisible entity, and uncertainty toward the future. At the same time, media exposure of the pandemic was overwhelmingly contributing to an increase of anxiety and depression in the population with potential traumatic effects for many (Garfin et al., 2020). At the time of writing this paper, many European countries, including Italy, are going through a second wave that reached its peak around the end of November. As of November 30, 2020, Italy has lost more than 55,000 people and 33,000 people are still hospitalized, of which 3,700 are in intensive care. The national emergency is still ongoing and lockdown measures are in place again after a relaxation in the summer.

Despite the fact that traumas are usually individual experiences, there are circumstances in which they are experienced by entire communities bringing out collective traumatic dynamics (Alexander et al., 2004). Circumstances generally include natural disasters, such as hurricanes (Lowe et al., 2013; Manove et al., 2019), earthquakes (Włodarczyk et al., 2016), and, for what concerns this work, epidemics. Given its health and social impact on the Italian population, the COVID-19 pandemic presents characteristics of a collective trauma experience. According to Kinston and Rosser (1974), this is a situation of massive collective stress. Others (Cuzzolaro and Frighi, 1998) defined an event to be traumatic when it impacts a community overall causing social, emotional, and behavioral

reactions. Crocq (1987) emphasized the characteristics of brutality and immediacy. More recently, Hirschberger (2018) highlighted the crisis of meaning that follows collective traumas. According to the author, as individual trauma changes the view of oneself and the perception of the world, collective traumas disrupt social contexts as well as intra-group and inter-group relations. Thus, the sense and meaning that people attribute to their world can be dramatically changed (Updegraff et al., 2008).

By examining the COVID-19 emergency in Italy, this paper will reflect on the psychological implications of collective trauma, both in terms of the effects of individuals' social identity at the national level and the interplay with different dimensions of personal growth in response to such trauma.

## Collective Trauma, National Identity, and Trust Toward Others

During collective traumatic experiences, community members are exposed to events that leave indelible signs in their group consciousness through the construction of new collective memories (Alexander et al., 2004). According to Tajfel and Turner (1979), these new collective memories facilitate both the formation of new social identities and the strengthening and salience of pre-existing ones. There is evidence that strong and salient identities contribute to effective coping with stressful events (Kira et al., 2019) and help in safeguarding mental health (Berzonsky, 1992) because they mediate the relationship between perceived threat and psychological well-being (Schmid and Muldoon, 2015). In other words, when their social group is threatened, people tend to strengthen their social identities which in turn play a significant role in coping processes to traumatic events and dealing with the adverse event and anxiety that results from it (Griswold et al., 2018).

National identity is the type of social identity that derives from the sense of belonging to a nation or a state (Triandafyllidou, 1998). The construction of national identity is a complex phenomenon in which many aspects of a subject's social life interact. It evolves gradually during infancy and adolescence to become an integral part of our self. National identity originates from categorization processes and allows people to differentiate between different groups of nations. The division of the world into categories permits people to distinguish between what is considered home and what is foreign, thus acquiring territorial and cultural values. National identities derive from a perception of belonging which implies cognitive, evaluative, and emotional processes, both at the individual and social level. This allows people to identify with their significant national traits, thus regulating their behavior. Through national identity, people share

beliefs, representations, and values that contribute to foster emotional bonds with compatriots (Smith, 1992).

It is important to stress that national identities may have practical implications. The consequences of the categorization process, such as the outgroup homogeneity effect and the ingroup bias, also materialize in the distinctions between the different national groups (Tajfel and Turner, 1986): one's own nation will be perceived as more varied in comparison with foreign nations, which will instead be more likely to be stereotyped. Nationalism, for example, often derives from the intergroup confrontation and breeds from favoritism toward the ingroup. Radical forms of nationalism include elevating one's nation above the others, judging it as superior, and legitimizing its dominance over the other groups. This may have consequences including discriminant behaviors and rejection toward members of other national and ethnic groups (e.g., the immigration issue in Europe) (Smith, 1992). At the same time, national identity can enhance closeness among people which in turn boosts social support. People's national identity can become salient in cases whereas during the COVID-19 pandemic, the entire nation is affected by a traumatic event involving its citizens as a whole. Facing a common internal or external, natural or biological threat is supposed to enhance people's feelings of being part of a nation (West and Smith, 1997; Guibernau, 2004). As previously stated, this national sentiment became evident during collective manifestations such as singing in the balconies and support networks' activation (e.g., volunteering, elderly care, psychological support), and contributed to people coping with the negative emotions that the situation triggered (Venuleo et al., 2020).

The idea of nation can be identified with its institutions resulting in the establishment of in-group boundaries (Jelen, 2011), and fostering a sense of belonging and national identity (Harttgen and Opfinger, 2014). According to Gibson and Condor (2009), national institutions can be considered as hybrid entities including group of peoples, material objects (buildings, places), and procedures (laws, constitutions, government measures). In times of emergency and threat, institutional representatives often emphasize the notion of "we" as a nation with the intent of strengthening people's national identity. Moreover, if people trust the government and its institutions, the sense of belonging to the most salient social group at that time, the national one, is generally stronger. In Italy, the pandemic has been managed for the most part by national institutions such as the government, the National Health System (NHS), the police, and the civil protection agency. The European Union (EU) had a relatively marginal role and it has often been considered as an entity external to the nation.

The implications of social identities in regards to relations with others have been extensively examined (Tyler, 2001; Tanis and Postmes, 2005; Voci, 2006). It has been widely acknowledged that threatening situations, such as pandemics, strengthen the salience of social identities and foster solidarity, cooperation, and norm compliance within the group (Dovidio et al., 2020). For what concerns national identity, it has been demonstrated that its salience and strength are positively related to trust toward other people and cooperative behavior, and this is especially true under

conditions of risk and uncertainty (Brewer, 2008; Ntontis and Rocha, 2020). Interpersonal trust can be considered as a positive expectation toward others' behavior (Robinson, 1996) and the sincerity of their words (Hosmer, 1995). Trust is important both during an emergency and the following period of recovery because it helps people to coexist and cooperate (Righetti and Finkenauer, 2011). In fact, as Kramer and Wei (1999) highlighted, in conditions of social identity threat, interpersonal trust is based more on common membership of the salient group (identification-based trust) rather than on individual reciprocal benefits (calculus-based trust), thus explaining the link between one's social identities and how we relate with others.

## Post-traumatic Growth

Because of its fundamental importance in mental health, trauma has been extensively analyzed in the psychology literature (Prati and Pietrantonio, 2006; Luszczynska et al., 2009). Despite the majority of studies focused on the psychopathological consequences of traumatic events at the individual level, others have examined positive psychological and social changes after trauma and adverse experiences (Linley and Joseph, 2004). Post-traumatic growth (PTG) (Tedeschi et al., 1998) has been defined as the subjective experience of positive psychological changes in the aftermath of a traumatic experience (Tedeschi and Calhoun, 1995). Importantly, PTG is not a monolithic construct, but it encompasses five distinct dimensions (Prati and Pietrantonio, 2009): changes in how people relate with others (relating to others: i.e., an increased willing to express emotions or even accepting more likely help from others), recognition of new possibilities (new possibilities: i.e., seen as an increased attitude to take new paths in life and redefine priorities), a sense of greater personal strength (personal strength: i.e., improved sense of self-efficacy, strength, and self-confidence), changes toward spirituality (spiritual change: i.e., religious beliefs, spiritual matters, and existential/philosophical questions), and greater appreciation of life (appreciation of life: i.e., considering meaningful and worth in life's little things).

Some studies (Wasco et al., 2002; Cacioppo et al., 2015) highlighted how a collective experience of trauma can help people reflect on their traumatic experiences and consequently learn from them. Social identities are involved in this process (Calhoun and Tedeschi, 2012; Tedeschi et al., 2018; Muldoon et al., 2019): a renewed sense of belonging to a group or community, including the national level, significantly contributes to the meaning-making process. In turn, it is crucial for the positive processing of trauma and its implications in terms of social interactions, which include increased self-disclosure and trust within social relationships.

In summary, it has been established that social identities, including the national level, have implications in regard to how individuals relate to others and put their trust into them. What is lacking is a deeper understanding of the interplay between social identities and PTG in determining such coping responses to emergency situations that involve the social sphere. Importantly, despite its multidimensional nature that encompasses both individual and social aspects, the PTG has generally been examined in the literature as a unique dimension. This may have

resulted in overlooking the role of each specific dimension. Those dimensions encompassing changes at the social level (i.e., the relating to others dimension) may play a role in the connection between social identities and responses of trust toward others, whereas the other dimensions involving changes at the individual level (e.g., personal strength) may not.

## Aims

This study investigated how each of the five post-traumatic growth dimensions mediates the association between the salience of national identity and interpersonal trust in a sample of Italian young adults. Trust in national and European institutions were expected to positively predict the strength of the Italian national identity (Hypothesis 1), which in turn was expected to be positively associated with interpersonal trust, and the PTG relating to others dimension to mediate this association (Hypothesis 2). Because the other PTG dimensions involve changes at the individual level (i.e., personal strength and appreciation of life, new possibilities, and spiritual change), they were expected to play a less significant role (Hypothesis 3). **Figure 1** depicts the overall conceptual model.

## MATERIALS AND METHODS

### Data

This study involves the secondary analysis of data collected by the Osservatorio Giovani of the Istituto Toniolo di Studi Superiori (Milan, Italy). Since 2012, the Osservatorio conducts yearly computer-assisted web interview (CAWI) surveys regarding topics related to young people, such as social and economic inclusion of people that are Not in Employment, Education, or Training (NEET), as well as healthy behaviors, cultural issues, and participation (Alfieri et al., 2015; Marta et al., 2016; Aresi et al., 2018, 2020; Pistoni et al., 2019). The authors contributed to the design of the major study. Sampling and data collection were conducted by Ipsos s.r.l. between March 27 and March 31, 2020 during the peak of the COVID-19 crisis in Italy. Out of 4,116 contacts, a sample of 2,000 responders was achieved to be representative of the Italian young adult (18 to 34 years old) population in respect of several sociodemographic characteristics including gender, age range, educational level, occupation status, and geographic area (Istituto Nazionale di Statistica, 2020). About half (49%) of the respondents were female and mean age was 27.1 (SD = 4.69). The sample consisted of the following age ranges: 18–22 (19.3%,  $N = 387$ ), 23–25 (18.9%,  $N = 379$ ), 26–28 (19.9%,  $N = 398$ ), 29–31 (19.9%,  $N = 398$ ), and 32–34 (21.9%,  $N = 438$ ). Participants' occupation status was distributed as follows: 54.3% workers, 36.9% students, and 8.9% unemployed. In terms of geographic area, 24.8% lived in the Northwestern, 17.8% in the Northeastern, 19.2% in the Central, and 38.2% in the Southern region.

### Measures

#### Trust in National Institutions

Trust in institutions was measured by asking: "Since the beginning of COVID-19 emergency how has your confidence

in these institutions changed?" A 5-point Likert scale was used with values ranging from 1 ("Strongly increased") to 5 ("Strongly decreased"). Scores were reversed before data analysis. The following institutions were considered: the government, the NHS, the police, the civil protection agency, and the EU.

#### National Identity

To assess Italian national identity, the In-Group Identification Scale was adapted (La Barbera and Capone, 2016). Specifically, the sub-scales Satisfaction (four items), Solidarity (three items), and Centrality (three items) were used. Items were rated using a 10-point Likert scale with values ranging from 1 ("Totally disagree") to 10 ("Totally agree"). Examples of items are as follows: "I'm glad to be Italian" (Satisfaction); "I feel committed to Italians" (Solidarity); "The fact that I'm Italian is an important part of my identity" (Centrality). All three subscales were of high reliability: Satisfaction ( $\alpha = 0.81$ ); Solidarity ( $\alpha = 0.79$ ); Centrality ( $\alpha = 0.79$ ).

#### Post-traumatic Growth

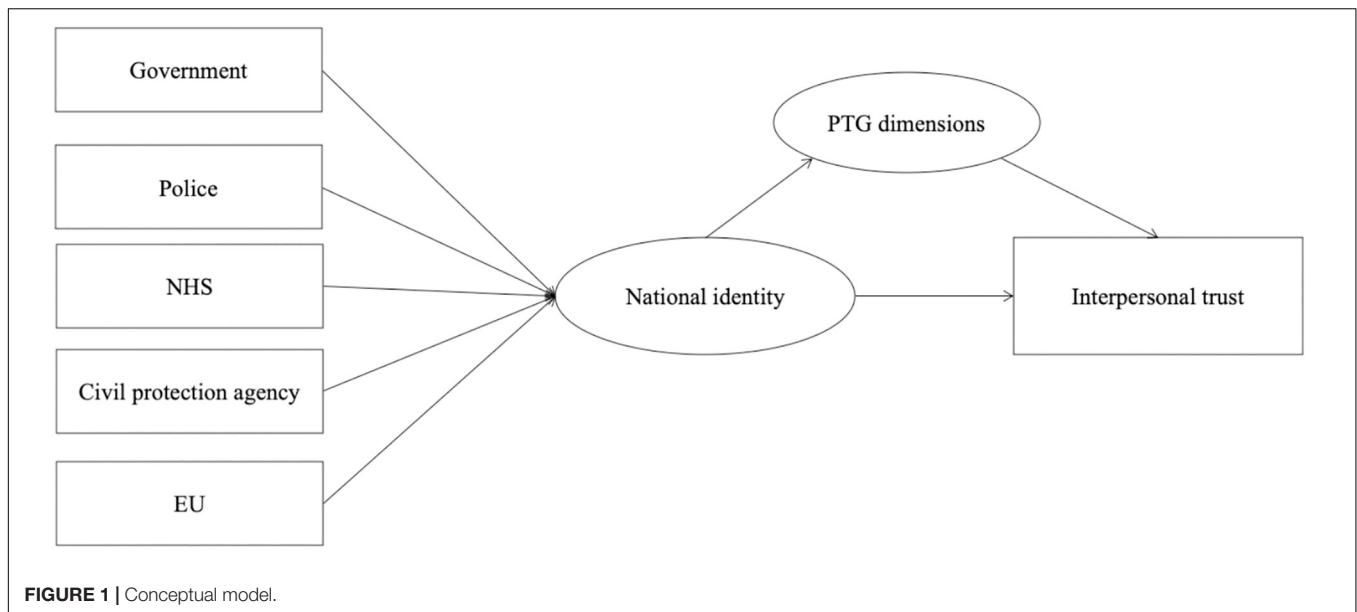

To measure post-traumatic growth, the Italian version of the PTG Inventory (PTGI) was used (PTGI; Prati and Pietrantonio, 2014). The scale has demonstrated construct validity. It consists of five subscales measuring perceptions of trauma-induced changes in (1) relating to others (example of item: "I learned a great deal about how wonderful people are"), (2) new possibilities (example of item: "I developed new interests"), (3) personal strength (example of item: "I have a greater feeling of self-reliance"), (4) spiritual change (example of item: "I have a better understanding of spiritual matters"), and (5) appreciation of life (example of item: "I have a greater appreciation for the value of my own life"). Respondents were prompted by asking "Compared to before the COVID-19 emergency, how has your position changed today with respect to the following statements?" Items were rated using a 5-point Likert scale with values ranging from 1 ("Much less than before") to 5 ("Much more than before"), and 3 considered the midpoint ("No changes"). In the validation study, the PTGI showed acceptable reliability for both the total score ( $\alpha = 0.93$ ) and the subscales, with Cronbach's alphas for the subscales relating to others ( $\alpha = 0.86$ ), new possibilities ( $\alpha = 0.84$ ), personal strength ( $\alpha = 0.80$ ), spiritual change ( $\alpha = 0.78$ ), and appreciation of life ( $\alpha = 0.74$ ).

#### Interpersonal Trust

A single item adapted from Zmerli and Newton (2008) was used to measure levels of interpersonal trust: "Since the start of COVID-19 emergency, how has your attitude toward this statement changed? Most people are trustworthy". A 5-point Likert scale was used with values ranging from 1 ("Strongly increased") to 5 ("Strongly decreased"). Scores were reversed before data analysis.

### Data Analysis

Descriptive statistics (mean and proportions) were calculated, and the data were checked for normality. We analyzed the construct validity (i.e., measurement model) of the Italian national identity and the five PTG dimensions

through confirmatory factor analysis. In accordance with the hypothesized conceptual model, we performed structural equation modeling to investigate predictors of national identity and the relationship between the latter and interpersonal trust. The mediating effect of each of the five PTG dimensions was tested using the accelerated-bias-corrected bootstrap estimation procedure, which yields the most accurate confidence intervals (CIs) for the indirect effects (MacKinnon et al., 2004). In the procedure, the given sample size was randomly resampled 10,000 times with replacement, and then 10,000 estimations of the indirect effect were calculated. When the 95% CI for an indirect effect did not include zero, the indirect effect was significant. The overall fit of the model was evaluated considering the values for acceptable absolute, relative, and parsimony fit indices. Selection of these indices was based on their statistical power and widespread use in relevant statistical literature (Hu and Bentler, 1999; Ullman, 2006; Kline, 2011). As indicative of absolute fit, we considered the root mean square error of approximation (RMSEA < 0.08) and the standardized root mean square residual (SRMR < 0.08). As a relative fit index, we used the values of the comparative fit index (CFI > 0.90) and the Tucker–Lewis index (TLI > 0.90) (Hu and Bentler, 1999; Ullman, 2006; Kline, 2011). Mplus version 7 (Muthén and Muthén, 1998–2015) was used to analyze data.

## RESULTS

### Descriptive Statistics and Measurement Model

**Table 1** displays the means, SDs and correlations among measured variables. In our sample, we found medium to high levels of national identity. This is comparable with those found by La Barbera and Capone (2016). In regard to PTG dimensions,

we found that scores of “appreciation of life” were the greatest and of “spiritual change” the lowest. The result on the latter dimension is consistent with the validation study, although Prati and Pietrantonio (2014) found that the “relating to others” dimension scored the highest.

The data showed a normal univariate distribution, given that most skewness values and kurtosis values fell within the range of  $-1.0$  to  $+1.0$ . As hypothesized, national identity scores were positively related to interpersonal trust and the five PTG dimensions. In addition, each PTG dimension was positively associated with interpersonal trust.

The measurement model for the six latent variables (national identity and the five PTG dimensions) was tested, and the results revealed an acceptable fit to the data: [ $\chi^2(419) = 2,111.028, p < 0.001, CFI = 0.948, TLI = 0.942, RMSEA = 0.045, SRMR = 0.031$ ]. All the standardized factor loadings for the indicators on the latent variables were statistically significant ( $|\lambda|$  ranging from 0.55 to 0.87,  $ps < 0.001$ ), signifying that the six latent variables were well represented by their respective indicators. Given the adequacy of the measurement model, the structural model was examined next.

### Structural Model and Mediation Analyses

The structural model was estimated modeling trust in the EU and the four national institutions as predictors of national identity, and national identity as a predictor of interpersonal trust as the outcome variable. The indices in the estimated model revealed an acceptable fit for the observed data (CFI = 0.944; TLI = 0.934; RMSEA = 0.075; SRMS = 0.029). As presented in **Figure 2**, trust in national institutions, except the civil protection agency, positively predicted national identity. Conversely, trust in EU institutions negatively predicted national identity. Thus, Hypothesis 1 was partially confirmed. The effect of national identity on interpersonal trust was positive and significant ( $\beta = 0.167, p < 0.001$ ).

We conducted five separate models to examine whether each of the five PTG dimensions would serve singly as a mediator in the relationship between national identity and interpersonal trust (Figure 3). All models evidenced an acceptable fit to the data. The results showed that the PTG relating to others, perceptions of having new possibilities, and spiritual change dimensions mediated the positive relationship between national identity and interpersonal trust, whereas personal strength and appreciation of life did not (both indirect effects were not significant). The indirect effect of the relating with others dimension on interpersonal trust was significant [indirect effect = 0.99,  $p < 0.001$ , 99% CI = (0.061, 0.136)], as well as that of perceptions of having new possibilities [indirect effect = 0.33,  $p < 0.01$ , 99% CI = (0.005, 0.061)] and spiritual change [indirect effect = 0.33,  $p < 0.01$ , 99% CI = (0.08, 0.058)]. In regard to the relating with others dimension, inspection of CIs suggests that, despite the direct effect of national identity on interpersonal trust remained significant at a 0.05  $p$ -value [ $\beta = 0.068$ ,  $p < 0.05$ , 99% CI = (-0.002, 0.138)], it was markedly decreased and CIs overlapped zero. Therefore, this mediation can be considered full (Hypothesis 2). Conversely, after accounting for the mediating effect of perceptions of having new possibilities

and spiritual change dimensions, the direct effect was only slightly decreased and CIs did not include zero [ $\beta = 0.134$ ,  $p < 0.001$ , 99% CI = (0.065, 0.202),  $\beta = 0.133$ ,  $p < 0.001$ , 99% CI = (0.067, 0.200), respectively]. Thus, these are partial mediations (Hypothesis 3).

## DISCUSSION

This work has examined some implications of the COVID-19 pandemic in Italy from a social identity perspective. Given the collective nature of this public health emergency, national identity was expected to be salient and to be involved in coping processes that included cooperative behavior and trust toward other people (Griswold et al., 2018; Kira et al., 2019; Dovidio et al., 2020). During the first weeks of the health crisis, feelings of national identity were manifested through people hanging national flags on balconies and performing traditional Italian music out of their windows with neighbors. These expressions can be considered a way of reacting to the anxiety and fear that the epidemic was evoking, thus highlighting the coping strategy feature of the shared social identity (Haslam et al., 2014). The

more people feel part of a group, the more capable they feel of facing adversities (Scarf et al., 2016).

First, our study indicates which aspects of their life and personal growth people gave the most thoughtful attention to during the first phase of the health emergency. The “appreciation of life” dimension received the highest score and “spiritual change” the lowest. We speculate that this is because the virus represented a threat to people’s health and was potentially fatal, thus accentuating concerns about one’s life and physical integrity. Spirituality was involved to a lower extent. The literature presents mixed findings on this matter. On the one hand, because the COVID-19 pandemic significantly altered the standard way of life, people may have been more prone to reflect on spiritual matters, thus allowing spirituality to be a resource to cope with stress (del Castillo, 2020). On the other hand, according to a new Pew Research Center survey (Gecewicz, 2020), a minority of people have changed their spirituality or religious behavior during the health emergency so far. We can hypothesize that for young people to reflect on spiritual issues, such as life’s meaning, requires more complex processes and more time than an immediate greater “appreciation of life” would require. Longitudinal data could offer insight on whether, after the turmoil of the pandemic’s first phase, young people have reflected on their spirituality to a greater

extent. Interestingly and contrary to previous studies (Prati and Pietrantonio, 2014), we found the “relating to others” dimension scored the lowest. This result is likely to be due to the substantial reduction of social interactions that people experienced during the lockdown.

For what concern national identity, our results confirm the importance of the national identity by the clear distinction between feelings toward national and supranational (i.e., the EU) institutions. The greater the trust in the Italian government and national institutions highly involved in the management of the crisis was, the feelings of national identity increased. However, the opposite was found for the EU suggesting that trust in this supranational institution clashed with feelings of “we” as a nation. In light of Italians’ ambivalent feelings toward the EU, this institution was perceived as an external entity that did little to support Italy during the emergency and was therefore considered an outgroup by most Italians (Laflan, 2004). This was likely to be further accentuated by the fact that during the first weeks of the pandemic, the media in other European countries portrayed the Italian government and national health system as culpably unprepared to cope with the virus, thus strengthening in-group boundaries increasing the gap between an “us” (ingroup) and a “them” (outgroup) (Jelen, 2011). In other words, these conjoint factors strengthened the salience of a social identity as Italians and

in its national institutions in contrast to supranational ones (Ruiz Jiménez et al., 2004; Harttgen and Opfinger, 2014). To promote national identity as a resource capable of conveying feelings of belonging, union, closeness, and solidarity, institutions could communicate an all-encompassing and supportive idea of “us,” and avoid evoking feelings of hate, discrimination, and fear for the “other.” As such, national identity would become an asset and not an obstacle for cooperation, allowing people to manage fear and anxiety by building networks, including virtual ones, and participating in collective events based on positive values. The result would likely be greater reflexivity on the health emergency and its social and psychological consequences, possibly accompanied by greater psychological growth (Venuleo et al., 2020).

By indicating that social identity salience can lead to a more generalized trust in interpersonal relationships in an emergency context, our findings are consistent with those of previous studies on this issue (Brewer, 2008; Ntontis and Rocha, 2020). Their novelty lies in the nuanced examination of the mediation role in this association played by each of the five post-traumatic growth dimensions.

Four out of the five PTG dimensions appear to be at best weakly involved, and the most “social” dimension (i.e., relating to others) only fully mediated the national identity—interpersonal trust association. This means that without a re-attribution of meaning to one’s relationships with others, renewed social identities do not result in positive changes in how people relate with others. In other words, trust in interpersonal relationships does not come automatically from salient social identities, but is the outcome of a meaning-making process whereby people go through a process of reflection and growth, especially when it comes to relationships with others (Muldoon et al., 2019). Furthermore, because collective traumas affect social bonds, during emergencies where other people can be considered a threat (in this specific case: a source of contagion), understanding that they can be part of the solution and not part of the problem is fundamental to cope with it.

In regard to the other PTG dimensions, a renewed spirituality and the perception of having new possibilities in life demonstrated to have a partial and modest role in mediating the association between national identity and trust toward others. We speculate that changes in these dimensions may involve the way people see others and the relationships they establish with them, i.e., seeing others as brothers and sisters in a religious community, thus explaining this effect of partial mediation (Tedeschi et al., 2018). Both PTG dimensions of personal strength and appreciation of life include changes closely related to the individuality of each person, i.e., the perception of being stronger and able to better accept negative things, as well as the value that people give to their lives and the ability to appreciate the positives of every day (Tedeschi et al., 1998). Despite these positive outcomes of the process of personal growth after a traumatic experience, we have demonstrated that they do not play a significant role in reshaping how people see others and relate with them.

## Limitations

The present study contains some limitations that are noteworthy, the most important being its cross-sectional nature. Further research with longitudinal designs is needed to better examine the causal relationships and mediation effects. Besides, this study did not consider the variables that can promote post-traumatic growth which are necessary to understand better the design of clinical and community interventions that create psychological well-being. Lastly, data of this study came from a sample of Italian young adults and it is unclear to what extent results encompass other age cohorts and countries in Europe.

## Conclusion

Findings of this study contribute to the literature by providing empirical evidence to the notion that, in a collective emergency and trauma context, the salience of national social identities is related to a more generalized trust in interpersonal relationships. This can also be understood from the perspective of living a “common fate” in the face of mortal danger and can determine a growth in a more relational and prosocial dimension, which in turn impacts on general trust toward others and consequently on well-being (Haslam et al., 2014).

Results of this study have implications for the work of social and clinical psychologists. Reinforcing positive identities through psychosocial interventions and consultation can be the basis for psychological growth at an individual and community level (Haslam et al., 2008; Yakushko et al., 2008; Alexander Haslam, 2014). This is because salient and positive social identities offer greater access to solidarity and social support (Muldoon et al., 2019), and play a protective role toward stressors resulting in more favorable psychological outcomes (Zoellner and Maercker, 2006). Those who have experienced trauma affirm that they need to express their feelings and confide their emotions to someone (Lehman et al., 1986), and there is evidence that sharing thoughts about traumatic experiences with others contribute to a better post-traumatic adjustment and more favorable outcomes (Pennebaker, 1989, 1993). Moreover, having valid social support appears to be a predictor of post-traumatic growth which in turn represents a healthy way to respond to trauma (Nolen-Hoeksema and Davis, 1999; Lev-Wiesel et al., 2004; Ramos and Leal, 2013). On this basis, it seems crucial to raise clinician awareness of the possibility of growth to encourage the development of those elements that predict the outcome in clinical practice.

During the current COVID-19 pandemic, and especially in the absence of availability of an effective treatment or a vaccine, the main health measure is neither chemical nor biological, but behavioral. To reduce the exponential growth of infections due to the new coronavirus (SARS-CoV-2) and the resulting overburdening of the healthcare system, many European Countries, parts of the US and Switzerland gradually implemented measures of quarantine and isolation defined as lockdown. This consideration leads to the need to understand how individuals are motivated to protect themselves and others. Recent research suggested that prosocial mental dispositions, such as empathy, might promote adherence to social norms of distancing. Other research conducted during the COVID-19 outbreak indicates, however, that empathy levels might fluctuate according to anxiety linked to the risk of death, and this negatively predicted prosocial willingness. The present protocol proposes a study on whether people's empathic dispositions, interacting with the levels of risk, influence the psychological impact of lockdown. The rationale is that emphatic dispositions, encouraging the acceptance of the lockdown, determine a better psychological adaptation and less distress. One retrospective study will be developed in Switzerland and, if the pandemic conditions force a new wave of lockdown on the population, one prospective study as well. A total of 120 participants will be involved, distinguished by their level of objective risk: (1) high objective risk (COVID-19 positive patients, hospitalized in isolation in post-acute phase); (2) moderate objective risk (COVID-19 positive patients, isolated at home); (3) minimum objective risk (non-positive adults, in lockdown). Measures of perceived risk of being contagious for third parties, empathic dispositions and acceptance of lockdown will be collected. The expected results provide important answers related to the immediate impact of empathic dispositions, effective risk and risk perception on the psychological impact of lockdown during a pandemic outbreak. Data gathered from this study could inform policy makers

and public health managers about the best communication strategies that will take into account the various stages of health risk and, in particular, to modulate messages to the population aimed at inducing self-isolation behaviors.

**Keywords: COVID-19, isolation, lockdown, psychological distress, risk, empathy, prosocial, ethics**

## INTRODUCTION

In December 2019, originating in Wuhan, China, a new coronavirus disease (COVID-19) emerged which led to an epidemic of an acute respiratory syndrome (SARS-CoV-2). Within 3 months, the virus had caused more than 118,000 cases and resulted in 4,291 deaths in 114 countries, leading the World Health Organization to declare a global pandemic. The pandemic has led to a massive global effort by local health systems to deal with the cases of infection and to reduce the number of deaths. The most common and useful preventive measures require an increase in hygiene practices (e.g., frequent hand washing, reducing face touching, use of tissues, sanitization of environments). However, in most cases, these measures have not been sufficient, and COVID-19 has forced people to change their habits, from wearing masks in public to physical or social distancing.

On February 24, 2020, Switzerland registered the first case of COVID-19 infection in Canton Ticino, the Italian-speaking part of the country. The number of positive cases increased rapidly in the following days, as did the number of deaths. Three months later, there were 358 confirmed laboratory cases and 19 deaths per 100,000 of the population in Switzerland (1). Neighboring Italy, one of the countries worst affected by the coronavirus, announced 380 confirmed cases and 54 deaths per 100,000 of the population (2). To reduce the exponential growth of infections and the resulting overburdening of the healthcare system, the Swiss Federal Government, like many European Countries and parts of the US, gradually implemented measures to restrict individual freedom (i.e., lockdown for non-health workers).

Other more restrictive measures were implemented in Canton Ticino because of the faster spread of the virus (with an incidence of 958/100,000 confirmed cases on May 25, 2020) due to the proximity of the region with the most affected area of Italy. At first, when the pandemic started to spread across Canton Ticino, contact-tracing measures were applied. Then, when the number of infections increased, those who presented any kind of symptom attributable to the coronavirus infection and people who came into contact with a suspected or positive case of COVID-19 were asked to quarantine at home. Positive COVID-19 patients were isolated either at home or, if so required by their health conditions, in special hospital wards dedicated to COVID-19. For the over-65s, the population group most affected by the virus, the Ticino government strongly recommended not leaving their homes. Care homes were closed to the public. At the end of April, the quarantine and physical distancing measures for non-infected people were progressively reduced in most countries, including Switzerland. Contact tracing and selective isolation in case of contact with a positive case of COVID-19

were re-established for the Swiss population. In the meantime, the scientific community started to fight against COVID-19. Laboratories and researchers in every part of the world have been testing pharmaceutical interventions for COVID-19 [see (3, 4)].

Social behavioral and psychological research has been studying the impact of the pandemic on individuals' well-being and psychosocial functioning. A rapid review of the studies carried out during previous pandemics (e.g., SARS, Ebola, H1N1 influenza) revealed a negative psychological impact on the general population generated by physical isolation and quarantine (5). Short-term effects involved emotional disorders, anxiety, depression, stress, mood decline, irritability, insomnia and PTSD. Whereas long-term effects included increased depressive symptoms, addiction symptoms (i.e., alcohol consumption, substance use) and persistence of avoidance behaviors. The same authors found that the psychological impact of the restrictive measures was boosted by the duration of the quarantine, existing psychiatric disorders, infection fears, financial loss and loss of accessibility to necessities or daily routines, and insufficient information. These pre-COVID-19 results have also been confirmed by further systematic review and meta-analysis of mixed lists of diseases prioritized in public health emergencies (6, 7). This evidence tends to be confirmed by research on confinement conducted during the COVID-19 outbreak (8, 9). Ammar et al. (8) insist on a crisis-oriented interdisciplinary intervention and Serafini et al. (9) suggest focusing on identified protective factors such as resilience and social support or preventive strategies such as effective communication and the provision of adequate psychological services. Public health condition during the epidemic have been acknowledged as a major stressor contributing to an increased risk of psychiatric illness (10). Likewise, regional data on the general population published in Italy highlight the fact that vulnerable people may experience distress during lockdown (11–15).

Evidence emerging from literature has stimulated a debate on what aspects may protect individuals from the negative side-effects of quarantine and isolation. There is a growing body of evidence about communication features that might contribute to mitigating the psychological impact of isolation/quarantine during pandemic outbreaks. To this end, the five review has identified five key public health measures: reducing quarantine duration, providing adequate supplies, providing information, improving communication, protecting vulnerable groups and promoting altruism. These authors also recommend that "public health officials should emphasize the altruistic choice of self-isolating" [5, p. 1].

People's willingness to adhere to preventive public health behaviors is known to be associated with risk perception, which is influenced during the COVID-19 outbreak by various social factors among which are prosocial attitudes (16, 17). Prosocial dispositions have been particularly identified as a core factor in reducing the psychological impact of quarantine during previous pandemic outbreaks (18, 19), and are at the center of an emerging field of research in this domain for adapting public health messages. A recent study in the US (20) confirmed the need for promoting prosocial values: compared to messages that induce fear, prosocial messages capable of arousing a positive emotional state have proved to be more effective in the willingness to accept self-isolation. Another recent study (21) suggests that prosocial mental dispositions, such as empathy, might promote adherence to social norms of distancing, hygiene practices, and ultimately may influence the psychological impact of measures restricting individual freedom. The emphasized rationale is that engaging in physical and social distancing not only protects oneself but also others, especially the most vulnerable, and in this sense is a prosocial behavior. Following this principle, Pfattheicher and colleagues, comparing people from three different countries, demonstrated that empathy increased the motivation for physical distancing.

Other research conducted during the COVID-19 outbreak indicates, however, that empathy levels might fluctuate according to anxiety linked to the risk of death, and this could modulate prosocial willingness (22–25). Perceived risk of infection have been found to be higher in individuals leaving in locations with higher H1N1 incidence and likely to influence the adherence to disease control measures (26). Research on the domain of vaccination for influenza demonstrated that both subjective and objective risk perception were associated with the propensity to take the vaccine (27). Therefore, it seems that, together with empathy, objective and perceived risk may be a variable influencing the adherence to behavioral measures. Perceived risk may be relative to the individual, in other words concern associated with one's own health and survival, which can be experienced by both individuals with or without symptoms. However, the perceived risk can also be relative to third parties: the perception of being a danger to relatives, friends or even simple acquaintances, which again can be experienced by both infected or non-infected individuals.

There are no studies to date that have analyzed whether people's empathic dispositions, interacting with the levels of risk, influence the psychological impact of quarantine/isolation. The rationale that underlines this is that empathic dispositions, encouraging the acceptance of the quarantine, determine a better psychological adaptation and less distress. On the other side, a high subjective risk perception and a high objective risk should increase the negative psychological impacts of the lockdown because the negative feelings and the emotional concerns caused by the uncertainty of the situation. It might also be that the empathic disposition and the objective and subjective risk interact each other in determining the psychological impacts of the lockdown. For clarity of terminology, the term quarantine/isolation has been replaced by lockdown, which is currently used in the

international and local media to refer to collective physical and social distancing or isolation during a health emergency.

In particular, the following hypotheses and research questions will be tested:

HP1: high empathic dispositions (vs. low) are associated with the positive psychological impact of the lockdown directly (HP1a) and through the mediation of the acceptance of the lockdown (HP1b).

HP2: high subjective risk perception and high objective risk, independently, are associated with the negative psychological impact of the lockdown.

RQ1: what are the interrelations between risk perception and empathic dispositions on the psychological impact of the lockdown?

RQ2: to what extent does objective risk in combination with empathic dispositions predict the psychological impact of the lockdown?

Figure 1 shows the model tested.

## METHODS

This research will take place in Switzerland, specifically in Canton Ticino. The aim will be to measure the effects of the interaction between empathic dispositions and perceived or objective health risk on the psychological impact of lockdown during the COVID-19 outbreak. One retrospective study will be developed and, if the pandemic conditions force a new wave of lockdown on the population, one prospective study will be also developed. The two studies share the same hypotheses and method.

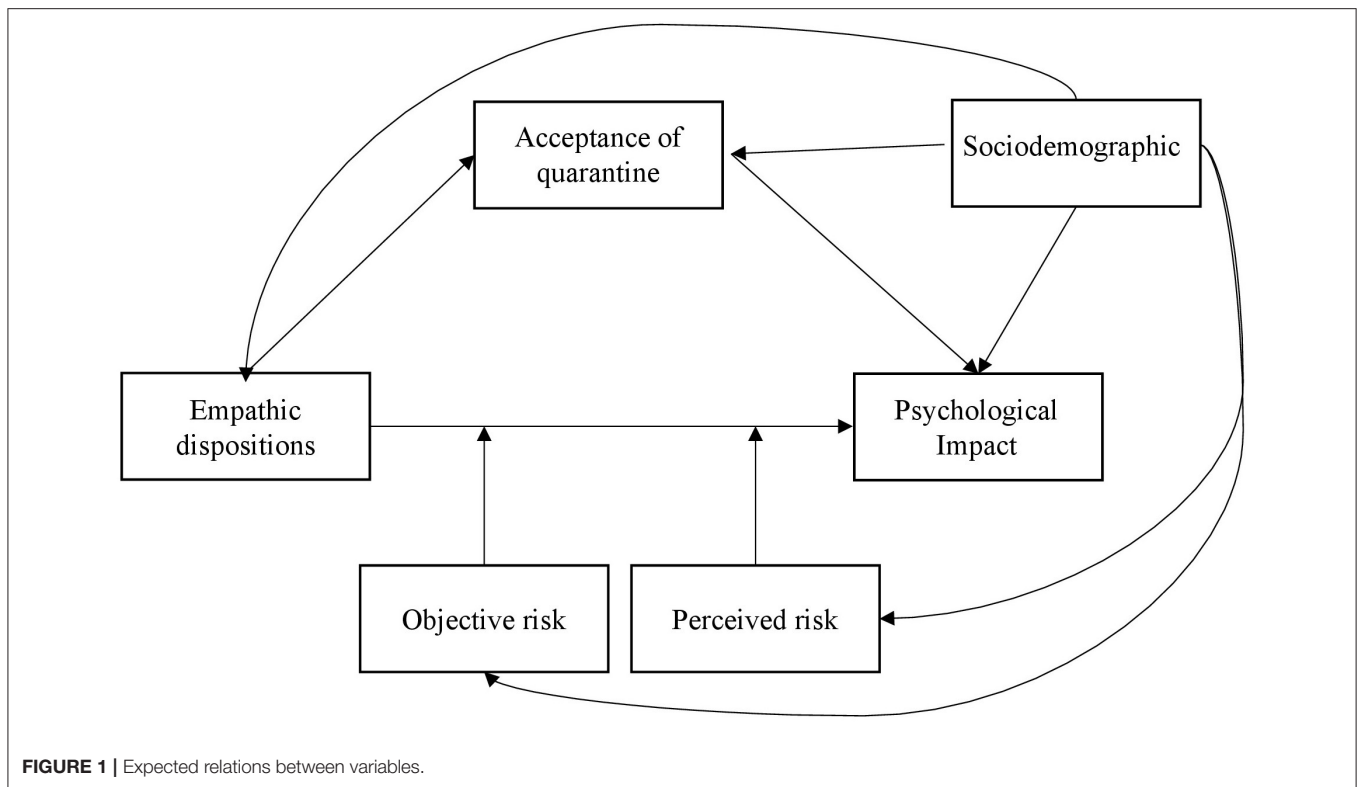

## Participants

A total of 120 participants will be involved in the research. The number of participants has been calculated based on an a-priori statistical estimate (applying GPower v.4), which guarantees adequate statistical power. Retrospective and Prospective studies will involve three groups of participants:

- Group 1: High objective risk ( $n = 60$ ): patients over 18 years of age, tested positive for COVID-19 and hospitalized in isolation in post-acute phase.
- Group 2: Moderate objective risk ( $n = 60$ ): patients over 18 years of age, tested positive for COVID-19 and isolated at home.
- Group 3 (control group): Minimum objective risk ( $n = 60$ ): control group. Persons over 18 years of age, not positive for COVID-19 and in preventive social and physical isolation at home (lockdown).

## Procedure

COVID-19 patients will be recruited through local hospital database on COVID-19 cases provided by Ente Ospedaliero Cantonale (Cantonal Hospital Authority). Participants will complete the survey via a Qualtrics™ online link or by paper and pencil. In the retrospective study, participants in groups 1 and 2 will be contacted by phone and will receive the informed consent and questionnaires by post. In the prospective study, group 1 will be contacted directly in the ward and will receive the

informed consent and questionnaires to fill out. Group 2 will be contacted by phone and will receive the informed consent and questionnaires by post. Group 3 will be recruited by snowball sampling and data collection will be via Qualtrics™ online link.

## Measures

**Demographic.** Self-reported gender, age, living area, marital status, occupation, household composition, will be collected through medical files in EOC's database for Groups 1 and 2 and through specific questions for Group 3.

**Previous health problems.** Self-reported previous diagnosis of non-COVID-19 diseases and/or psychiatric disorder will be collected through medical files in EOC's database for Groups 1 and 2 and through specific questions for Group 3.

**Effective risk exposure (COVID-19 status).** Participants' COVID-19 status or presence of symptoms attributable to COVID-19 will be collected through medical files in EOC's database for Groups 1 and 2 and through specific questions for Group 3. Questions on COVID-19 status of the household, situation of risk in the household and duration of isolation will be also asked.

**Perceived risk.** One item developed *ad hoc* for this research will evaluate the individual's perception of risk of being contagious for third parties. The item will be formulated according to the measures of perceived relative risk applied in literature [see (28)]. Response options vary from 0 ("no risk") to 10 ("maximum risk").

**Empathic dispositions.** Empathic disposition will be measured with three items translated from Pfattheicher et al. (2020).

Response options range from 1 ("strongly disagree") to 5 ("strongly agree"). The items measuring empathy are mixed with three-filler items to reduce demand characteristics.

**Acceptance of lockdown.** Three items will be developed *ad hoc* for this research evaluating participants' acceptance of social and physical isolation measures (lockdown). The item will be formulated according to the measure of physical distancing practice used by Pfattheicher et al. (2020). Labels ranged from 1 ("strongly disagree") to 5 ("strongly agree").

**Psychological impact of lockdown (or Distress).** Psychological impact of lockdown (i.e., Distress) will be investigated with the Italian version of the NCCN Distress Thermometer without the Problem List (available at: <https://www.nccn.org/about/permissions/thermometer.aspx>) (29), Patient Health Questionnaire-9 (PHQ-9) (30) and the Generalized Anxiety Disorder 7-item Scale (GAD-7) (31). For both questionnaires, participants indicate how often they have been troubled during lockdown by each symptom, using a four-point Likert scale ranging from 0 ("Not at all") to 3 ("Nearly every day").

## Data Analysis

Data will be analyzed through Reliability Analysis, Anova and Ancova, Moderation and Mediation Analysis.

## Ethical Considerations

The study was reviewed and approved by the Cantonal Ethics Committee (N. 2020-01460 /CE3679). Participation is voluntary. All data will be collected and analyzed

in an anonymous form. Participants will be debriefed after the experiment. Data will be treated confidentially and used only by the collaborators in the present study for scientific purposes. Participants will receive a written informed consent and will give their consent for their participation.

Evaluating the basic psychological status associated with lockdown during coronavirus could enhance participants awareness of their mental health. The local public psychiatric organization number is included in the Study presentation form. Facilitating access to specific mental health care could be seen as a possible direct benefit for participants in this study.

## DISCUSSION

During a worldwide health risk situation like the one we are facing with COVID-19, especially if effective treatments or vaccines are not yet available for all, the main health measure is neither chemical nor biological, but behavioral. Prosocial behaviors are particularly solicited from the general population when lockdown measures force people to restrict personal freedom and sustain socio-economic and psychological burdens. The results of the present research will provide important answers related to the role of empathic dispositions, objective risk and risk perception on the psychological impact of quarantine during a pandemic outbreak. Data gathered from this study could inform policy makers about the best strategies that will take into account the various stages of health risk and, in particular, to adjust messages to the population.

Behavioral science aims to understand how individuals are motivated to protect themselves and others and how public health managers can promote such self-protecting and prosocial behaviors through specific measures or targeted communication (32–34). Communication at a time of health crisis may induce people to protect themselves and others through fear. However, evidence of the use of fear as a means in communication is inconsistent and often underlines a boomerang effect (35, 36). Individuals might be more prone to respect the quarantine if the communication in time of crisis, such as during the COVID-19 period, stressed the risk of vulnerable people being infected by a virus (37, 38), evoking the individual's empathic tendencies. In fact, some survey research shows that if a restriction of civil liberties (like quarantine and isolation) is oriented to protecting the health of the community and preventing deaths, people tend to accept it (39, 40). Acceptance of the quarantine and isolation measures might decrease the negative impact of the restriction of personal freedom. Measures limiting individual liberty used to reduce the risk of contagion can affect negatively both the mental and physical health of those involved. For the benefit of the wider community, individual freedom is compromised and while isolating sick patients tends not to provoke much concern, collective lockdown or quarantine of healthy people who only might be infected is controversial and

tends to provoke ethical concern (41–43). Ethical debate on public health pandemic behavioral prevention and management is open and recent perspectives stresses the value of solidarity and a relational autonomy approach able to ensure a common sense of social justice between the individual self and the others (44).

Finset et al. (45) highlights some elements particularly important in directing communication during a health crisis, such as the one with COVID-19. One of these elements is about the acknowledgment of the psychological impact related to the uncertainty of the situation and fear of infection. In this sense, communicators should express their empathy, demonstrating concern and understanding regarding the impact of the pandemic on individuals' lives. The results of the present research place themselves within this debate with the potential to add several practical considerations. The most important behaviors are well-known – wash your hands regularly, cough in a tissue, keep distance, wear mask, stay isolated if COVID-19 positive – but the way in which the message is implemented is not fully defined. Therefore, results from the present research will make it clear how to adapt the communication of personal and social risk, whether and how to include the empathic concern in the messages in order to maximize preventive behaviors and to decrease the negative psychological impact of quarantine. We also expect that the objective and perceived risk will play a role in determining the relationship between empathic concerns and psychological distress. We expect that the more the situation is uncertain and perceived as a risk for individual health, the more people would be willing to accept message explaining the importance of behavioral measures for their own safety and for the safety of the most vulnerable ones. We can speculate that the experience of those most exposed to risk for their own health could be informative for those less vulnerable. Such shared communication, if adequately promoted through public health messages, could enhance understanding of lockdown measures and ultimately social cohesion. The more health measures and individual restrictions are deliberately adhered to by the population without recourse to communications causing alarm or to coercive measures, the more the negative psychological impact will decrease and the ethical balance between the benefits and risks of personal restrictions will be advanced (46).

The present research has some limitations. First, the retrospective study has disadvantages such as memory bias and difficulty in analyzing the temporal relationship among variables. For this reason, a second prospective study was decided. However, its effective realization is not under our direct control, but depends on the contingent conditions (i.e., second wave). Currently, the retrospective study ensures the possibility to evaluate the state of mind of the individuals under different levels of objective risk without overwhelming people who are already in a difficult situation (i.e., positive to COVID-19). The second main limitation concerns the design. The two studies are cross-sectional and this limits the possibility to derive indications about causality. Another limitation concerns the fact that the measures are self-reported, which may biased the generalization

of the results through under-reporting, under-estimating, or having misunderstood the questions.

## AUTHOR CONTRIBUTIONS

NG, SP, and SB developed the idea and wrote the protocol. IM, RT, RM, and LG contributed to the development of the research questions and checked the final version of the protocol. All authors read and approved the final version of the manuscript.

**Introduction:** With the sudden onset and global dispersal of the SARS-CoV-2 virus, many nations including Canada attempted to reduce spread of the resultant COVID-19 syndrome with self-isolation and quarantine, while seeking a cure or vaccine for this disease. Understanding impacts of self-isolation and self-quarantine on stress, anxiety, and depression will help us to mitigate these issues through appropriate development of mental health services.

**Methods:** The sample was drawn from individuals who self-subscribed to Text4Hope, a service that delivers text messages based on a cognitive behavioral therapy framework. Text4Hope was developed to support Albertans during the COVID-19 pandemic. Subscribers were asked for demographic information and if they had to self-isolate or self-quarantine during the pandemic via a survey link. Mental health was assessed using the validated instruments: Perceived Stress Scale (PSS), Generalized Anxiety Disorder-7 item scale (GAD-7), and the Patient Health Questionnaire-9 (PHQ-9). Descriptive statistics and Chi-Square test results were derived using Statistical Package for Social Sciences (SPSS) version-26.

**Results:** 6,041 of 32,805 Text4Hope subscribers (18.4%) completed the survey. Of these respondents, 19.2% had self-isolated or self-quarantined in Alberta as of March 31, 2020 during the COVID-19 pandemic. *Post-hoc* analysis using adjusted residuals suggested that individuals aged 60 years of age or older, and retirees had a higher likelihood of self-isolation or self-quarantine, compared to respondents with other age or employment characteristics. One-week prevalence rates for self-reported measures of moderate to high stress, likely Generalized Anxiety Disorder (GAD),

and likely Major Depressive Disorder (MDD) were 84.9, 46.7, and 41.4%, respectively. Respondents who had to self-isolate or self-quarantine during the COVID-19 pandemic were significantly more likely to present with moderate to high stress, significant anxiety symptomatology, and significant depressive symptomatology.

**Conclusions:** Older age and employment status were significantly associated with the likelihood of self-isolation or self-quarantine. We found elevated self-reported levels of anxiety and depression associated with self-reported COVID-19 pandemic-related self-isolation and self-quarantine activity. These findings have mental health implications both during and after the pandemic and demonstrate the need for greater focus on psychological complications of self-isolation and self-quarantine, and development of optimal ways to manage these pandemic consequences.

**Keywords:** COVID-19, pandemic, stress, anxiety, depression, isolation, quarantine

## INTRODUCTION

Coronavirus disease (COVID-19) is primarily a respiratory disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (1, 2). Its origin traces back to Wuhan, China where it was first reported in December 2019 (1, 2). Following initial reports, it rapidly spread globally and was declared a pandemic by the World Health Organization (WHO) on March 11, 2020 (1). Nations soon took steps to reduce its spread by limiting access to certain facilities; implementing workplace hazard controls; introducing curfews and physical distancing measures, which include self-isolation and self-quarantine; imposing travel restrictions; and closing schools, shopping malls, and public spaces. These restrictions have caused substantial concerns, including the disruption of sport, recreation, and religious events, which individuals turn to for psychological and spiritual nourishment and entertainment. Panic buying was also observed, leading to a shortage of essential products, including toilet rolls and hand sanitizers.

Similar to other nations, Canada took steps to limit COVID-19 spread (2). Screening requirements were implemented for travelers returning from China to major airports in Montreal, Toronto, and Vancouver (January 22, 2020), later expanding to 10 airports in 6 provinces in early February 2020 (2). By mid-March 2020, voluntary, 2-week self-isolation was recommended for all individuals returning from travel abroad, a condition that was later mandated under the Canadian Federal Quarantine Act (March 25, 2020) (2). Self-isolation was also mandated for individuals diagnosed with COVID-19 and those who presented with disease-suggestive symptoms. Physical distancing measures, including maintenance of 2 m personal distance from others, and avoiding congregation, were put in place.

Self-isolation and self-quarantine measures deployed in the COVID-19 pandemic are based on public health knowledge gleaned from previous epidemics (3). Self-isolation, which is the separation of people who have been diagnosed with a contagious disease from those who are not sick (4, 5), differs from quarantine. Quarantine involves the separation and limitation of movement of individuals who have potentially been exposed

to a contagious disease to see whether they become unwell, thereby reducing the risk of infection to others (3, 6). As well-intentioned and effective as these measures are, they produce unintended consequences. Previous research has shown that isolation and quarantine may increase suicidality (7). Escalate boredom, heighten fears of infecting family, particularly among those with young children, limit supplies of essential goods, affect family finances, induce frustration, anger, and litigation (4, 7), and in some circumstances, result in the stigmatization of affected individuals.

Canada closed its southern border with the United States to all non-essential freight, services, and workers on March 18, 2020 (2). Similar mitigation strategies cascaded through Canadian provinces in order to limit COVID-19 spread. Provincial orders closed public schools, higher learning institutions, and daycare (March 15, 2020), followed by the closure of non-essential businesses (8). On March 25, 2020, Albertans were legally required under public health order to self-isolate after travel and when exhibiting symptoms, and to follow social distancing measures by limiting social interactions in public spaces, and maintaining 2 m personal distance from others (8).

Widespread public health efforts to try and limit rapidity of spread, to avoid overwhelming the healthcare system, caused cascading economic concerns as companies shut down and workers were laid off. Such economic worries are compounded by restrictions in social activities, limiting individuals to interaction primarily within their family units, including remote working for non-essential workers. Taha et al. showed that threats, such as those related to pandemics, affect physical health and cause psychological distress, with outcomes varying according to both appraisal and coping factors (3). They stress that emphasis on containment in family units and households gives rise to its own pressures, escalating pre-existing tensions in certain households, and/or giving rise to boredom. They also emphasize that individuals at home also may have increased time to tune in to media broadcasts, which are filled invariably with gloomy predictions about COVID-19 related morbidity and mortality and a degree of accompanying misinformation, both about the virus and disease spread. These factors produce fertile ground

for mental illness, and anxiety may become exacerbated in ambiguous or uncertain situations (3).

Furthermore, ideas concerning treatment of COVID-19 remain ambiguous and varied, including considerable public debate evolving over use and types of face masks as a protective measure, with prevention based primarily on hand-washing and physical distancing. This creates palpable tension between fear for the present and uncertainty about the future. While the public health response is focused on the fight to reduce infection rates due to community transmission of COVID-19, the overriding clinical goal is to save lives. These twin approaches, coupled with uncertain outcomes, have exacted a toll on the mental health of patients, families, and healthcare workers, as well as the population at large. Pandemic measures adopted so far, while effective, may also have widespread mental health implications that have not yet been examined. Mental health status, in turn, is likely to have significant effects on how well the population is able to comply with self-isolation and self-quarantine requirements.

Text messaging has demonstrated efficacy in public health interventions (9). To help address the potential stressors and mental health difficulties which inevitably arise during emergencies, Alberta Health Services (AHS), in conjunction with six health foundations and the Department of Psychiatry at the University of Alberta, launched the Text4Hope program. Text4Hope is an evidence-based tool providing daily free, cognitive behavioral therapy-based text messages for 3 months to Albertans who subscribe. Launched in March 2020, Text4Hope evolved from the pre-existing program infrastructure supporting the Text4Mood program, initially launched in January 2016 (10), and deployed to support patients in the aftermath of the Fort McMurray wildfires in 2016. Text messages were written by mental health therapists and were further refined from patient feedback. They are intended to help individuals identify and adjust negative thoughts, feelings, and behaviors arising from the COVID-19 pandemic. Understanding the extent of self-isolation and self-quarantine on stress, anxiety, and depression can help decision makers plan and allocate mental health resources more effectively for this, and future pandemics. This study examined the demographic characteristics of Albertans who self-isolated or self-quarantined during the early stages of the COVID-19 pandemic, and assessed the influence of self-isolation or self-quarantine on stress levels, anxiety, and depression.

## METHODS

We conducted a cross-sectional survey with online data collection. The study was approved by the University of Alberta Human Research Ethics Review Board (Pro00086163); consent to participate was implied when participants completed and submitted online survey responses. Demographic and clinical data were collected from subscribers to the Text4Hope program which was launched March 23, 2020 by the Chief Medical Officer for the Government of Alberta as part of the official government COVID-19 announcements. Using posters, email,

and social media, individuals were invited to subscribe to the program by texting “COVID19HOPE” to a short-code number. Subscribers then received a survey link to assess respondent self-isolation or self-quarantine activity during the COVID-19 pandemic and gather demographic characteristics including age, gender, ethnicity, education, employment status, relationship status, and housing status. The survey assessed clinical correlates using validated tools: the Perceived Stress Scale (PSS, to measure stress with moderate to high stress indicated with scores 14 and higher) (11), the General Anxiety Disorder-7 item scale (GAD-7) (12), to measure anxiety with likely Generalized Anxiety Disorder (GAD) represented by scores of 10 and higher), and the Patient Health Questionnaire-9 scale (PHQ-9, to measure depression with likely Major Depressive Disorder (MDD) represented by scores 10 and higher) (13). An *a priori* sample size of 4,200 was required to estimate mental disorder prevalence rates in Alberta (2019 population: 4,371,316) with a confidence level of 99% and 2% margin of error. With an expected 20% response rate (10), we planned to extract data upon recruitment of at least 20,785 Text4Hope subscribers. Data were extracted 1-week post-program launch with a total of 32,805 active Text4Hope subscribers. We analyzed data with Statistical Package for Social Sciences (SPSS) version 26 (IBM 2019) to generate descriptive statistics and Chi-square tests. Two-tailed significance ( $p < 0.05$ ) was used to assess the relationship between self-isolation or self-quarantine activity and clinical outcomes. There was no imputation for missing data and the results are based solely on completed survey responses.

## RESULTS

Of the 32,805 individuals subscribed to Text4Hope at 1-week post-launch, 6,041 individuals (18.4%) completed the baseline online survey. Overall, 86.4% of respondents identified as female ( $n = 5,185$ ) and 19.2% of respondents ( $n = 1,126$ ) self-isolated or self-quarantined by March 31, 2020 as part of public health measures put in place to contain the spread of the coronavirus in Alberta during the COVID-19 pandemic. **Table 1** provides descriptive summaries of respondent demographics and clinical correlates.

One-week prevalence rates for moderate to high stress, likely GAD, and likely MDD in Alberta were 84.9% ( $n = 4,683$ ), 46.7% ( $n = 2,360$ ), and 41.4% ( $n = 2,129$ ), respectively.

**Table 2** suggests there were significant associations between need to self-isolate and self-quarantine with two demographic variables: age and employment status. Specifically, individuals >60 years of age and retirees had a higher likelihood of self-isolation or self-quarantine, compared to respondents with other age or employment characteristics.

**Table 3** shows that respondents who had had to self-isolate or self-quarantine during the COVID-19 pandemic were significantly more likely to present with moderate to high stress, significant anxiety symptomatology, and significant depressive symptomatology. Small effect sizes were observed for each association.

**TABLE 1** | Gender distribution of demographic and clinical characteristics of respondents.

Variables	Male <i>N</i> (%)	Female <i>N</i> (%)	Gender Diverse <i>N</i> (%)	Overall <i>N</i> (%)
<b>Age (Years)</b>				
≤25	74 (10.3)	550 (10.8)	15 (30.6)	639 (10.9)
26–40	247 (34.3)	1,905 (37.4)	21 (42.9)	2,173 (37.1)
41–60	308 (42.8)	2,213 (43.5)	11 (22.4)	2,532 (43.2)
>60	91 (12.6)	423 (8.3)	2 (4.1)	516 (8.8)
<b>Ethnicity</b>

## DISCUSSION

This is the first Canadian study to survey the impact of self-isolation or self-quarantine measures on self-reported stress, anxiety, and depression, during the COVID-19 pandemic. The study included a large sample size as well as validated self-report measures. The majority of respondents in this survey identified as Caucasian ( $n = 4,904$ , 82.3%), between the ages of 26–60 years ( $n = 4,705$ , 80.3%), with post-secondary school education ( $n = 5,115$ , 85.6%), married or cohabiting ( $n = 4,277$ , 71.6%), employed ( $n = 3,721$ , 72.2%), and living in their own home ( $n = 3,907$ , 66.6%). These figures suggest pre-existing socioeconomic stability within the sample, prior to onset of the COVID-19 pandemic, thereby potentially mitigating the effects of these variables on their experiences of mental health difficulties. The

underrepresentation of those aged 60 years and above in this study is similar to what is observed in other studies (14) and may limit our inferences for this cohort. Social isolation and quarantine are effective methods of achieving prevention of the spread of infectious diseases, yet also limit individual rights (15), and are associated with negative impacts on mental health. Some studies demonstrate negative psychological effects that outlast the pandemic (16, 17). A recent review by Brooks et al. (4) examining the psychological impact of quarantine suggested that the psychological impact of quarantine is substantial, wide-ranging, and long lasting.

Respondents who self-isolated or self-quarantined during this early COVID-19 pandemic stage were significantly more likely to present with moderate to high stress, likely GAD, and likely MDD, with small effect sizes for each association. The rates

of anxiety (46.7%,  $n = 2,360$ ) and depression (41.4%,  $n = 2,129$ ) reported by respondents were substantially higher than both anxiety (6.3%) and depression (17.2%) rates reported by Wang et al. (18) in this context in China. Sensitization of the Canadian cohort by the free flow of information about the disease and its complications, as well as the inability to curtail disease transmission may have shaped the differences noted, in comparison to the Chinese sample.

Our study also showed that older adults and those who were retired were more likely to self-isolate or self-quarantine. This could reflect an increased likelihood of recent travel abroad (e.g., snow-birds or winter vacations) or may reflect greater awareness or knowledge of the risks to the elderly from reported COVID-19 fatalities, bearing in mind the greater

preponderance of medical comorbidities within this age group. This is a hypothesis that merits further exploration. Self-isolation, boredom, increased access to pessimistic information about the pandemic, occupational disruption and financial difficulties, and an increased number of deaths amongst older adults may collectively pose a higher burden on those in this age cohort, thereby increasing their risk of stress, anxiety, and depression (19).

There are many documented socio-demographic factors that predict which individuals are more likely to be vulnerable to disaster-related mental health impacts, including lower individual resilience, poor coping skills, disaster severity, degree of victim involvement, pre-existing mental health issues, gender, age, social support and relationships, government and insurance

**TABLE 3** | Chi-Square-test of association between self-isolation/self-quarantine and perceived stress, likely GAD, and likely MDD.

company support, and duration of the mental health issue (20, 21). Our present study did not examine the effects of employment type on the likelihood for individuals to self-isolation or self-quarantine, or on the mental health effects of the pandemic. However, Qiu et al. (19) found that migrant workers experienced higher distress levels in China during the COVID-19 pandemic. Previous studies also reported that age likely increases the risk of development of mental illness following natural disasters (22) and in particular, that individuals between the ages 18–30 years and those aged above 60 years were at increased risk of distress during the COVID-19 pandemic (19). Although individuals that self-identified as female may exhibit substantially increased anxiety risk (three-fold greater than self-identified males) in COVID-19 pandemic findings drawn from China (18, 19), no gender differences were noted in respect to self-isolation or self-quarantine in the present study.

The practical utility of this study is rooted in its potential to guide healthcare planners in making targeted evidenced-based decisions in deploying resources to assist individuals who self-isolate or self-quarantine during the COVID-19 pandemic. The deployment of simple technology like text messaging may be used to provide hopeful and encouraging information to individuals who are isolating or quarantining. The elderly are more likely to self-isolate or self-quarantine and therefore more likely to experience symptoms of stress and anxiety. They may also be less technologically savvy and therefore may not rely much on social media, instead depending on newspapers, radio, and television for entertainment and news. Public health measures should be directed at upskilling the elderly in the use of phones and the internet, as well, news articles on mass media should have a blend of the negative facts about the virus with more positive news about recoveries, and focus less on sensationalism which fuels uncertainty and panic. Guarantees about jobs and income during periods of self-isolation and self-quarantine may help to reduce anxieties about finances and loss of earnings and may deter individuals from disregarding policy guidelines suggesting that they self-isolate or self-quarantine.

Data collection for this study was completed by March 31, 2020, a week into the commencement of public health measures to limit the spread of COVID-19, and thus we are looking at early stage effects. This early stage data capture is a strength of our study as is the inclusion of an anxiety scale. Most studies have investigated post-traumatic stress disorder (PTSD) and depression in the aftermath of disasters and, in that context, generalized anxiety disorder is less frequently studied (20). Anxiety may fluctuate across time (19) during an epidemic, variation that has been attributed to trait anxiety, situation-appropriate coping strategies of avoidance, and personal hygiene practice (23). How the pattern and prevalence of anxiety evolves as the COVID-19 pandemic continues is an ongoing focus of our work.

Limitations of this study include a lack of baseline data on stress, anxiety, and depression levels before self-isolation and self-quarantine measures were implemented in Alberta: our study was initiated shortly after these measures were introduced. Another limitation of the study is that subscribers of the Text4Hope program could be residents who were seeking mental health

supports because they were more psychologically impacted by the pandemic than non-subscribers, there-by introducing a selection bias. For example, in a cross-sectional survey of subscribers to Text4Mood (the precursor to the Text4Hope program), about half of those surveyed indicated they signed up for the program to help elevate their mood (51.6 %,  $n = 461$ ) or to help them feel better (49 %,  $n = 440$ ), and a quarter indicated that they signed up for the program to help them worry less (24.5 %,  $n = 219$ ) (10). This suggests that individuals experiencing psychological distress are more likely to enroll on supportive text messaging programs.

Non-response bias may have also affected the results, given the low response rate in our study sample (22). It is possible that non-respondents may differ in a systematic way compared to respondents. For example, they may be more (or less) affected by the pandemic, or may have limitations in literacy or English fluency. Despite the low survey response rate, this study provides useful data about the mental health characteristics of individuals who self-isolate or self-quarantine in the early stages of a pandemic. Our findings present an important initial source of information for government and healthcare planners in determining the nature and quality of services required to address mental health challenges arising during this pandemic, as well as future pandemics that employ self-isolation or self-quarantine measures. Specifically, planning for and implementing virtual care programs including supportive text messages may be a fruitful approach to supporting isolated or quarantined individuals. Our research contributes to a larger program of research that is deliberately responding to the ongoing call for transformation of mental health care service to meet the needs of populations during the COVID-19 pandemic. Our study also aligns with our research program advocacy for mobilizing supportive text message technology (24–32) to reach populations disparately affected by mental health concerns.

The COVID-19 pandemic resulted in the abrupt closure of circus schools, venues, and companies, introducing a myriad of novel stressors. Performers and students must now attempt to maintain their technical, physical, artistic, creative, and cognitive abilities without in-person support from their coaches and must manage the isolation from their training and performing spaces. For circus artists, the transposition of the work space to a home environment is not possible, which creates novel stressors that could lead to the exacerbation and escalation of mental health issues. The purpose of this study is to develop, implement and evaluate a holistic interventional program based on the socio-ecological model of resilience and operationalized through physical literacy. This will be a prospective longitudinal study with a retrospective comparison to data from a similar student cohort pre-pandemic. Interventions were designed using a population-specific, participant-based developmental model within a knowledge translation framework. The interventional program includes group webinars, small group information sessions, and one-on-one Zoom meetings, in addition to the distribution of electronic educational materials. The interventions will holistically provide psychological, physical, social, technical, artistic, and creative supports. Resources will be deployed throughout the closure period and through recovery, as transitions to return to training after prolonged hiatus will magnify known psychological and physical difficulties. Repeated, longitudinal assessment of students will be utilized to track changes over time at key transitions in the pandemic and school year and will be compared to a pre-pandemic school year. The framework for this program will be translatable to other performing arts and high-performance contexts. The program has implications for the mental health and overall wellbeing of artists and for cultural and economic recovery of the industry.

**Keywords:** circus arts, human performance, psychological distress, resilience, physical literacy

## INTRODUCTION

In March 2020, performing arts training facilities, schools and professional companies in Canada were mandated to close in response to the COVID-19 outbreak. Thousands of performing artists were laid off and left uncertain about their future employment. Without proper instruction and facilities for the maintenance and development of their craft in artistic, psychological and physical

terms, they risk being under-prepared to re-join the workforce when their industry re-opens. Failure to make allowances for realistic return could result in artists and technical staff seeking alternative employment pathways. While other sectors of the entertainment industry, including professional sports, are working to return to modified seasons, the performing arts industry remains largely shut down, unlikely to reopen in a conventional manner in the near future.

Mental health issues are expected to increase in the general population with the experience of the pandemic (Torales et al., 2020). For instance, increased uncertainty about the future caused by the COVID-19 outbreak has been shown to result in cognitive dissonance, negative emotions, and lower life satisfaction leading to feelings of mental discomfort (Li et al., 2020). It is important to examine the biopsychosocial impacts of the pandemic (Castelnuovo et al., 2020), which could be amplified in performing artists who face additional challenges due to their unique work and training context. Performing artists strongly rely on their bodies to express their art which becomes intimately linked, or embodied, with cognition and emotion, and vice versa (Rokotnitz, 2018). Not only is cognition embodied in performing artists, it can also be considered as embedded and extended, especially in circus artists (Bessone, 2017; Malinin, 2019) who frequently play, interact, and connect deeply with the environment (e.g., props, apparatus, and audience). When performing, some even consider their apparatus as an extended part of their cognitive system (Sevdalis and Wöllner, 2016). As such, these physical artists could be uniquely vulnerable to psychological challenges associated with the COVID-19 outbreak through the forced separation of material, social, and mental spaces, in addition to general psychological distress related to the pandemic and unemployment.

Additionally, prior to the pandemic, when compared to age- and sex-matched peers, a similar percentage of circus students were classified as having severe psychological distress (9 versus 10–13.6% normative), yet a substantially higher percentage were classified in the moderate distress category (42 versus 24–31% normative; Decker, 2020). Given the high proportion of circus students in the moderate category, the added stressors of the pandemic have the potential to shift them into the severe category, thus increasing their risk of mental distress. Furthermore, it was shown that circus students were less well adapted in their mental, social, and physical health than professionals circus artists (Donohue et al., 2018). Therefore, interventions aimed at maintaining circus skills while also maintaining mental health are important for this population.

## Psychological and Holistic Health of Circus Artists

Little is known about how the psychological experiences of circus artists compared to other performance domains such as sport. Yet, findings of a qualitative investigation revealed that mental skills such as confidence, concentration, energy management, and emotional management are crucial to support artist development (Ross and Shapiro, 2017). Since circus arts exemplifies a truly embodied cognition context, a holistic

approach is required to simultaneously address cognitive, affective and performance demands (Rokotnitz, 2018). There is currently no research examining holistic health interventions in circus students and limited evidence in performance artists in general; however, leaders in the field argue that integrating interventions supporting coping, resilience, and creativity as part of the circus school curriculum is key to optimize artists' wellbeing (Ménard and Hallé, 2014; Filho et al., 2016; Burt and Lavers, 2017).

## Resilience

Because the pandemic situation presents multiple adversities for the performing arts community, a holistic health intervention using a resilience approach has the potential for positive impact in this population. Resilience is a multidimensional construct influenced by the intertwined relationship between the body and the mind (Jefferies et al., 2019). "In the context of exposure to significant adversity, resilience is both the capacity of individuals to navigate their way to the psychological, social, cultural, and physical resources that sustain their wellbeing, and their capacity individually and collectively to negotiate for these resources to be provided and experienced in culturally meaningful ways" (Ungar, 2008, p. 225). It involves nurturing internal resources such as self-efficacy and self-compassion (Ledesma, 2014; Masten, 2015). According to the socio-ecological model of resilience (Ungar et al., 2013), environments that provide resources to develop or maintain optimal psychological, social, and physical wellbeing facilitate the capacity of individuals to withstand, overcome, and adapt to adversity. Specifically, resilience-promoting interventions should consider the principles of *equifinality* (i.e., different interventions may produce conditions for individuals' potential to be optimized), *differential impact* (i.e., interventions exert a different impact across individuals, time, and context) and *contextual and cultural moderation* (i.e., protective interventions are culturally and contextually grounded) (Ungar et al., 2013). According to these principles: (1) an intervention with multiple modalities is important as resilience could be influenced by various pathways, including biological, social, and environmental (Cicchetti and Blender, 2006); (2) environmental factors, including family, and community should be taken into account as they will influence the impact of the intervention on individuals (Sanders et al., 2017); and (3) the intervention needs to be appropriate to the individuals' culture and context (Sanders et al., 2017). Importantly, addressing both internal and external resources ensures a community-based approach so the individual is not left to manage on their own (Jefferies, 2020). Interventions based on the socio-ecological model of resilience have shown positive impacts on both optimal growth and development in school and home settings (Twum-Antwi et al., 2020). This will be the first project using a resilience approach based on this model in a performing arts context. The resilience model needs to be operationalized in a manner that works in the circus context.

## Physical Literacy

Physical literacy offers a unique holistic approach and process (Jefferies et al., 2019) which includes crucial psychological

components that are essential for maintaining and restoring competencies and capacities (Cairney et al., 2019). It also provides a putative pathway to overall wellbeing in the performance arts contexts (Cairney et al., 2019). The physical literacy process has been identified where movement competence, confidence, motivation and social participation are linked in a positive feedback cycle (Cairney et al., 2019; Jefferies et al., 2019; **Figure 1**). Self-determination theory can be integrated to bolster the process for self-motivation in a social context (Deci and Ryan, 2012). Additionally, this core cycle does, at least partially, address the embodied nature of performance arts (Whitehead, 2013). Importantly, strong linkages between resilience and physical literacy have been demonstrated (Jefferies et al., 2019), and recent work has demonstrated that the construction of positive challenges in the training context of circus arts pupils may be the critical element for improving resilience (Jefferies et al., 2019; Jefferies, 2020). Furthermore, circus arts have shown simultaneous positive enhancement of physical, social and psychological attributes in youth (Kriellaars et al., 2019). Enhancing the understanding of physical literacy by all the actors [artists, coaches, health care professionals, artistic staff, safety staff (riggers), etc.] involved in the circus training context may be one key element of a holistic approach to foster protective environments for artists. Further, this common resilience and physical literacy framework would serve to form a collective approach to the development and care of artists, rather than the traditionally siloed models, and may facilitate a higher level of authentic exposure and trust between artist and all staff when under pandemic duress.

## The Current Study

The impact of the COVID-19 pandemic on the performing arts industry provides a unique opportunity to examine the effects of an intervention grounded in resilience and physical literacy on the holistic health of circus students. This study may provide a foundation for translating this intervention framework to other

performance and movement contexts where it can holistically address physical, psychological, social, and creative needs and emphasize resilience and overall wellbeing.

## METHODS AND ANALYSIS

### Design

A prospective longitudinal design with retrospective comparison to temporally matched data from a pre-pandemic school year, since previous research showed differences between circus students and the general population, as well as the existence of temporal variation in psychological characteristics within the school training year (Decker, 2020).

### Setting and Participants

The study will be conducted at an elite-level circus training school in Montreal, Canada. The school provides high school and three-year college level programs to prepare students for a professional career in circus arts. A more detailed description of the program of study can be found in Decker et al. (2019). Since the intervention will be implemented within the school curriculum, the entire cohort of college students will be included in the intervention and will be offered the opportunity to participate in the evaluation (nominally over 110 students for the college program, age range from 16 to 27, Male:Female ratio 1.5:1).

### Intervention

The intervention will be deployed for one full calendar year, aligning with the end of the upcoming school year (April 2020–April 2021). In accordance with the multisystemic model of resilience and physical literacy principles, our previously developed Circus for Development Model (CfD – see **Figure 2** left) will be used to guide the development of the intervention. Informed by empirical work and applied intervention done within the circus context (e.g., Ménard and Hallé, 2014; Burt and Lavers, 2017), CfD presents a continuum of competencies to be developed through and for circus artists' optimal growth from novice to expert. Namely, it integrates four key attributes that have been shown to contribute to artists' performance and wellbeing, including *physical attributes* (Decker et al., 2019; Kriellaars et al., 2019; Barker et al., 2020), *psychological attributes* (Shrier and Hallé, 2011; Filho et al., 2016; Ross and Shapiro, 2017; Donohue et al., 2018; van Rens and Filho, 2019), *interpersonal and social attributes* (Filho et al., 2017; Filho and Rettig, 2018), and *creative attributes* (Leroux and Batson, 2016). These four attributes will inform the learning domains of the intervention delivered to students to ensure that their holistic development and wellness are addressed.

The CfD is connected to our internal knowledge translation framework, the Actionable Dashboard framework, which adapts Graham et al. (2006) Knowledge to Action framework to the performing arts context (**Figure 2** – right). This combination creates a framework foundation for our COVID-19 intervention that necessarily includes stakeholders in continued communication with researchers to ensure the environment continues to support needs as the intervention is adapted to react

to the progression of the pandemic. The program will evolve with the pandemic, be culturally grounded in circus reality, and continuously adapted to specific student needs. It will also provide specific support to key stakeholders responsible for the students' development. Importantly, students will have access to resources including coaching (technical and artistic), safety (rigging and cleaning), healthcare (athletic therapists, medical doctor, social worker, and mental performance consultant), and educational staff, and will be supported to navigate to the resources in a timely manner.

The intervention will be delivered in phases aligning with the school year and pandemic restrictions. From April to June 2020, reactive online classes and programs were put in place to rapidly respond to the sudden temporary closure of the school and cessation of in-person training and courses. From July to August 2020 online support for students to maintain their wellbeing during the summer break will be provided. From September 2020 to April 2021 online support will be provided to students to supplement their in-facility training time, which will be significantly reduced to abide by jurisdictional limitations imposed due to the pandemic. In accordance with the contextual limitations, the program will use various delivery methods, such as (1) formalized regular communication to provide relevant information, (2) weekly interactive webinars on pre-determined

specific topics, (3) weekly "open office hours" offered by specific staff, (4) online delivery of physical preparation programs, (5) one-on-one meetings for individualized support as required, and (6) identification and communication of community-based resources.

The content and topics addressed by the various facets of the program will be designed around the CfD model and will be tailored to address the needs identified by the repeated assessments. Both internal and external resources will be addressed. It is expected that the topics will include:

- 1) Psychological
  - Emotional regulation, uncertainty management, motivation, resiliency, and dealing with catastrophic thoughts, and substance use.
- 2) Physical
  - Physical maintenance, sleep, body composition, nutrition, injury prevention, artistic, and technical training.
- 3) Social
  - Relationship management, meaningful connections while maintaining physical distance.

#### 4) Creativity

- Internet-based methods of creative expression, creativity fueling, character development, acting, and entrepreneurship.

### Procedures

In a previous series of studies, a battery of health and wellbeing assessments were administered to a similar cohort of circus students at strategic timepoints within the school year: September (commencement of semester one and upon return from summer break), December (conclusion of semester one and immediately prior to technical and academic exams), January (commencement of semester two and upon return from winter break), and April (conclusion of semester two and immediately prior to summative technical and academic exams). For the COVID interventional project, students will be assessed at key milestones during the COVID pandemic, as well as time points consistent with prior measurement to allow for temporally matched comparisons to the pre-COVID status (Table 1). With the ever-changing restrictions due to the pandemic, it is challenging to predict the exact milestones that may occur during the upcoming school year and the full impact it will have on students at all levels. It is likely that all students will have a modified training year with significantly fewer 1-on-1 training hours, and the assessment schedule allows both comparison with previous years, and to assess how well students are adjusting to the changed environment.

**TABLE 1 |** Rationale for post-COVID data collection points.

Time	Potential COVID-related challenges
May 2020 Post-COVID outbreak, during school closure	<ul style="list-style-type: none"> <li>• School closure</li> <li>• No access to training facilities</li> </ul>
July 2020 Post-COVID outbreak, end of school year	<ul style="list-style-type: none"> <li>• Completion of spring semester (optional for some)</li> <li>• First session of online training;</li> <li>• Potential for some minimal re-opening of facilities.</li> </ul>
Sept 2020 Beginning of fall semester	<ul style="list-style-type: none"> <li>• Potential for return to training</li> <li>• Extended deconditioning</li> <li>• Travel restrictions for international students.</li> </ul>
Dec 2020 End of fall semester	<ul style="list-style-type: none"> <li>• Potential plan to travel home with travel restrictions</li> <li>• Technical assessments following first 'COVID-modified' semester</li> <li>• Potential effects of second closure with second wave of outbreak</li> </ul>
Jan 2021 Return from winter break	<ul style="list-style-type: none"> <li>• Potential for travel issues with mandatory quarantine for international students</li> <li>• Possible deconditioning from 3-week winter break</li> </ul>
April 2021 Summative assessment for college students	<ul style="list-style-type: none"> <li>• Completion of a full school year with COVID-related modifications.</li> </ul>

### Measures

All measures will be distributed to participants via a single online questionnaire according to the schedule in Table 1. Measures were selected to align with the four domains of the CfD model (psychological, physical, social, and creative).

#### Circus Daily Challenges Questionnaire

Information regarding the daily challenges (hassles) of the students will be attained via the Circus Daily Challenges Questionnaire (CDCQ), adapted from the validated College Student-Athletes' Life Stress Scale (CSALSS; Lu et al., 2012). The questionnaire scores each of sixteen daily challenges relevant to a developing circus artist context based on the level (intensity) of the challenge and the self-perceived difficulty to manage the challenge. The level score ranges from 0 (none) to 3 (high) and the management score ranges from 0 (no difficulty) to 2 (high difficulty).

#### Perceived Coping

The students' evaluation of their physical and mental capacity to manage stress will be measured using a scale ranging from 1 (very poor ability) to 7 (very good ability) combined with an assessment of their perceived access to coping resources inside and outside of the school (0 = not really to 4 = very good). The four scores were summed to derive a total perceived coping score (0 – 18). The questions related to perceived coping were included as a section within the CDCQ.

#### State Anxiety

State anxiety will be assessed using a single-item (0 = no anxiety to 4 = high anxiety), based on the work of Davey et al. (2007).

#### Habits and Behaviors

A five-point scale (improved a lot, improved, not changed, slightly worse, and substantially worse) was used to assess self-reported changes in eating, technical training, physical preparation, artistic development, fitness, sleep, physical activity level, mental health, alcohol, and marijuana use in the current circumstance (measurement period) relative to the pre-COVID state.

#### Non-specific Psychological Distress

The six item Kessler Psychological Distress Scale (K6; Kessler et al., 2002) will be used to screen for moderate to severe non-specific psychological distress. K6 scores between 8 and 12 indicate moderate psychological distress, while scores equal to or greater than 13 indicate severe psychological distress.

#### Sleep and Fatigue

Sleep and fatigue metrics will be assessed using a modified version of the validated Consensus Sleep Diary (Carney et al., 2012). Sleep duration is derived from the recorded times for falling asleep and waking. Sleep quality, sleep latency, wakefulness (feeling refreshed upon waking), and fatigue will be assessed using ten-point numerical rating scales, whereby a score of one indicates a desirable score and 10 indicates an undesirable score. Students were also asked to record their daily napping behavior via a simple yes/no question each day.

## Creativity

Two creativity assessment tools were developed to assess artists “creative state and challenges related to the pandemic situation. According to the five A’s framework ‘creativity is concerned with the action of an actor or group of actors, in its constant interaction with multiple audiences and the affordances of the material world, leading to the generation of new and useful artifacts’ (Glăveanu, 2013, p. 76).” Building on the 5A model of creativity, both tools investigate *actors* (i.e., motivation, mindset, perception, and identity), *actions* (i.e., imagination, ideation, and exploration), *affordances* (i.e., constraints, available material, and use of the body), *audiences* (i.e., support and communication), and *artifacts* (creative outcomes). The first tool uses a five-point agreement scale from 1 (strongly disagree) to 5 (strongly agree) while the second tool, inspired by the Creative Activity Checklist (Runco and Jaeger, 2011), uses a frequency scale from 1 (never) to 5 (always).

## Data Collection and Analysis

All data will be collected electronically through the surveys and exported to Microsoft Excel, then imported to SPSS and Jamovi for statistical analysis. Between-group analysis will be used to examine differences between sexes and pre- and post-COVID (Mann-Whitney test), differences between disciplines (Kruskal Wallis), and differences between years in training program (Kruskal Wallis). Within-group analysis (Friedman test with Durbin-Conover pairwise comparison) will be used to assess variation in measures over time. Spearman correlation will be used to examine the relationships between key variables at specific times.

## Data Interpretation and Knowledge Articulation

All data will be analyzed upon receipt and presented to the school’s wellbeing committee. Following the actionable dashboard, differences between the pre- and post-COVID outbreak data will be interpreted carefully to allow for an accurate identification of consequences specifically caused by the pandemic. The assumption of consequences of such an unprecedented situation, without direct assessment of the students’ states, could misguide interventions and lower impacts. The proposed approach will, thus, generate contextualized knowledge to guide the school’s time and energy allocation to the most pressing matters to provide appropriate support as a means to optimize students’ wellbeing.

Based on the socio-ecological model of resilience, it is imperative to use data to identify resources that could be tailored to the individual (from assessments) and provide means to navigate to and negotiate for the resources that have been created (Marttila et al., 2012). One often neglected, yet important aspect for resource allocation in crisis settings is the issue of trust. Positive functioning in compromised settings requires the development of trust (Marttila et al., 2012); specific to the school’s context, trust between staff and students. The key findings will, thus, shape ongoing knowledge dissemination and presentations among these

two groups to instill a community that values transparent communication, which is essential to build a trusting rapport. Furthermore, knowledge will be articulated to promote clear understanding of the reasons behind each intervention to enhance engagement.

The school has established strong partnerships over time with other performing arts schools and professional organizations. These partnerships will create a knowledge conduit, providing a multi-directional process for sharing and tailoring knowledge to the context. As knowledge is created from this applied research project, a collaborative approach will be established with partners to adapt it to local contexts, to identify barriers, to tailor the interventions to align with their artists’ needs, and, where possible, share resources and platforms to augment the collective ability. Such an approach will result in an augmented learning experience for performing arts stakeholders, allowing for more evidence-based and culturally grounded intervention programs.

The dissemination of the results will enrich the body of literature that is emerging since the COVID outbreak by highlighting the specific impacts of this unprecedented situation on the performing arts community. The comparison with longitudinal baseline data collected from a previous student cohort is a strength of the current program. It will enable the analysis to go beyond a mere description of the students’ holistic states by pinpointing specific issues that are derived from the pandemic situation. Findings will also give valuable insight and provide guidelines to partners and the performing arts community at large for establishing meaningful programs to sustain and improve artists holistic wellbeing facing massive changes in the industry. The program has the potential to significantly improve the mental and physical wellbeing of students and provides a leading-edge approach to handling pandemic circumstances. The resources invested to support the artists through this crisis will facilitate a safe, efficient transition back to training and performing, enhance holistic wellbeing, and will also facilitate the recovery of the performing arts industry, which has important implications for the economy and culture.

## Ethics and Regulatory Approval

Baseline data collection was approved by the relevant academic research ethics boards. Ethics approval for the use of the new data generated by program evaluation will be sought.

## Limitations

Analysis of the survey data may necessitate revisions and/or additions to the intervention frameworks, as these models and their use in pandemic context are not validated, but have ecological validity. Additional psychological constructs may need to be considered to align with new iterations of the framework. Furthermore, the implementation of interventions will be secondary to providing training and academic instruction related to the professional degree. Finally, there may be very different circumstances due to travel restriction for international students.

## DISCUSSION

This applied research study will examine the effects of a holistic, resilience-promoting program based on the CfD model founded in physical literacy on the wellbeing of circus students over the course of a school year affected by COVID-19 restrictions compared to a typical school year. The goal of the intervention is to help the community thrive through the remainder of and following the pandemic. This study will provide valuable information about the mechanisms used by students to respond and rebound from adversity and will increase collective knowledge about successful interventions to enhance students' wellbeing in a physically restricted context. Hence, the results of the current investigation could guide future intervention on how equifinality, differential impact, and contextual and cultural moderation can be addressed within a circus community to shape an environment promoting holistic wellbeing. Furthermore, combining this socioecological approach to resilience with the CfD framework to design interventions supporting artists in a time of intense adversity raises promising research and applied opportunities. Findings will provide empirical ground for the CfD framework while better defining interventions that are effective to sustain physical, psychological, social and creative competencies through adversity as exemplified next. Importantly, while the CfD model was developed specifically

in circus arts, its foundation in physical literacy makes it applicable to many contexts where people engage in learning and development through movement. Our comprehensive model could have implications for human development and performance optimization in all performing arts, sport and athletics, military, rehabilitation, and health and wellbeing in the general population.

## ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. Written informed consent from the participants' legal guardian/next of kin was not required to participate in this study in accordance with the national legislation and the institutional requirements.

## AUTHOR CONTRIBUTIONS

MS and VR drafted the manuscript and which was critically reviewed with significant input from all authors. All authors contributed significantly to the design of the project, analysis plan, and authorize the submission of this manuscript and accept responsibility for the publication.

# Epidemic Risk Perception, Perceived Stress, and Mental Health During COVID-19 Pandemic: A Moderated Mediating Model

Xiaobao Li<sup>1,2,3</sup> and Houchao Lyu<sup>1,2,3\*</sup>

<sup>1</sup> Faculty of Psychology, Southwest University, Chongqing, China, <sup>2</sup> Time Psychology Research Center, Southwest University, Chongqing, China, <sup>3</sup> China Community Psychology Service and Research Center, Southwest University, Chongqing, China

The aim of the present study was to investigate relationships among epidemic risk perception, perceived stress, mental health (depression and anxiety), future time perspective, and confidence in society during the novel coronavirus disease (COVID-19) pandemic in China. Especially, we wonder that whether perceived stress mediates associations between epidemic risk perception and mental health and that whether future time perspective and confidence in society moderate the link between perceived stress and mental health. This cross-sectional study was conducted among 693 Chinese adults aged 18–60 years. The results showed that epidemic risk perception was positively related to perceived stress, depression, and anxiety. The correlations between epidemic risk perception and depression and anxiety were reduced when perceived stress was included, suggesting that perceived stress mediated these relationships. Moreover, the boundary conditions for the associations among perceived stress, depression, and anxiety were found in the study. Specifically, positive future time perspective could buffer the negative effects of perceived stress on depression, and confidence in society could weaken the negative effects of perceived stress on anxiety. Based on these findings, practical guidance and theoretical implications are provided for the public to maintain mental health during COVID-19 pandemic. Limitations and future directions are also discussed.

**Keywords:** future time perspective, confidence in society, coronavirus disease, epidemic risk perception, perceived stress, anxiety, depression

## INTRODUCTION

The novel coronavirus disease (COVID-19) pandemic has spread across the globe. Owing to its rapid and extensive transmission, high infectivity, and lack of specific treatment so far, it has posed great threat to people's mental and physical health. Unexpected public crisis events can easily cause the public to develop psychological reactions such as tension, anxiety, and even panic, which may lead to psychological disorders such as stress disorder and depression (Zhao et al., 2009). Therefore, it is of great practical significance and theoretical implications to study the impact of unexpected public crisis events on public mental health, and how to help individuals cope better with the crisis to maintain mental health.

Perceiving and avoiding risks are natural instincts of living beings. Risk perception is the core variable that induces psychological and behavioral responses among people in public crisis events, and exerts significant influences on both daily life decisions and behaviors (Slovic, 2000; Erdem and Swait, 2004; Li et al., 2009). Risk perception refers to an individual's subjective judgment of risk based on objective crisis events, including the uncertainty about threats and severity of consequences (Cho and Lee, 2006). Perceived risk puts people in a distressed and anxious state, which in turn motivates them to engage in problem-solving activities to resolve it (Cho and Lee, 2006). People are likely to employ information search as a problem-solving strategy to reduce perceived risk, and they may also pay attention to existing problems and take precautions in advance to avoid more serious consequences (Shi et al., 2003; Li et al., 2009). However, if an individual stays in a highly threatening environment over a long period of time, certain physical and psychological problems tend to arise (Peters and McEwen, 2015; Nie et al., 2018). A study has revealed that people with a higher risk perception of the severe acute respiratory syndrome (SARS) epidemic are more likely to panic and respond unfavorably (Shi et al., 2003). A previous study on the Wenchuan Earthquake has shown that having a risk perception for unexpected natural disasters is negatively associated with public mental health (Li et al., 2009). Taking these together, we posit Hypothesis 1: Epidemic risk perception is positively related to depression (H1a) and anxiety (H1b).

The core of risk perception is the threat posed by uncertainties about the environment (Cho and Lee, 2006). In the context of an epidemic, people face huge uncertainties with respect to the life, work, economic prospects, and international relations. In such situations, the immediate feeling of the public is psychological stress. Perceived stress is the psychological response to threatening stimuli in the environment after cognitive evaluation and can be manifested as physical and mental tension, as well as loss of control (Cohen et al., 1983). The stress mainly stems from the sense of threat and expectation of adverse results in the future (Peters and McEwen, 2015; Peters et al., 2017). Individuals predict future results through comprehensive judgments of risk information in the present environment. If this prediction is filled with uncertainties, or if the expected results pose serious harm, stress will ensue, and even blood pressure may rise (Greco, 2003). Therefore, the higher the level of risk perception, the greater the psychological stress people will develop (Webster et al., 1988). This leads to the question that if risk perception causes stress, how does stress exert its impact on mental and physical health? Stress is one of the leading causes of mental and physical health problems (Gayman et al., 2011; Peters and McEwen, 2015). Research has shown that the body is likely to produce negative responses to cope with stress in a threatening environment (Gayman et al., 2011; Peters and McEwen, 2015), and increased stress is associated with many physical diseases (McEwen, 1998; Peters and McEwen, 2015) and mental health disorders, such as anxiety and depression (Olson and Surrence, 2004; Bardeen et al., 2013; Liu et al., 2015). Although researchers have investigated the relationship among risk perception, perceived stress, and mental health, few studies have been explored how risk perception affects mental health

through the mediation of perceived stress. The risk perception of COVID-19 outbreak may lead to an increase in people's perceived stress. On the one hand, people's perception of uncertainty about the threat of being infected has caused them to maintain a stressful state. On the other hand, since the outbreak, a series of prevention and control measures such as lockdown of cities, road closures, work stoppages, and production shutdowns have exerted a huge impact on the daily life of the public. With the increased duration of preventive measures and lockdown, the circumstances of businesses being unable to resume work, sharp declines in individual incomes, fear of being infected, and inability to repay car loans and mortgages, etc., have imposed great psychological stress on people. In such a stressful environment, people become prone to allostatic overload, which could lead to negative psychological symptoms (Pedrelli et al., 2008). To sum up, we propose H2: Perceived stress mediates the link between epidemic risk perception and both depression (H2a) and anxiety (H2b).

The psychological resilience theory (Luthar et al., 2015) holds that individuals can successfully cope with stress and maintain mental health even in the face of adversity, because internal and external protective factors can alleviate the negative effects of stress on individuals. A research on which factors can help people cope with stress and respond with active adaptation for them to maintain mental health in times of crises carries great significance. Studies have pointed out that beliefs play an important role in human behaviors and mental health (Bandura, 1997; Luszczynska et al., 2009). People's beliefs in the face of uncertainties moderate the intensity of stress responses (de Berker et al., 2016). The better one adjusts one's beliefs in the face of uncertainties, the better the future results can be predicted, which in turn eases the stress response. With respect to protective factors within individuals, their beliefs and confidence in society constitute mental resources with which they respond effectively to environmental threats and uncertainties, and a high level of trust can reduce uncertainties and buffer the negative impact of environmental stress (Keller et al., 2011).

As a kind of important belief in the future, future time perspective (FTP) refers to an individual's thought, feeling, and action tendencies toward the future (Lyu, 2014; Lyu and Huang, 2016). Individuals with a high level of FTP have three main characteristics: focusing on the future, being optimistic and cherishing hope, and valuing goals (Chin and Holden, 2013). Active attention to the future helps improve individuals' life satisfaction (Pallini et al., 2016). When anticipating the future, an individual either looks forward to the future with optimism and bears confidence and hope for realizing future goals, or considers the future to be threatening (Ringle and Savickas, 1983). People with positive future orientation maintains an optimistic and hopeful attitude toward expectations of future results (Chin and Holden, 2013; Pallini et al., 2016), which can buffer the impact of environmental stress on negative emotions (Denovan and Macaskill, 2013) and reduce the tendency of depression (Hirsch et al., 2011). Individuals who value their future goals are able to predict the future values of their current behaviors, which stimulates their current adaptive behaviors (Chin and Holden, 2013). In the face of stressful situations, individuals with positive

future orientation have strong adaptability, such as finding a job or shelter more quickly when they are homeless (Epel et al., 1999). Research on people's mental health after the September 11 attacks have found that FTP is associated with higher levels of positive emotions (Holman, 2015; Holman et al., 2016) and reduced psychological stress 2 years post-9/11. In short, individuals with a positive attitude toward the future are able to maintain optimism and hope for the future, as well as focus on constructive behaviors that add to their future benefits. On the contrary, individuals with a negative attitude toward the future feel confused and pessimistic, which may easily lead to worry and anxiety about the future (Shipp et al., 2009). In summary, in this study, FTP is regarded as an important psychological resource that can buffer the adverse effects of perceived stress on mental health. Thus, H3 is proposed: Positive future time perspective negatively moderates the effect of perceived stress on both depression (H3a) and anxiety (H3b), while negative future time perspective positively moderates the effect of perceived stress on both depression (H3c) and anxiety (H3d).

Confidence in society refers to the positive expectation that society, based on its past performance, has its future under control (Keller et al., 2011). From a sociological perspective, confidence in society is a core component of social capital (Cook, 2005). If the members of a society have confidence in the ability of the social system to deal with future problems and risks, then social capital will increase. High levels of confidence in society make individuals feel calm and safe and show more cooperative behavior when responding to threats (Earle et al., 2007), so as to ensure the continuous operation of society (La Porta et al., 1997). From a psychological perspective, confidence in society is assumed to act as a psychological buffer against the influence of environmental stress and uncertainties evoked by societal transformation (Keller et al., 2011). Research has shown that confidence in society is negatively correlated with trait anxiety and neuroticism, and positively correlated with self-esteem, self-efficacy, and life satisfaction (Keller et al., 2011). Individuals lacking confidence in society do not believe that society can cope with crises and maintain control and stability, and they are likely to experience greater tension and anxiety. Thus, this study considers confidence in society as a psychological buffer against the effect of perceived stress and mental health. In a situation of lack of sufficient information to reduce fear of the unknown, high levels of confidence in society can effectively reduce anxiety and depression, thus buffering the negative effects of perceived stress on mental health. Although dealing with uncertainties brought by changes in the environment is essential to individuals' life and mental health, little research has been conducted in this area so far. Therefore, we posit that H4: Confidence in society negatively moderates the effect of perceived stress on both depression (H4a) and anxiety (H4b).

In summary, the aim of the research is to investigate the mediating effect of perceived stress on the relationship between epidemic risk perception and mental health (anxiety and depression), and examine the moderating effect of FTP and confidence in society on the relationship between perceived stress and mental health. The validation of the protective effect

of FTP and confidence in society may help to support the public in maintaining their mental health and carrying out psychological prevention and intervention during an epidemic from the perspective of positive psychology.

## MATERIALS AND METHODS

### Participants and Procedure

During the outbreak of novel coronavirus disease (COVID-19) in China, we recruited participants via wjx.cn, a reliable Chinese online platform for data collection and randomly distributed questionnaire links in the participant pool. The data collection began on February 6, 2020. A week later, 701 participants answered the questionnaires. All participants consented to attend the study after being informed about the purpose of the study. After excluding cases with invalid responses (e.g., too-short answering time or same answers for each item), we retained a final sample of 693 participants. Participants were given a packet of questionnaires that included questions regarding demographics, epidemic risk perception, perceived stress, anxiety, depression, future time perspective, and confidence in society. No direct compensation was provided for study participation.

The samples of the present study were mainly from Henan Province (32.6%), Shandong Province (28.6%), and Chongqing city (29.9%), accounting for 91% of the total samples. Only 17 participants were from Wuhan, Hubei Province, and the remaining 45 participants were scattered in other Chinese cities. The sample consisted of 619 general public, 17 quarantined personnel, 29 frontline medical workers, and 12 community service workers. Among all participants, 62.0% were females and 38.0% were males. Moreover, 29.9% were between 18 and 25 years old, 18% were between 26 and 30 years old, 22.7% were between 31 and 40 years old, 21.2% were between 41 and 50 years old, and 8.2% were between 51 and 60 years old. Also, 82.4% of participants received at least a college degree.

### Measures

#### Epidemic Risk Perception

One single item was used to measure epidemic risk perception. Participants were asked to evaluate the perceived risk of infection during the outbreak of COVID-19. Ratings were given on a 10-point Likert scale (1 = not at all threatening, 10 = extremely threatening). In this study, the average score of epidemic risk perception of all participants was 6.03 ( $SD = 2.26$ ).

#### Perceived Stress

The perceived stress scale-10 (PSS-10; Cohen et al., 1983) was used to measure the extent to which respondents feel that their stress is unpredictable, uncontrollable, and overwhelming. It comprises 10 items that allow five responses in a Likert scale: never (0), almost never (1), sometimes (2), often (3), and very often (4). Total scores range from 0 to 40, with higher scores indicating greater perceived stress. Cronbach's alpha with the current sample was 0.85.

## Mental Health

Anxiety and depression were used as indicators of mental health.

**Anxiety:** The generalized anxiety disorder-7 scale (GAD-7) was used to measure participants' worry and general somatic tension (Spitzer et al., 2006). It has seven items rated on a four-point Likert scale indicating symptom frequency, ranging from 0 (not at all) to 3 (nearly every day). Higher scores indicate higher levels of anxiety symptoms. In this study, Cronbach's alpha of the scale was 0.92.

**Depression:** The center for the epidemiological studies of depression-10 (CES-D-10; Andresen et al., 1994) was used to measure depression. This scale consists of 10 items to assess symptoms of depression (e.g., "I felt depressed"), and response anchors range from 0 (rarely) (less than 1 day) to 3 (most or all of the time) (5–7 days). Participants indicate how true each statement is to them over the past week. Cronbach's alpha for the present sample was 0.84.

## Future Time Perspective

Future time perspective was assessed by the future subscale of Time Attitude Scale (TAS, Worrell et al., 2013). The scale consists of 30 items on six subscales: past positive, past negative, present positive, present negative, future positive, and future negative, which has demonstrated adequate reliability, validity, and generally strong psychometric properties in adolescent and adult samples (Mello et al., 2016). In the present study, we mainly adopted the future dimension of TAS, with 10 items and 2 subscales (future positive and future negative). Participants were asked to answer the questions on a five-point scale from 1 (strongly disagree) to 5 (strongly agree). In the present sample, Cronbach's alphas of future positive and future negative were 0.85 and 0.73, respectively.

## Confidence in Society

Confidence in society was assessed by the general confidence scale developed by Keller et al. (2011). The scale has six items rated on a seven-point Likert scale (1 = totally disagree, 7 = totally agree). Higher scores indicate higher levels of confidence in society. In this study, Cronbach's alpha score of the scale was 0.89.

## Control Variables

We controlled for participants' gender (0 = female, 1 = male), age (1 = 18–25 years; 2 = 26–30 years; 3 = 31–40 years; 4 = 41–50 years; 5 = above 51 years), and education level (1 = vocational school, technical secondary school; 2 = high school; 3 = vocational/junior college; 4 = undergraduate; 5 = graduate) because these demographic variables have been reported to link to individuals' mental health (e.g., Cauce et al., 2000; Halpern-Manners et al., 2016).

## Data Analysis

Statistical analysis was performed using SPSS 22.0 and AMOS 21.0 software packages. The normal distribution of all variables was tested using the Kolmogorov–Smirnov test, and all continuous variables follow the normal distribution. The statistical methods included descriptive statistics, correlation analysis, regression analysis, structural equation model, and

bootstrap analysis, etc. The significance level of all variables was set as  $\alpha = 0.05$ .

## RESULTS

### Descriptive Statistics and Correlation Analyses

Descriptive statistics, including means, SDs, correlations, and reliabilities, are presented in **Table 1**. Epidemic risk perception, perceived stress, anxiety, and depression were found to be positively related to one another. Moreover, future negative was positively associated with anxiety and depression. Future positive and confidence in society were negatively linked with anxiety and depression.

### Associations Between Epidemic Risk Perception and Mental Health

In the current study, regression analysis was used to explore the association between epidemic risk perception and mental health. Hypotheses 1a and 1b posit that epidemic risk perception is positively related to depression (H1a) and anxiety (H1b). As shown in **Table 2**, after the effects of gender, age, and education level had been controlled, epidemic risk perception positively related to depression ( $\beta = 0.19$ ,  $SE = 0.04$ ,  $p < 0.01$ ) and anxiety ( $\beta = 0.28$ ,  $SE = 0.04$ ,  $p < 0.01$ ). Thus, Hypothesis 1a and 1b were supported.

### Examination of Moderated Mediation Model

More also, path analysis was conducted in Amos21.0 to test the mediating effect of perceived stress between epidemic risk perception and mental health, and the moderating effect of FTP and confidence in society on the relationship between perceived stress and mental health. Given that anxiety and depression were used as indicators of mental health, we developed two models with anxiety (Model 1) and depression (Model 2) as outcome variables, respectively. Both model 1 and model 2 had a reasonably good fit to the data [Model 1:  $\chi^2/df = 2.30$ , comparative fit index (CFI) = 0.98, Tucker–Lewis index (TLI) = 0.96, root mean square residual (RMR) = 0.04, root mean square error of approximation (RMSEA) = 0.04; Model 2:  $\chi^2/df = 2.29$ , CFI = 0.98, TLI = 0.96, RMR = 0.04, RMSEA = 0.04]. **Table 3** shows the results of path analysis of the hypothesized model.

Hypotheses 2a and 2b predict that the positive relationships between epidemic risk perception and depression/anxiety are mediated by perceived stress. As shown in **Table 3**, epidemic risk perception was found to be positively related to perceived stress ( $\beta_{Model\ 1} = 0.16$ ,  $SE = 0.03$ ,  $p < 0.001$ ;  $\beta_{Model\ 2} = 0.16$ ,  $SE = 0.03$ ,  $p < 0.001$ ), and perceived stress was positively related to depression ( $\beta = 0.62$ ,  $SE = 0.03$ ,  $p < 0.001$ , Model 1) and anxiety ( $\beta = 0.67$ ,  $SE = 0.04$ ,  $p < 0.001$ , Model 2). When perceived stress was included, epidemic risk perception positively related to anxiety ( $\beta = 0.15$ ,  $SE = 0.03$ ,  $p < 0.001$ , Model 2) but not related to depression ( $\beta = 0.04$ ,  $SE = 0.03$ ,  $p < 0.05$ ,

\**p* < 0.05, \*\**p* < 0.01.

Model 1). These results suggest that perceived stress partially mediates the link between epidemic risk perception and anxiety, and fully mediates the link between epidemic risk perception and depression. We further tested the two mediating effects using 5,000 bootstrapping samples. The analyses indicated a significant mediating effect between epidemic risk perception and depression through perceived stress [indirect effect = 0.10, *SE* = 0.02, 95% CI (0.06, 0.14), excluding zero]. The results also indicated a significant mediating effect between epidemic risk perception and anxiety through perceived stress [indirect effect = 0.10, *SE* = 0.02, 95% CI (0.07, 0.15), excluding zero]. Thus, Hypotheses 2a and 2b were supported.

Hypotheses 3a, 3b, 3c, and 3d propose the moderating effect of future positive/future negative on the relationship between perceived stress and depression/anxiety such that the relationships become weaker when future positive is high rather than low and when future negative is low rather than high. We centered all continuous variables before creating their product terms. The results from path analysis show that only the interaction term of future positive and perceived stress is negatively related to depression ( $\beta = 0.15$ , *SE* = 0.03, *p* < 0.001;

Confidence in society × perceived stress		–0.01 (0.03)		–0.11** (0.03)

*N* = 693.

Statistics reported are standardized regression coefficients (and SEs).

\**p* < 0.05, \*\**p* < 0.01.

Model 1). To further interpret the results, we conducted a simple slopes analysis. The interaction plot in **Figure 1** shows that with low future positive (1 SD below the mean), perceived stress is negatively related to depression (*simple slope* = 0.79, *SE* = 0.04, *p* < 0.001) and stronger, while with high future positive (1 SD above the mean), perceived stress is significantly related to

depression (*simple slope* = 0.55, *SE* = 0.03,  $p < 0.001$ ) and weaker. Thus, Hypothesis 3a was supported, but hypotheses 3b, 3c, and 3d were not supported.

Hypotheses 4a and 4b predict that the positive relationships between perceived stress and depression/anxiety are negatively moderated by confidence in society such that the relationships become weaker when confidence in society is high rather than low. The results from path analysis indicated that only the interaction term of confidence in society and perceived stress was negatively related to anxiety ( $\beta = 0.11$ , *SE* = 0.03,  $p < 0.05$ ; Model 2). The interaction plot in **Figure 2** indicates that with low confidence in society (1 SD below the mean), perceived stress was negatively related to anxiety (*simple slope* = 0.79, *SE* = 0.05,  $p < 0.001$ ) and stronger, while with high confidence in society (1 SD above the mean), perceived stress was significantly related to anxiety (*simple slope* = 0.51, *SE* = 0.04,  $p < 0.001$ ) and weaker. Thus, hypothesis 4a was not supported and hypothesis 4b was supported.

## DISCUSSION

This study investigated the mediating effect of perceived stress on the relationship between epidemic risk perception and mental health (anxiety and depression), and the moderating effects of FTP and confidence. The results revealed that epidemic risk perception has a significant positive effect on anxiety and depression, which is consistent with previous research results

on public crisis events and mental health (Shi et al., 2003; Li et al., 2009; Nie et al., 2018). The occurrence of public crisis events sharply increases individuals' perceived risks, and such an environment, filled with threats and uncertainties, can easily cause anxiety and depression (Zhao et al., 2009; Peters and McEwen, 2015). The risks during an epidemic also lead to a loss of the sense of control and a feeling of powerlessness, wherein the public can only passively await the development of the epidemic, and people may thus experience higher level of depression and anxiety.

More importantly, this study found that perceived stress exerts a partial mediating effect on the relationship between epidemic risk perception and anxiety, and a full mediating effect on the relationship between epidemic risk perception and depression. This difference may be caused by the different cognitive features of anxiety and depression. Given that the cognitive bias of depression is a combination of emotions and negative memories, people with excessive psychological stress tend to indulge in the negative emotions and unable to escape; therefore, perceived stress may fully mediate the association between epidemic risk perception and depression. However, the cognitive features of anxiety is characterized by excessive attention bias to specific negative stimuli, reflecting the activity of the fear system, thus there may have been other factors such as worries about the future that also could explain the link between epidemic risk perception and anxiety. The results of the present study demonstrate perceived stress is the main underlying mechanism that explains the effect of perceived risk on mental health. When people are exposed to negative life events, such as the COVID-19 pandemic, concerns about current terrible situations and future adverse consequences may lead to a lot of psychological stress, which in turn activate an individual's diathesis or vulnerability, transforming potential diathesis into a reality of psychopathology (Monroe and Simons, 1991). The relationships among stress, anxiety, and depression mainly lie in the subjective perception of pain and lack of ability to cope with stress (Hewitt et al., 1992). If stress could be effectively alleviated, negative emotions and mental symptoms will be avoided easily.

The current study found that FTP moderates the relationship between perceived stress and depression. Compared with individuals with negative future orientation, those with positive future orientation are relatively weaker in perceiving the impact of stress on depression. According to the diathesis-stress theory (Monroe and Simons, 1991), perception of future self and the world is the direct cause of depression. Individuals with a position future orientation can maintain optimism and hope for the future when an epidemic occurs (Chin and Holden, 2013; Pallini et al., 2016). Thus, they are likely to have more adaptable behaviors in stressful situations, which contribute to alleviate the effects of stress on depression. However, individuals with a negative future orientation hold a negative attitude toward the future. When facing stressful situations, they will be easily trapped in the pain of the past and present, further exacerbating their depression (Holman et al., 2016).

In this study, we found that confidence in society can moderate the relationship between perceived stress and anxiety. Individuals with high confidence in society can avoid excessive

**FIGURE 1** | Interactive effects of future positive and perceived stress on depression.

**FIGURE 2** | Interactive effects of confidence in society and perceived stress on anxiety.

anxiety under environmental threats and stress. According to Bandura (1997) and Luszczynska et al. (2009), beliefs (such as self-efficacy) play an important role in human behaviors and mental health, and confidence in society is similar to a sense of collective efficacy, which is an individual's positive belief in society's ability to deal with threats (Keller et al., 2011). The unexpected COVID-19 pandemic brought varied risks and dangers in people's lives, and has become a source of uncertainties and tension. In such a setting, individuals with high confidence in society have positive expectations for the future, and believe that the society is capable of coping with threats to achieve a sense of certainty and control, thereby avoiding tensions and maintaining calm. In contrast, individuals with low confidence in society are more emotionally vulnerable, and tend to be nervous and anxious when faced with an epidemic. It should be noted that confidence in society is not an irrational belief but a positive illusion that makes it easier for people to cope with difficult life situations (Bandura, 1998). Individuals with high confidence in society can fully recognize the causes of danger without overestimating risks, and thus are able to remain calm and are more likely to take effective preventive measures as necessary.

In sum, the present study supports that perceived stress mediates the link between epidemic risk perception and mental health, and that FTP and confidence in society are both important variables of psychological buffer with which individuals deal with stress from the epidemic and effectively reduce the adverse effects of perceived stress on mental health. These results help to better explain how and when epidemic risk perception leads to depression and anxiety and provide theoretical guidance and inspiration for studies on epidemic intervention. First, perceived stress is an important mechanism by which the risk perception of unexpected public crisis event affects mental health, and stress relief is an important means for reducing mental problems. It is well known that fear stems from uncertainties; therefore, helping people gain necessary epidemic knowledge about COVID-19, such as epidemic characteristics, prevention and control measures, etc., would transform uncertainties into understanding, thereby correcting the perception of threat events and false beliefs to better predict future results and cope with environmental threats (Peters et al., 2017). Previous studies have found that social skills are correlated with a decrease in stressful experiences, and that people with strong social skills gain more social supports when faced with stress (Segrin et al., 2007); therefore, they should communicate with family and friends over the phone or the Internet to encourage one another and strengthen mutual mental support to alleviate tension and psychological stress. Second, correct understanding of the impact of the epidemic and a positive belief in the future are effective ways to reduce depression. Crises are always accompanied by dangers as well as opportunities. Although the COVID-19 pandemic has caused huge losses, it has also reminded all sectors of society to pay attention to physical and mental health and the prevention and control of epidemics, which offers experiences of reference value for similar events in the future. Individuals should strengthen self-management and adjustment, adopt a dialectical approach to crises, and establish a correct and positive conception of the future to maintain mental health. Furthermore,

it is necessary to attach importance to the improvement and cultivation of confidence in society. The public's judgment on confidence in society is mainly based on the past performance of the society (Keller et al., 2011) as well as the positive role of the government and the media. When individuals feel a lack of control during an epidemic, the government and social organizations should provide sufficient guarantees and supports to allow them to feel that society is still functioning with order and certainty, thereby avoiding anxiety and panic. In addition, the media's coverage of crisis events is the main source from which people obtain epidemic-related information. Negative news reports often lead to negative emotional experiences among people. Therefore, the media should pay attention to positive and favorable news about responses to the crisis from all walks of life, and ensure objectivity and scientific nature of media information in guiding people to correctly understand the impact of epidemic crisis events, and cultivate optimism, positive emotions, and positive attitudes toward the future.

Despite its strengths, this study has some limitations. With a questionnaire survey targeting the nationwide public, only about 700 entries of data were collected in the study. As the sample size was relatively small, the distribution was uneven with respect to region (small sample from Hubei province), education level (bachelor's degree and above accounted for 82.3%), and personal status in the epidemic (few participants representing those in quarantine, frontline medical workers, and community service workers). Second, the study was not conducted in special regions and among special groups. Future research should pay more attention to people in quarantine, frontline medical workers, community service personnel, etc. For instance, more attention should be paid to the mental health of people in Wuhan, as the COVID-19 started in Wuhan and most of the infected cases in China were also found in Wuhan. Instead of self-isolation of other areas, people in Wuhan were forcibly quarantined to confirm whether they have become sick and minimize the risk of them passing on the infection to others. During the period of the quarantine, fear of infection with a fatal disease, the lack of information, frustration and boredom, lack of supplies, and not being able to go to work or earn an income could lead to problems in both mental and physical health (Brooks et al., 2020). People in Wuhan also suffer a lot of social stigma, which may lead to worse psychological problems than people in other regions. Third, only one item was used to measure overall risk perception in the present study. While it could be useful to use an item to measure overall risk perception, the current study did not distinguish the effects of different aspects of risk perception (uncertainty about threats and severity of consequences) on perceived stress and mental health. Future research could benefit from improving this tool. Finally, as cross-sectional design was used, this study did not track the mental health of people during the epidemic and had inadequate understanding of the public's emotional or mental changes during the period of epidemic outbreak. Therefore, causal relations among variables could not be confirmed, and future research should adopt longitudinal design and interventional experiments to provide better assistance for building mental health in times of crises.

## CONCLUSION

The present study demonstrated that risk perception of COVID-19 was significantly correlated with depression and anxiety. Perceived stress was established as a mediator of epidemic risk perception and depression/anxiety. Future time perspective was found to moderate the effect of perceived stress on depression and social confidence was found to moderate the effect of perceived stress on anxiety.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethics Committee of Faculty of

Psychology at Southwest University. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

HL and XL designed the study idea and research framework. XL contributed to the data collection, data analysis, and writing. HL contributed to manuscript writing and modification. Both authors read and approved the manuscript.

Since the outbreak of coronavirus disease 2019 (COVID-19) in China, people have been exposed to a flood of media news related to the pandemic every day. Studies have shown that media news about public crisis events have a significant impact on individuals' depression. However, how and when the duration of attention to pandemic news predicts depression still remains an open question. This study established a moderated mediating model to investigate the relationship between the duration of attention to pandemic news and depression, the mediating effect of risk perception, and the moderating effect of future time perspective on the relationship. In early February 2020, 701 individuals from 29 provinces, autonomous regions, and municipalities across China were asked to self-report their duration of attention to pandemic news, level of depression, risk perception, and future time perspective during the COVID-19 outbreak. Results show that there is a significant positive correlation between the duration of attention to news on COVID-19 and depression; risk perception mediates the association between the duration of attention to pandemic news and depression; and future time perspective plays a moderating role between risk perception and depression. The findings of the present study provide theoretical implications and practically throw some light on alleviating the public's depression during pandemic periods. We highlight that the individual's hope for a better future, focusing on positive news, and time perspective balance during an epidemic disease are also beneficial to promoting positive emotion and reducing depression.

**Keywords:** COVID-19, duration of attention to pandemic news, depression, risk perception, future time perspective

## INTRODUCTION

The pandemic of novel coronavirus disease (COVID-19) is raging across the globe and has become a worldwide public health crisis (Bao et al., 2020). Being confronted with major catastrophic events, the public not only suffers from threats to their lives and safety but also faces psychological impact and even psychological trauma. The occurrence of major disasters has a great adverse impact on people's mental health, leading to negative emotions such as tension, panic, and depression (Hobfoll et al., 2006; Lau et al., 2010). For example, a recent study by Wang et al. (2020), which included 1,210 participants from 194 cities in China during the initial stage of the COVID-19 outbreak, showed that 53.8% of the participants rated the psychological impact of the pandemic as moderate or severe. According to the study of Serafini et al. (2020), various psychological problems and serious consequences in terms of mental health including stress, anxiety, depression, frustration, and uncertainty emerged progressively during this pandemic. More importantly, the public displayed more vicarious traumatization than front-line medical staff (Li et al., 2020). Previous studies have shown that most public perceptions of public crisis events come from the media, which in turn affects public response to those events (Lau et al., 2010). Therefore, the effect of media news on the public's physical and mental health is an issue of particular concern.

As the pandemic was emerging, various news related to the pandemic also exploded. The WHO declared a COVID-19 "infodemic"—"an overabundance of information, some accurate and some not that makes it hard for people to find trustworthy sources and reliable guidance when they need it" (World Health Organization, 2020). Furthermore, cues that are vague, inadequate, unfamiliar, contradictory, numerous, or lacking information prompt uncertainty (Budner, 1962; Mishel, 1984). Therefore, when individuals are faced with a large amount of news about the pandemic, it is difficult for them to distinguish right from wrong and make a judgment. Accordingly, they may feel a sense of uncertainty. Uncertainty is a cognitive state that occurs when one cannot construct events well because certain diseases have many unknown factors (Mishel and Braden, 1988). Uncertain viral transmission may take part a crucial and underestimated role in sustaining the epidemic (Sarkar et al., 2020). Many studies directly linked uncertainty to depression (Mullins et al., 2000; Kang, 2006). Swallow and Kuiper (1992) showed that uncertainty is often associated with depression. When uncertainty was evaluated as a danger, it was generally associated with a pessimistic view of events and the future and resulted in harmful outcomes such as anxiety, depression, and distress (Mishel, 1988). People living in a volatile and insecure environment (e.g., an insecure job, unhappy relationship, poverty, etc.) have a high risk of depression (Mcewen, 1998; Peters and Mcewen, 2015). Therefore, the "infodemic" of pandemic news may bring uncertainty, thus leading to depression. We proposed that, during the pandemic, the more time individuals paid attention to news about the pandemic, the higher the level of depression they might feel. Hence, we predicted that:

H1: The duration of attention to pandemic news will be positively correlated with individuals' depression.

Media news also affect individuals' risk perception (Cooper and Nisbet, 2016; Paek et al., 2016). Research has shown that TV news on a series of public health issues (such as cancer, AIDS, heart disease, and smoking) are positively correlated with risk perception (Paek et al., 2016). The theory of social amplification of risk holds that the interaction of risk information through multiple propagation mechanisms and repeated feedback during the transmission process leads to signal amplification, which then enhances individuals' risk perception (Kasperson and Kasperson, 1996). The agenda-setting theory holds that the media can direct people's attention through the degree of emphasis placed on relevant issues, thereby conveying the key points in the communication of the public agenda. For example, if the media repeatedly communicates risk information related to drug usage, individuals might perceive that the issue has become more and more important. Furthermore, their perceptions of risk, sensitivity, and severity are directly related to the degree of media coverage of drug usage (Gelders et al., 2009). In summary, it could be inferred that during the pandemic of COVID-19, various real-time pandemic news reports and related information have been communicated frequently and repeatedly to the public through multiple transmission mechanisms, which caused the public's risk perception to rise dramatically. Accordingly, this study predicted:

H2: The duration of attention to pandemic news will be positively related to risk perception.

In addition, risk perception, as an important variable affecting mental health, refers to a subjective assessment of the likelihood of threat events (Slovic, 1987; Li et al., 2009). Brewer et al. (2007) proposed that risk perception includes three components: uncertainty (probability of being injured by danger), susceptibility (physical vulnerability in the face of danger), and severity (degree of harm caused by danger). Studies on the SARS epidemic and Wenchuan earthquake in China have shown that risk perception is not conducive to people's mental health (Shi et al., 2003; Li et al., 2009). COVID-19 has become a stressor for many people (Li et al., 2020). Lazarus and Folkman (1984) proposed that the consequences of environmental stressors on health depended on the assessment of threats (primary assessment) and the assessment of available personal resources for responding to threats (secondary assessment). Thus, individuals will have a risk perception of the pandemic that is full of uncertainties and a risk perception of uncontrollable and involuntary exposure; such unavoidable situations with loss of control for negative events cause individuals to develop depression disorders (Abramson et al., 1978). As susceptibility (a kind of diathesis) is a negative cognition, the hopelessness theory of depression (Abramson et al., 1989) holds that when exposed to negative life events, people who show negative inferential styles are more likely to make negative judgments when exposed to stressful events and thereby have an increased likelihood of experiencing depression. The severity of public crisis events can also aggravate an individual's depression. For example, during

the SARS outbreak, the level of depression and anxiety among medical staff was higher than that during the prevention period (Chen et al., 2006).

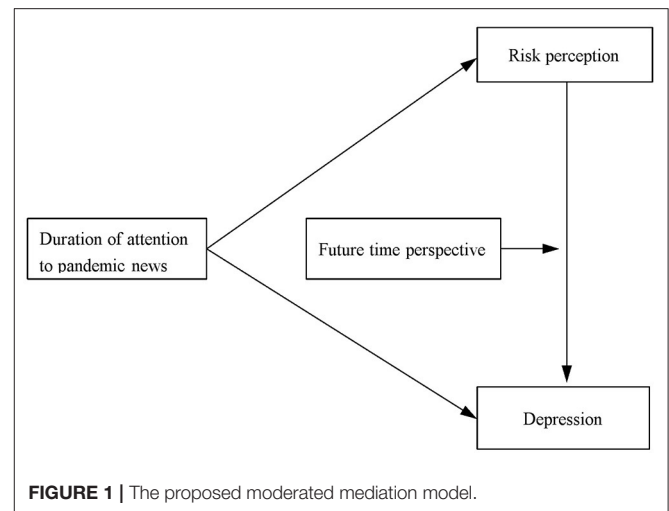

In conclusion, the duration of attention to pandemic news would motivate individuals' depression and risk perception, which, in turn, would also lead to depression. With this view in mind, this study proposed the following predictions:

H3: Risk perception will be positively correlated with individuals' depression.

H4: Risk perception plays a mediating role in the relationship between the duration of attention to pandemic news and depression.

Social cognitive theory holds that, as an important factor affecting mental health (Bandura, 1997; Henshaw and Freedman-Doan, 2009), individual belief is a psychological resource that effectively responds to environmental threats (Keller et al., 2011). Future time perspective (FTP), as a belief for the future, is a relatively stable personality trait that represents individual's cognition of, emotional experience of, and action (action tendency) toward the future (Huang, 2004; Lyu, 2014). Individuals with higher FTP are more optimistic about the future, more confident in achieving future goals, and firmly believe that their current behaviors will help in achieving future goals (Kooij et al., 2018). FTP helps individuals achieve self-adjustment by postponing gratification, and individuals with high FTP could perceive the higher value of delayed rewards so that they are able to focus on the future even in the absence of immediate rewards (Bembenutty and Karabenick, 2004; Lyu and Huang, 2016).

FTP has also been shown to be related to mental disorders (Kooij et al., 2018). In the face of adversity, individuals with higher FTP have greater adaptability and show less depression (Epel et al., 1999), and adolescents with longer FTP have lower depression levels (Diaconu-Gherasim et al., 2017). Conversely, individuals with lower FTP are less clear and more pessimistic about the future and may have greater worries and anxieties about an unpredictable and uncertain future. With the individual's perception of time being as one of the potential predictors of PTSD, traumatic events may cause the individuals to lose expectations for the future, to sink into their current pain and past experience, which can then place their mental health at risk (Holman et al., 2016). The core concept of cognitive behavioral therapy of depression—the “cognitive triad” model of depression—also includes individuals' negative views of the future. The theory holds that for individuals who have negative attitude toward their own abilities and believe that success is impossible and life has no hope, such negative views of the future will lead to depression (Beck and Weishaar, 1989). This suggests that FTP may be an important factor affecting individuals' depression during the pandemic. Allemand et al. (2012) demonstrated the moderating role of FTP in the relationship between tolerance and subjective well-being, and those who believed that the future was open-ended tended to report more life satisfaction and less pessimism than those who perceived their future as restricted. Therefore, FTP may play a moderating role in the relationship between individuals' risk

perception and depression. Studies by Andre et al. (2018) and De Volder and Lens (1982) show that those who believe the future is open-ended tend to score higher in positive emotions and in the sense of life and lower in negative emotions (Hicks et al., 2012). Therefore, higher FTP may help facilitate positive emotions of individuals, ease negative emotions under a stressful environment of risk perception, and then mitigate depression. Hence, this study predicted:

H5: FTP may play a moderating role in the relationship between risk perception and depression.

In sum, the current study aims to investigate the mediating effect of risk perception in the relationship between the duration of attention to pandemic news and depression during the outbreak of COVID-19, as well as the moderating effect of FTP on this mediating effect. The hypothetical model is shown in **Figure 1**.

## MATERIALS AND METHODS

### Participants and Procedure

Due to the infectivity of the novel coronavirus, this study adopted a cross-sectional online survey (in Mandarin) with Survey Star (wjx.cn), a platform providing functions equivalent to Amazon Mechanical Turk. The questionnaires were released on February 6th, 2020, through WeChat platform during the outbreak of COVID-19 in China. As of February 15, 2020, 701 participants from China completed the questionnaires. All participants consented to participate in the study after being informed about the purpose of the study, and the investigation was approved by the Faculty of Psychology at Southwest University. Among all participants, 37.8% ( $n = 265$ ) were males and 62.2% ( $n = 436$ ) were females. As for age, 1.4% were under the age of 18, 28.8% were between 18 and 25 years old, 18.0% were between 26 and 30 years old, 22.5% were between 31 and 40 years old, 21.1% were between 41 and 50 years old, 7.6% were between 51 and 60 years old, and 0.6% were over 60 years old.

**TABLE 1** | Distribution of participants' duration of attention to pandemic news.

Rate	N (%)
1 = no attention	4 (0.6)
2 = within 10 min	58 (8.3)
3 = 10 to 30 min	167 (23.8)
4 = 0.5 to 1 h	145 (20.7)
5 = 1 to 2 h	180 (25.7)
6 = 3 to 5 h	120 (17.1)
7 = 6 to 9 h	17 (2.4)
8 = more than 10 h	10 (1.4)

## Materials

### Duration of Attention to Pandemic News

One single item “How long do you browse, read or watch the pandemic news every day?” was used to collect the participants' daily attention to the pandemic news. Ratings were given on an eight-point scale with higher scores indicating longer duration of attention to pandemic news. The distribution of participants' duration of attention to pandemic news is shown in **Table 1**.

### Risk Perception of the Pandemic

We developed a six-item scale to measure individuals' risk perception of COVID-19 according to the study by Brewer et al. (2007). Items are as follows: “I am very worried that my family and I will be infected with the novel coronavirus (uncertainty)”;

“I feel that washing my hands and wearing a mask cannot stop the invasion of the novel coronavirus (susceptibility)”;

“I think the actual numbers of people infected are much higher than the official figures (severity)”;

“I am afraid that I will be infected with the novel coronavirus (uncertainty) when I go out”;

“When it is necessary to go out (such as purchasing daily necessities), I will be far away from the crowds (serious impact on life)”;

and “I am afraid to touch things touched by others, such as supermarket receipts, elevator buttons, etc. (serious impact on life).” All items were rated on a five-point Likert scale (1 = strongly disagree to 5 = strongly agree). Higher scores reflect an increased perceived risk of the pandemic situation. The Cronbach's alpha score of the scale was 0.74.

### Future Time Perspective

The Chinese version of the ZTPI Future Subscale (Lyu et al., manuscript under review; Zimbardo and Boyd, 1999) was used to measure FTP. This scale contains five items, rated on a five-point Likert scale (from 1 = very uncharacteristic to 5 = very characteristic). Sample items were as follows: “When I want to accomplish something, I will set a goal and consider specific ways to achieve it” and “I can usually complete the plan step by step.” In this study, the Cronbach's alpha score of the scale was 0.86.

### Depression

We adopted the Center for Epidemiological Studies Depression scale (CES-D; Andresen et al., 1994) to assess depressive symptoms. The CES-D has 10 items, which are rated on a four-point scale from 0 (rarely or none of the time) to 4 (most or all

the time) based on how often participants felt that way in the previous 2 weeks, with higher scores indicating more depression. Sample items were as follows: “Even though my family and friends helped me, I couldn't get rid of my depression” and “I feel that my life is a failure.” The Cronbach's alpha in this study was 0.84.

## Statistical Analysis

IBM SPSS Statistics 22.0 was used for data entry, sorting, and analysis. We used model 4 of the Hayes (2017) PROCESS macro to examine the mediation effect of risk perception and model 14 to examine the moderating effect of FTP. Bootstrapping (5,000 bootstrap samples) with 95% confidence intervals (CIs) was conducted to test the significance of indirect effects (Hayes, 2017). The 95% CIs did not include zero, indicating a significant effect.

## RESULTS

### Correlations Analysis

**Table 2** shows the means, standard deviations, and correlation matrix of each variable. As expected, the duration of attention to pandemic news was positively correlated with risk perception ( $r = 0.13$ ,  $p < 0.01$ ) and depression ( $r = 0.11$ ,  $p < 0.01$ ). Also, there were a significant positive correlation between risk perception and depression ( $r = 0.26$ ,  $p < 0.01$ ) and a significant negative correlation between FTP and depression ( $r = 0.32$ ,  $p < 0.01$ ). These results provided preliminary support for our hypotheses. Moreover, gender and age were associated with duration of attention to pandemic news, risk perception, depression, and FTP, so they were included as control variables in the following analysis.

### Mediation Analysis

We used a series of regression analysis to test our hypotheses. As shown in **Table 3**, after the effects of gender and age had been controlled, the duration of attention to pandemic news emerged as positively related to both risk perception ( $B = 0.13$ ,  $SE = 0.04$ ,  $p < 0.01$ , model 1) and depression ( $B = 0.14$ ,  $SE = 0.04$ ,  $p < 0.01$ , model 3), thereby supporting Hypotheses 1 and 2. When controlling for the duration of attention to pandemic news, risk perception was positively related to depression ( $B = 0.26$ ,  $SE = 0.04$ ,  $p < 0.01$ , model 2), so Hypothesis 3 was supported. Moreover, bootstrapping indicated that the mediation effect of risk perception was significant [ $B = 0.03$ ,  $SE = 0.01$ , Boot 95% CI (0.01, 0.06)]. Taken together, risk perception mediated the relationship between the duration of attention to pandemic news and depression. Thus, Hypothesis 4 was supported.

### Moderated Mediation Analysis

Controlling for age and gender, we conducted the moderated mediation analysis. As shown in **Table 4**, the interaction (model 5) between risk perception and FTP significantly predicted depression ( $B = -0.07$ ,  $SE = 0.03$ ,  $p < 0.05$ ), suggesting that FTP moderated the effect of risk perception on depression. In order to more clearly interpret the interactive effect of FTP and risk perception on depression, FTP scores were divided into

**TABLE 2 |** Means, standard deviations, and correlations.

Variable	M	SD	1	2	3	4	5	6
1. Duration of attention to pandemic news	4.33	1.37	1					
2. Risk perception	3.56	0.73	0.13**	1				
3. Depression	1.83	0.48	0.11**	0.26**	1

\**p* < 0.05; \*\**p* < 0.01; \*\*\**p* < 0.001.

high and low groups according to plus or minus one standard deviation. We conducted a simple slope analysis to examine the predictive effect of risk perception on depression at high and low FTP levels. Simple slope tests (Figure 2) suggested that for individuals with high FTP level, risk perception has a significant predictive effect on depression [*B* = 0.20, *SE* = 0.05, 95% *CI* (0.10, 0.29)]; for individuals with low FTP level, risk perception is also a significant predictor of depression [*B* = 0.33, *SE* = 0.05, 95% *CI* (0.24, 0.41)]. The positive effects of risk

perception on depression were stronger for those respondents with low FTP. It was found that the interaction term between FTP and risk perception significantly predicted depression. For depression, the index of moderated mediation was -0.01 [95% *CI* (-0.02, -0.00), excluding zero]. When the level of FTP was high, the duration of attention to pandemic news had a significant indirect effect on depression through risk perception [*B* = 0.03, *SE* = 0.01, 95% *CI* (0.01, 0.05)]; when the level of FTP was low, the duration of attention to pandemic news also had a significant indirect effect on depression through risk perception [*B* = 0.04, *SE* = 0.02, 95% *CI* (0.01, 0.07)]. The positive effects of the duration of attention to pandemic news on depression through risk perception were stronger for those respondents with low FTP. Thus, Hypothesis 5 was supported.

## DISCUSSION

In this study, we found that there was a significant positive correlation between the duration of attention to pandemic news and depression. Xu and Sattar (2020) also found that there was a positive correlation between pandemic information from media and panic, which indicates that the news of the pandemic has an important impact on individuals' physical and mental health. During the pandemic, the public generated a lot of negative emotions, such as panic and depression. Specifically, since COVID-19 is an emerging, infectious, and unknown disease, there is a lack of knowledge about it. Under the implementation

of the isolation measures, the public mostly formed their perception and understanding of the pandemic through news media. Faced with the “infodemic” of pandemic news, on the one hand, it is difficult for individuals to judge the authenticity of the news and form an accurate cognition. On the other hand, in the early stages of the pandemic, many contradictory news in the media led people to doubt the valid information. They also even doubted the official data because of the prevailing rumors (Xu and Sattar, 2020). Therefore, surrounded by various pandemic news, it is difficult for people to find trustworthy sources and reliable guidance. With individuals getting more news about the pandemic, they still cannot accurately understand the epidemic itself, its consequences, and its prevention and control, which lead them to feel uncertainty (Xu and Sattar, 2020). Uncertainty, as we all know, is one of the important factors that lead to depression (Swallow and Kuiper, 1992). Therefore, as H1 predicted, the duration of attention to pandemic news is positively correlated with individuals’ depression.

Few studies have been done to investigate the psychological mechanism of the effect of duration of attention to pandemic news on depression. The current study showed that the duration of attention to pandemic news has a predictive effect on people’s risk perception, and according to the theory of social amplification of risk and agenda setting, the duration of attention to pandemic news will increase people’s risk perception (Gelders et al., 2009; Paek et al., 2016). For example, when receiving reports of the rapid growth of confirmed cases from the media, which exacerbates individuals’ risk perception, people may overestimate their possibility of infection on the one hand and put in place more protective measures on the other hand, such as wearing masks, washing hands frequently, and staying away from crowds, which are all behaviors that follow after intensified risk perception. Behind these behaviors, the media’s coverage of tragic events has resulted in people’s emotional changes, which has caused them to frequently overestimate the frequency of risks and other adverse events (Johnson and Tversky, 1983). From the perspective of the dual process theories, emotion is exactly the basis of a heuristic system, and relying on intuitive emotions is a faster, easier, and more effective way of judgment,

especially in complex, uncertain, and even dangerous situations (Slovic and Peters, 2006). Therefore, individuals often use initial emotional impressions of information to judge risk (Cooper and Nisbet, 2016). By this line of reasoning, the emotions conveyed *via* media reports are important factors influencing individuals’ risk perception. News information that triggers fear is more likely to intensify individuals’ level of risk perception. Thus, there is a positive correlation between fear and risk perception (Paek et al., 2016). Moreover, when the media reports contain emotional vocabulary, they may create an alternative experience, causing similar emotional experiences between the public and the victim (Kupchik and Bracy, 2009). Therefore, the emotional information (such as fear and alternative experiences) conveyed by news media during the pandemic will affect public’s perception of risks.

The present study showed that risk perception also had a significant direct predictive effect on depression, which is consistent with the hopelessness theory (Abramson et al., 1989) and the diathesis–stress model (Monroe and Simons, 1991). First of all, the possibility of danger is uncertain. When an individual has not developed a cognitive schema for the disease event, vague, insufficient, and unfamiliar information helps the individual perceive an uncertainty and, thus, cannot accurately predict the results. Uncertainty is considered to be a risk, not an opportunity; with risk assessment positively correlated with depression and opportunity assessment negatively correlated with depression, uncertainty affects depression through risk assessment (Kang, 2006). The hopelessness theory (Abramson et al., 1989) points out that when people are exposed to negative life events, those who exhibit negative inferential styles are more likely to suffer from depression. The diathesis–stress model also proposes that stress may activate an individual’s diathesis or vulnerability, transforming potential diathesis into a reality of psychopathology, and thus, the impact of stress on depression risk depends on diathesis (Monroe and Simons, 1991). Amid this pandemic, the individuals’ perception of the uncertainty of infection, their diathesis, and the serious consequences that may occur after infection have affected their levels of depression. Therefore, risk perception plays a mediating role between the duration of attention to pandemic news and depression. As individuals spend more time being exposed to pandemic news, their risk perception is also higher, which in turn leads to an increase in the levels of depression.

We also found that FTP plays a moderating role in the indirect relationship between the duration of attention to pandemic news and depression, and FTP can buffer the impact of risk perception triggered by the duration of attention to pandemic news on depression. As FTP increases, the indirect effect of the duration of attention to pandemic news on depression through risk perception weakens. The motivational role of FTP is not only reflected on the cognitive and behavioral levels but also on the emotional level. The more optimistic individuals are about the future, the more confident they are in achieving future goals (Shipp et al., 2009). These positive feelings about the future can alleviate the effects of negative emotions caused by risk perception on depression. Moreover, the greater an individual’s risk perception, the greater the pressure will be

(Webster et al., 1988). Zhao et al. (2020) found that during the COVID-19 pandemic, perceived stress was positively associated with anxiety. The level of FTP can affect an individual's pressure perception (Fookan, 1982). The weaker an individual's feeling of time control, the greater the perceived pressure (Nonis et al., 1998). Therefore, higher levels of FTP can alleviate the pressure caused by an individual's perception of risks and thereby reduce the level of depression. In a word, FTP plays a negative moderating role in the indirect relationship between the duration of attention to pandemic news and depression.

The results of this study provide insight for reducing the level of depression among the public during the pandemic and in other major emergencies in the future. First, the findings show that the information conveyed by news reports could affect an individual's level of depression. This conclusion helps to understand the impact of media exposure on an individual's psychological distress during major crisis events, which provides valuable contributions to the ongoing improvement of news media work. On the one hand, the official information helps to reduce people's concerns about the continued development of the situation. For example, previous research shows that positive news information after an earthquake has a protective effect against the continued development of depression and suicidal thoughts (Lau et al., 2010). Moreover, Khajanchi and Sarkar (2020) apply the model to forecast the development of COVID-19 pandemic in India, which suggests that media effect can play a key role in mitigating the transmission of COVID-19. By this line of reasoning, the media should not only report quickly and accurately but also balance the coverage of positive and negative news. On the other hand, the duration of attention to pandemic news may lead to uncertainty, which aggravates individuals' depression. Zhang et al. (2020) have shown that participants who spent more time watching TV and on cellphones or computers were significantly more likely to report elevated stress; those who participated in family entertainment activities were significantly less likely to report elevated stress. Therefore, when the news surges, individuals should attempt to reduce their attention to it and divert their attention to other topics or activities (such as watching entertainment programs, developing hobbies and interests, upgrading personal skills, and spending quality time with family) aimed at alleviating negative emotions. Second, accurate understanding of risks is also an important way to maintain mental health. Individuals should pay attention to official information from formal channels and should not make unfounded speculations or exaggerate the severity of the pandemic and other events. Individuals should also develop an objective and scientific understanding of the pandemic situation, reduce the perceived uncertainty, and develop a sense of control. In order to mitigate uncertainty, individuals should seek to change negative perceptions and develop positive coping behaviors and, thus, reduce risk perception and tendency toward depression. Finally, FTP shows a negative moderating role in the indirect relationship between the duration of attention to pandemic news and depression. Given the plasticity of FTP (Kooij et al., 2018), it is very important to intervene with FTP. Specifically, individuals should be trained to shift their time focus, engage in more positive future thinking, and enhance the

role of positive emotions. With the negative news environment surrounding the pandemic, individuals can be instructed to extend their timeline to the future and feel the malleability of the future in order to balance the current negative emotions. The individual's good hope for the future and the confidence in winning the battle against COVID-19 are conducive to promoting positive emotion and reducing depression caused by the negative emotion under the pandemic.

This study has some limitations that should be considered. First, due to its cross-sectional nature, this study could not determine the causal relationship between variables by longitudinally tracking changes during the pandemic. It is suggested that future research should examine causal relationships among variables through a longitudinal study. Second, the study measured the duration of attention to pandemic news but did not distinguish among negative, positive, and neutral information; different types of information may have different effects on risk perception. For example, among the negative information that is closely related to individuals, information concerning whether there is a confirmed case in the same community can most affect the individuals' risk perception (Shi et al., 2003). Therefore, future research needs to explore the impact of different types of information on risk perception and their internal mechanisms. Third, the sample selection was biased, as the sampling did not take into account a balance of different regions. The severity of the pandemic varied greatly in different regions of the country; thus, we should be cautious about generalizing the research results to other regions. Finally, this study did not examine whether individual FTP is also affected by the pandemic, as the view of time will change with personal and situational factors (Kooij et al., 2018). Therefore, future research should further test the interaction and effect of FTP and pandemics.

## CONCLUSION

The current study found that there is a significant positive correlation between the duration of attention to pandemic news and depression, and risk perception plays a mediating role in the relationship between them. FTP plays a moderating role between risk perception and depression, and individuals with high FTP have a weaker positive effect on depression than those with low FTP.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the corresponding authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Faculty of Psychology at Southwest University. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## AUTHOR CONTRIBUTIONS

HL designed the research framework and contributed to manuscript writing and modification. LW contributed to the data analysis and writing. XL contributed to the data collection and manuscript modification. All authors contributed to the article and approved the submitted version.

The coronavirus disease 2019 (COVID-19) pandemic has been regarded as a public health emergency that caused a considerable degree of public panic (such as anxiety and insomnia) during its early stage. Some irrational behaviors (such as excessive search for information related to the pandemic and excessive hoarding of supplies) were also triggered as a result of such panic. Although there has been plenty of news coverage on public panic due to the outbreak, research on this phenomenon has been limited. Since panic is the main psychological reaction in the early stage of the pandemic, which largely determines the level of psychological adaptation, time of psychological recovery, and the incidence of PTSD, there exists a demand to conduct investigation on it. From a public governance perspective, the government's assessment of public panic may affect the efficiency and effectiveness of pandemic prevention and control. Therefore, it is of obvious practical significance to investigate public panic during the COVID-19 pandemic and analyze its influential factors. The self-compiled COVID-19 Social Mentality Questionnaire was used to collect data from a total of 16,616 participants online, and 13,511 valid responses were received. The results from the chi-square test showed that there were differences in gender, educational level, age, pandemic-related knowledge, self-efficacy, risk level, and objective social support. Furthermore, multiple linear regression analysis results showed that self-efficacy, gender, educational level, age, risk level, pandemic-related knowledge, and objective social support were significant predictors of public panic. Among the research variables, self-efficacy, gender, educational level, and age were negative predictors of panic while risk level, pandemic-related knowledge, and objective social support were positive predictors of panic.

**Keywords:** COVID-19, panic, pandemic-related knowledge, self-efficacy, risk, objective social support

## INTRODUCTION

The coronavirus disease 2019 (COVID-19) is a respiratory infection transmitted by airborne droplets and close contact caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The World Health Organization (WHO) declared the novel coronavirus pneumonia outbreak a "public health emergency of international concern" on January 31, 2020, Beijing time. As of May 24, there were 5.29 million confirmed cases and 342,306 deaths worldwide. COVID-19 not only threatens people's health and safety, but also has a profound impact on people's lives and work.

The COVID-19 pandemic typically brings stress to the general public. According to the stress theory, stress refers to a series of physiological, psychological and behavioral reactions that occur when people face harmful substances, threats, and challenges inside and outside, and know that such stimuli will pose a threat to them after their own subjective evaluation (Folkman and Lazarus, 1984). The causes of these reactions are called stressors. Studies have pointed out that in various major stress events, infectious diseases not only have a more lasting impact on human physiology, but also produce a variety of adverse psychological reactions in victims (Li and Hua, 2003). In the face of the pandemic, people often experience negative emotions such as anxiety, fear, depression and, in severe cases, some somatic symptoms (Chinese Association for Mental Health, 2020), which have negative impacts on people's physical and mental health as well as their future life. Although there has been a lot of news about panic during the pandemic, there have been very few studies on public panic. Since panic is an important psychological response to COVID-19, it largely determines the level of subsequent psychological adaptation, time of psychological recovery, and incidence of PTSD. Therefore, in order to overcome the novel COVID-19 as soon as possible, it requires not only the efforts of medical researchers and the professional treatment of front-line medical staff, but also the trusted scientific evidence and knowledge of psychological researchers to provide the public with science-based guidelines to establish a positive social mentality to avoid excessive panic caused by the pandemic (Castelnuovo et al., 2020).

The COVID-19 pandemic, as a public health emergency, is also an emergent risk event for the public. It has the typical characteristics of high-risk events and causes a considerable degree of panic in the society (such as anxiety and insomnia etc.). According to the risk perception theory (Slovic, 1987), a risk event can be interpreted as a "signal"; the nature of the "signal" and the conditions of its transmission process will influence the receivers' feelings and reactions toward the event. Usually, people rely on their intuition to know and make judgments about risk events, which is called risk perception. Svenson (1988) proposed the mental model of risk, believing that individuals will form different mental models due to their differences in knowledge, experience and other individual characteristics, thus forming a unique perception and value judgment of risk events. Therefore, in the process of forming public risk perception from a risk signal, two factors are involved. First, the characteristics of risk events themselves; second, the receivers' personal characteristics, such as their personality or cognitive biases. The interaction among these characteristics will also produce a certain effect. People's risk perception of crisis events can be measured from two dimensions: familiarity and controllability. The high risk end is perceived as "unknown and uncontrollable." Previous studies found that if risk factors can be classified according to their nature, their risk characteristic dimensions can be significantly correlated. For example, a factor perceived as a voluntary risk is often perceived as controllable; a risk factor perceived as unknown is often perceived as a factor of high anxiety. In the case of COVID-19, on the one hand, the massive, collective stressor of a pandemic far exceeds the capacity of individuals and communities to respond; on the other hand, as

COVID-19 is an emerging infectious disease, information about its source, post-infection detoxification time, and pathogenesis is still unclear, which further exacerbates its "uncontrollability." In previous studies on SARS, Shi and Hu (2004) pointed out that information related to the pandemic, such as etiology, route of transmission and cure rate, is an effective indicator to reflect the controllability of the pandemic, which can significantly affect people's risk perception. Xie et al. (2005) pointed out that the individual characteristics of the public, such as gender, educational background, personality and relevant knowledge, are the conditions for the "signal" transmission process of risk events. They affect the individual's ability and willingness to accept risk events, and when such exceeds the individual's tolerance, it will produce adverse psychological reactions such as panic and even lead to some irrational behaviors, such as excessive search for information related to the pandemic, excessive hoarding of food, and blind use of drugs. Therefore, this study intends to explore the influence of factors such as gender, educational background, risk level, social support, pandemic knowledge and self-efficacy on public panic during the pandemic period. This study aims to analyze the causes of public panic by exploring the influencing factors, help the government in conducting counseling and achieving control, and lay a foundation for subsequent psychological reconstruction.

## MATERIALS AND METHODS

### Samples

In this study, a convenient sampling method was adopted to carry out a survey in Henan province using the online platform wjx.cn from 17:00 January 27, 2020 to 17:00 January 29, 2020. The questionnaire was uploaded to the platform, which automatically generates a network link. The link was then posted via the researcher's social media account and the organization's website, inviting people to answer the questions and forward the questionnaire. Excluded the close contacts, a total of 16,616 questionnaires from general public were collected in this study, with 1,551 questionnaires from medical workers and 1,554 questionnaires answered in less than 200 s or by one aged less than 16 years or more than 100 years old, which were deleted. A total of 13,511 valid questionnaires were left, with a response rate of 81.3%. The samples cover 18 cities in Henan Province, China. Among the participants, there are 4,267 males (31.6%) and 9,244 females (68.4%), their average age are  $32.10 \pm 11.11$ , with the largest being 77 years old and the youngest 16 years old. Among the participants, 2,930 (21.7%) have a high school education and below, 2,761 (20.4%) have a junior college degree, and 7,820 (57.9%) have a bachelor's degree or above. 1,900 (14.1%) have healthcare workers in their family, while 11,611 (85.9%) had none.

### Measures

The self-compiled COVID-19 Social Mentality Questionnaire was used as a measurement tool in this study (Chen et al., 2020). The questionnaire was compiled by psychological professors and doctoral students at the early stage of the COVID-19 pandemic after referring to previous researches on the Severe

Acute Respiratory Syndrome (SARS) epidemic and relevant literature on sudden public health events (Qian et al., 2003; Shi et al., 2003; Shi and Hu, 2004; Xu et al., 2005; Xie et al., 2009). The questionnaire has six contents: (1) risk level during the COVID-19 pandemic, (2) social support during the COVID-19 pandemic, (3) knowledge of COVID-19, (4) self-efficacy in seeking help during the COVID-19 pandemic, and (5) the public panic during the COVID-19 pandemic. After determining the basic framework, the team members modified and improved the questionnaire through several discussions, and screened and integrated questions that were similar. Psychological scholars and postgraduates were then invited to conduct a pilot test, and the questionnaire was refined and processed according to their feedback, which was used to formulate the final questionnaire. The final questionnaire was then uploaded to the online platform wxj.cn and was tested among a large population.

### Risk Level

Risk level is measured by a self-rated question that asks, “Have you found any cases or suspected cases of COVID-19 around you?” The answer “yes” is scored as 1, and the answer “no” is scored as 0.

### Objective Social Support

Objective social support is measured by a self-rated question that asks, “whether someone in the family is a health care worker.” The answer “yes” is scored as 1, and the answer “no” is scored as 0.

### Pandemic-Related Knowledge

The sub-questionnaire “Cognition Questionnaire on COVID-19 Pandemic” in the self-compiled COVID-19 Social Mentality Questionnaire was used as the measurement tool for pandemic-related knowledge. The questionnaire mainly consisted of 8 items, which respectively examined the cognition of the participants on the characteristics of COVID-19 infection, the main symptoms, the route of transmission, the knowledge of prevention and the difference between the symptoms and the common cold/flu, as well as the research progress related to the disease and the development stage of the pandemic (see **Appendix 1**). The score range is from 0 to 8; “very unclear” and “relatively unclear” answers are counted as 0, and “very clear” and “relatively clear” answers are counted as 1, then the total score is calculated. The Cronbach’s alpha for this questionnaire was 0.697.

### Self-Efficacy

The sub-questionnaire “The Public’s Self-Efficacy in Seeking Help During the COVID-19 Pandemic” in the self-compiled COVID-19 Social Mentality Questionnaire was used as the measurement tool for self-efficacy. The public’s self-efficacy during the pandemic includes four items, which respectively examine people’s information acquisition efficacy, information identification efficacy, medical treatment acquisition efficacy and psychological assistance acquisition efficacy. The answer “yes” is counted as 1 score, “no” and “uncertain” as 0, then the total score is calculated. The Cronbach’s alpha for this questionnaire was = 0.750.

### Public Panic

Projection measurement was used to measure public panic. The proportion of people around the participants that felt panic actually reflected the degree of panic of the subjects themselves. Participants were asked to answer the question, “How many people around you feel panic about COVID-19?” The 5 Likert scale was adopted, which indicated the participants’ panic from low to high.

### Data Analysis

SPSS 25.0 was used to analyze the collected data, and a descriptive analysis was used to describe public panic and other studied variables. Chi-square test was used to examine the existing differences in panic under different factors. Multivariate stepwise regression was conducted to explore how public panic was affected by other research variables.

## RESULTS

### The Distribution of Panic Among the Population During COVID-19

As shown in **Table 1**, generally 7,291 (53.96%) people thought that more than half of the people around them experienced panic, while only 1,442 (10.67%) people thought that people around them did not. The mean of public panic was 2.99 and the standard deviation was 1.28. Chi-square test results showed that there were significant differences in the public panic mood in terms of gender ( $\chi^2 = 115.09, p < 0.001$ ), age ( $\chi^2 = 515.14, p < 0.001$ ), educational background ( $\chi^2 = 462.59, p < 0.001$ ), objective social support ( $\chi^2 = 28.97, p < 0.001$ ), risk level ( $\chi^2 = 59.01, p < 0.001$ ), pandemic knowledge ( $\chi^2 = 111.46, p < 0.001$ ), and self-efficacy ( $\chi^2 = 263.36, p < 0.001$ ).

### Correlation Analysis

The descriptive statistics and correlation matrix of each research variable are shown in **Table 2**. Panic is significantly and positively correlated with objective social support ( $r = 0.023, p < 0.01$ ) and risk level ( $r = 0.055, p < 0.01$ ), and is negatively correlated with gender ( $r = -0.086, p \leq 0.01$ ), age ( $r = 0.044, p < 0.01$ ), educational background ( $r = 0.030, p < 0.01$ ), and efficacy ( $r = 0.125, p < 0.01$ ). There was no significant correlation between panic and pandemic knowledge.

### Multivariate Regression Analysis

In order to further study the influencing factors of public panic under the COVID-19 pandemic, we took panic as a dependent variable and conducted multiple linear regression analysis with gender, age, education, objective social support, risk level, pandemic knowledge and self-efficacy as independent variables. The stepwise method was used to determine the main factors and the criteria was set as “Probability-of-F-to-enter  $\leq 0.05$ , Probability-of-F-to-remove  $\geq 0.10$ .” As shown in **Table 3**, among the seven models obtained by stepwise regression, the  $R^2$  (0.028) value of the 7th model was the highest, which was selected as the final model. Multivariate regression analysis

results show that risk level ( $\beta = 0.048$ ,  $p < 0.001$ ), pandemic knowledge ( $\beta = 0.030$ ,  $p < 0.01$ ), and objective social support ( $\beta = 0.029$ ,  $p < 0.01$ ) can positively predict panic, while self-efficacy ( $\beta = -0.125$ ,  $p < 0.001$ ), gender ( $\beta = -0.073$ ,  $p < 0.001$ ), and education ( $\beta = -0.045$ ,  $p < 0.001$ ), age ( $\beta = -0.041$ ,  $p < 0.001$ ) negatively forecast panic.

## Markov Chain Monte Carlo (MCMC) Bayesian Estimation

Compared with the maximum likelihood estimation, the Bayesian estimation could benefit to evaluate the complicated likelihood functions and posteriors in model estimation. According to Washington et al. (2011), when the posterior estimates in a model are resulted from the statistical likelihood and the prior with a random sample, the Bayes' theorem would be adopted to estimate the model. Therefore, a standard Markov Chain Monte Carlo (MCMC) sampling method is needed to simulate the posterior densities of the model under the Bayesian framework. However, as the model was intractable in analysis, following the suggestions of Bolduc et al. (2005), a MCMC Bayesian estimation was applied to conduct the posterior inferences of the results from stepwise regression in this paper. As shown in **Table 4**, the results of stepwise regression were consistent with the positive and negative coefficients of

explanatory variables in the results of MCMC method, and the difference was not significant. In stepwise regression, coefficients of explanatory variables other than age were all within 95% Credible Interval of MCMC method.

## DISCUSSION

Public panic is an objective response to major risk events occurring on the public, but it is negative in nature and often causes more harm than good. If the spread of public panic cannot be controlled in a timely manner, it may cause a negative chain reaction, which will not only adversely affect the stability and management of the whole society, but also hinder the prevention and control process of the pandemic. Therefore, analyzing the influencing factors of public panic under the pandemic situation could help people find ways to overcome panic and help administration departments make scientific decisions and carry out pandemic prevention and control more effectively.

### Overview (Profile) of the Public Panic

The COVID-19 outbreak has had a huge psychological impact on the population. From the psychological projection perspective (Cai and Shen, 2010), sometimes people unconsciously reflect

Dependent Variable: Panic.

their emotions, attitudes and thoughts toward external things or others. Therefore, the perceived panic around a certain subject may reflect a certain degree of unawareness of one's own feelings of panic. The results of this study showed that 89.33% of the public believed that someone around them experienced panic, and the average measurement of public panic was  $2.99 \pm 1.28$  ( $M \pm SD$ ), indicating a high level of panic. Due to the lack of clear understanding and control over COVID-19, the theory of psychological stress explains that COVID-19 is a relatively serious stress event for both social groups and individuals. The conclusions are consistent with the relevant studies during the SARS period. Shi and Hu (2004) found through investigation that in the early stage of SARS, people often made irrational evaluations on the current situation and consequences of the epidemic, which led to panic. Xie et al. (2005) indicated that the level of psychological anxiety of the public generally increased during the SARS epidemic, and majority of the public's psychological anxiety turned into psychological panic due to the failure to receive effective feedback. It can be seen that panic is a normal and objective response to a major epidemic, yet, this seemingly completely negative emotional response actually has some positive meaning. Studies have shown that in life-threatening situations, negative emotions narrow the range of individual's momentary thought-action repertoire, improve people's ability to act quickly and firmly, and thus increase the survival probability of individuals, which has evolutionary significance (Xie, 2019).

Therefore, the purpose of dealing with the negative emotional reaction such as panic should not be aimed at total elimination, but to carry out reasonable guidance for such emotion, so that people can not only maintain reverence for nature, but also protect their mental health. Here, it is suggested that the administrative departments must actively encourage scientific research on psychological changes of the public during the pandemic, and formulate reasonable policies to effectively channel the public's panic, maintain social stability and speed up the process of fighting against the pandemic.

## The Role of Self-Efficacy

The results show that self-efficacy can negatively predict panic, that is, the higher an individual's level of self-efficacy, the less likely they are panic. According to the social cognitive theory, self-efficacy is the degree to which an individual is confident

in his or her ability to complete a task or behavior; whether a person can engage in a certain activity smoothly and successfully is affected by his self-efficacy because an individual's feeling of self-efficacy restricts their motivation level, behavior mode of activities and various psychological levels (Bandura et al., 1999). The self-efficacy investigated in this study is described as one where, during the COVID-19 pandemic, an individual initiates a request for help, and during the request process, the prediction of the outcome of the request reflects the individual's confidence level to complete it. In the process of seeking help, individuals with high self-efficacy can further improve their problem-solving ability and have more confidence when facing tasks and difficulties in the future (Williams and Takaku, 2011). At the same time, individuals with high self-efficacy will perceive more positive effects of help-seeking behavior, so their psychological cost in the process of help-seeking is also relatively low (Nadler, 1991). They are more likely to seek help to relieve stress (Aspinwall and Taylor, 1992), which helps reduce their anxiety, depression, panic and other emotional problems caused by situational factors, and maintain their emotional stability.

In this regard, it is recommended that the government should further broaden the channels of medical and psychological assistance for the public, encourage more social forces to invest in the fight against COVID-19, and transmit positive social energy while employing correct adverse actions in the fight against COVID-19 to show determination to overcome the pandemic, thereby boosting public confidence to increase the effectiveness of the fight against the pandemic.

## The Role of Gender

Gender is an effective indicator of panic; women are more likely to panic in the face of a pandemic. It may be related to the personality traits of women, such as sensitivity (Su and Wang, 2014). Therefore, when experiencing changes in their social environment, women are more likely to perceive the emotional state and changes of the people around them, making them feel more panic. It may also be related to the cognitive characteristics of females. Studies have shown that females are dominant in the emotional and intuitive dimensions, while males are dominant in the ideological and sensory dimensions (Peng et al., 2006). Therefore, women's emotions are more likely to be affected by stressful events. During the SARS epidemic, some researchers found that the degree of panic, stress intensity and stress influence of female college students were significantly higher than male college students (Yin et al., 2003). In addition, according to the emotional contagion theory (Doherty, 1997), women have higher emotional sensitivity than men; therefore, in a pandemic, women are more susceptible to being emotionally affected by the people around them, leading to panic and other negative emotions. It is consistent with the results of this study, which showed that the proportion of female college students who perceived panic around them is significantly higher than that of male college students (Zhao et al., 2020).

It is suggested to pay attention to the differences between different gender groups, fully understand their psychological needs, and carry out targeted psychological assistance.

## The Role of Risk Level

Risk level can also effectively predict panic, that is, the higher the risk level, the greater the possibility of panic. According to the mental model of risk (Svenson, 1988), when the risk faced by an individual exceeds the level of acceptance, a strong physical and mental reaction may occur, such as panic, anxiety and other adverse psychological reactions. The degree of risk perceived by an individual is negatively correlated with its geographic location; the farther the location of the pandemic, the lower the degree of risk. Because the geographical location of COVID-19 is close to people, it is also a reflection of psychological distance. Therefore, when confirmed/suspected cases appear around individuals, people will feel more danger and threat, and the emotional reaction of panic and anxiety will be stronger (Qian et al., 2003; Xie et al., 2009). Previous research has also confirmed this conclusion; Qian et al. (2003) found that during the SARS epidemic, when SARS first appeared in their city, people's negative emotions increased significantly, and when SARS appeared in the school, company or community, the spatial and psychological distance between SARS and the people was further reduced, and people showed more tension, fear, pessimism and helplessness.

The current situation of the COVID-19 pandemic worldwide is still very serious, thus, the government should adopt active prevention and control policies and concentrate its efforts on high-quality allocation of resources on the basis of science. Meanwhile, all sectors of society should work together, help each other, exchange needed goods and make joint efforts to reduce the risk level.

## The Role of Education and Age

Education background and age can also negatively predict panic, that is, the more highly educated people are, the less likely they panic, and the older the people are, the less they panic. In this study, samples were taken in the early stage of the pandemic outbreak, which was also a time when information was expanding rapidly and everyone was in an information storm. According to the signal theory (Spence, 2002), a large amount of information flooding in a short time produces information explosion. Information noise brought by a large amount of uncertainty and information redundancy causes information damage, thus disturbing people's ability to differentiate information (Miao and Zhu, 2006). In addition, the pandemic is an extraordinary period, and this special situational factor naturally becomes a condition for the formation and living space of rumors. Highly educated participants tend to have higher cognitive level, more information acquisition channels and stronger information collection ability (Xu et al., 2005), which helps them identify misinformation more effectively, obtain practical and effective coping strategies, avoid being misled by rumors and reduce unnecessary panic. Moreover, the aging rate of memory of highly educated people is low (Feng, 2005). The memory of overcoming SARS also brings them more positive mental motivation, which buffers their feelings of panic about COVID-19.

In terms of age, the research results show that age and educational background are significantly positively correlated, that is, the older the subjects are, the higher their educational background is. Combined with the previous discussion, it explains why the older the participants are less likely to panic. In addition, according to the social learning theory, individual concepts of reality are derived from the process of comparative verification of these concepts against some other real criteria (Bandura, 1986). In the same fuzzy information condition, for individuals with direct experience, although the direct experience itself is not pleasant or even compulsive, the direct experience will provide the individual with corresponding objective feelings, which can often correct the unnecessary psychological panic caused by information ambiguity (Xie et al., 2005). In this study, the older subjects may have experienced SARS, H1N1 and other infectious diseases, and the accumulated knowledge and experience makes them more informed and confident in coping with COVID-19, resulting in less panic.

## The Role of Pandemic-Related Knowledge and Objective Social Support

Surprisingly, pandemic-related knowledge and objective social support can positively predict panic, that is, people with more pandemic-related knowledge and objective social support are more likely to panic. However, reviewing the literature, it is found that the results are consistent with previous studies.

First of all, in terms of pandemic-related knowledge, the sampling time of this study was in the early outbreak of the pandemic, and it could not be ruled out that some participants misjudged rumors as knowledge, thus their panic level was relatively high. Shi and Hu (2004) pointed out in their study that the relevant information in the early stage of the pandemic had a strong negative effect on the public, which would significantly increase the public's perception of risk. Moreover, according to the social learning theory, the individual's conception of reality is derived from the process of comparative verification of these concepts and some other real standards (Bandura, 1986). Therefore, personal experience is of great significance to risk cognition, and subjects without direct personal experience are more likely to be induced by external information and thus produce corresponding psychological responses (Wiegman et al., 1991). Qian et al. (2003) conducted a survey of the Beijing population during the SARS epidemic and found that in the first 2 weeks of the outbreak, due to the explosion of all kinds of information and people's lack of knowledge about SARS and the epidemic, people could not effectively distinguish facts and rumors and were inevitably misled. Therefore, the more information they received, the more panic they felt. In addition, Xie et al. (2005) pointed out that for individuals without direct experience, when the information provided by the outside world is not of clear guiding significance, individuals are likely to have adverse psychological reactions such as anxiety and panic. Moreover,

at the outbreak period of the pandemic, information closely related to the public itself and negative information were of utmost concern to the public. At the beginning of a crisis event, the public tends to make a judgment on the risk of the event based on objective indicators such as the frequency of the occurrence and the severity of the consequences, which naturally leads to negative emotions such as panic (Shi et al., 2003).

In terms of objective social support, an operational definition of objective social support in this study is, "Is there anyone in the family engaged in medical care?" In the background of a major pandemic, the medical staff are fighting in the front line of resistance to the disease, and especially under the highly contagious COVID-19, the concern of family members for the occupational health of medical staff may result to a certain level of anxiety. Moreover, according to the spillover theory (Staines, 1980), medical workers are likely to share what they have seen and heard at the front line with their families; combined with the uncertainty of various information during the pandemic period, it is very likely that their families will experience a strong sense of panic.

Thus, it is recommended to adopt a diversified approach to spread accurate and timely information about the COVID-19 pandemic, repel rumors with factual reporting, and reduce panic among the public. Besides, in order to reduce the impairment of rumors and misinformation, it is highly necessary to call for psychological research to reveal the public's cognition towards the COVID-19 pandemic in time (Castelnuovo et al., 2020).

## CLINICAL IMPLICATIONS

Combined with the results, here are proposed three clinical recommendations for the general public during the COVID-19 pandemic.

First, it is a normal emotional response to feel panic when facing with great dangers, such as during COVID-19, and such response can help people staying away from dangers. When panic occurs, accept the existence of the emotion is initial and essential, and then make every effort to seek and practice the scientific solution, that is, adopt the standard science-based self-protection implements. For example, stay at home and do not to going out, gathering and visiting others. Besides, it is an obligation to wear a medical surgical/protective facial mask if someone has to go outside. Further, washing hands in accordance with the Seven-step method frequently, keeping the room ventilated, and eat fully cooked food during the COVID-19 pandemic are crucial personal protections. The proper personal protection can greatly reduce the risk of being infected.

Second, in the early stage of pandemic, people often panic because of excessive attention to the pandemic and ineffective screening of misinformation. Here, it is suggested to acquiring the pandemic-related knowledge/information through the authoritative media. A clear and objective understanding of the development of the pandemic can help people to reduce panic. Meanwhile, in times of emergency, the greatest

contribution to society is to manage oneself well without spreading or believing rumors.

In addition, studies have shown that only the pandemic-related knowledge acquisition is insufficient in reducing panic, rather than that, making the public to be more aware of the prevention and control measures seems to be more important to confine the pandemic (Liu et al., 2004), as it can effectively improve people's self-efficacy, thereby reducing the damage of COVID-19 pandemic to the people's mental health (Wang et al., 2020). At present, scientific analysis and interpretation of COVID-19 related information, guidance of public opinion correctly, clear prevention methods are of great importance to improving the psychological state of the public. In the long term, it is strongly recommended to improve people's public health literacy (Huang et al., 2015).

## LIMITATION

Due to the limitations of the overall sample size and the actual situation, this study adopts the on-line convenient sampling method. Therefore, due to the sample distribution, the representativeness is limited. The number of previous studies available for reference was limited owing to the unexpected and unknown nature of the COVID-19 pandemic; moreover, as time was limited, the self-compiled questionnaire used in this study was relatively crude. In addition, this study adopts a cross-sectional study design, which cannot fully reflect the psychological development of the public during the pandemic. It is suggested that future studies should adopt a longitudinal study design or mixed study design, in order to conduct a comprehensive and in-depth study of the psychological development of the public in emergencies.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Henan University Institutional Review Board. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## AUTHOR CONTRIBUTIONS

YL and SW were the principal investigators for the study, generated the idea and designed the study. XN and KF were the primary writers of the manuscript, and approved all changes. KF and SW supported the data input and data analysis. YL and XN supported the data collection. All authors were involved in developing, editing, reviewing, and providing feedback for

this manuscript and have given approval of the final version to be published.

## APPENDIX 1

The 15 items involved in this study are listed below:

Objective social support: “Is someone in your family a healthcare worker?”

Public panic: “How many people around you feel panic about COVID-19?”

Risk level: “Are there confirmed or suspected cases in your area?”

Pandemic-related knowledge:

- a) Do you know the main symptoms of COVID-19?
- b) Do you know how COVID-19 is transmitted?
- c) Do you know the difference in symptoms between COVID-19 and the common cold?
- d) Are you aware of the current pandemic?
- e) Are you aware of current research progress on COVID-19?
- f) Do you think wearing a mask can prevent COVID-19 infection?
- g) Do you know how to wash your hands properly?
- h) Do you think that the behaviors of dining and gathering is at risk of COVID-19 infection?

Self-efficacy:

- a) I am sure I have the resources I can use to gain knowledge about COVID-19.
- b) I’m sure I know how to distinguish the rumor from the truth.
- c) I’m sure I know how to get proper medical treatment if I need it.
- d) I’m sure I know how to get the proper psychological services if I need it.

# The Unprecedented Movement Control Order (Lockdown) and Factors Associated With the Negative Emotional Symptoms, Happiness, and Work-Life Balance of Malaysian University Students During the Coronavirus Disease (COVID-19) Pandemic

**Background and Aims:** Malaysia's first Movement Control Order (MCO) or "lockdown" was in place for 6 weeks to curb the spread of coronavirus disease (COVID-19). Consequently, all universities were forced to close temporarily with abrupt changes to teaching and learning activities. However, there has been a lack of consensus regarding students' actual psychological status and mental health during the MCO implementation. This study investigates the link, state, and differences of negative emotional symptoms, happiness, and work-life balance among university students during the COVID-19 pandemic.

**Methodology:** This study recruited 1,005 university students across Malaysia. Data was collected online using Qualtrics to measure negative emotional symptoms (The Depression, Anxiety, and Stress Scale), happiness (The Oxford Happiness Inventory), and work-life balance (Work-Family Conflict Scale). All data was analyzed using SPSS version 25 and AMOS version 26 using *T*-test, ANOVA, logistic regression analyses, and path analysis method.

**Findings:** Findings indicated that 22, 34.3, and 37.3% of the university students scored moderate to extremely severe levels of stress, anxiety, and depression symptoms, respectively. Half scored rather happy or very happy (50%) for happiness levels. Meanwhile, 50.4 and 39.4% scored high to very high levels of work-to-family and family-to-work conflict. Significant differences in stress, anxiety, depression, happiness, work-family conflict, and family-work conflict were recorded across different demographic factors. Happiness was found to be a protective

factor with a lesser likelihood of experiencing severe stress (OR = 0.240, 95% CI: 0.180, 0.321), anxiety (OR = 0.336, 95% CI: 0.273, 0.414), and depression (OR = 0.121, 95% CI: 0.088, 0.165) with higher happiness levels. Higher score of work-to-family conflict contributes to greater odds of having severe levels of anxiety (OR = 1.453, 95% CI: 1.161, 1.818). While greater likelihood of developing severe stress (OR = 1.468, 95% CI: 1.109, 1.943) and severe anxiety (OR = 1.317, 95% CI: 1.059, 1.638) under increasing score of family-to-work conflict. Besides, happiness is found to negatively linked with lower negative emotional symptoms, while work-family conflict and family-work conflict are positively linked with higher negative emotional symptoms.

**Conclusion:** Lockdown implementation during the COVID-19 pandemic appears to have a significant impact on university students' negative emotional symptoms, happiness, and work-life balance. Happiness was found to be a protective factor while the state of work-life balance is a risk factor that can predict students' negative emotional symptoms.

**Keywords:** anxiety, depression, students, lockdown, COVID-19 pandemic, stress, happiness, work-life balance

## INTRODUCTION

On 11 March 2020, the World Health Organization declared the coronavirus disease (COVID-19) a global pandemic resulting in many countries worldwide having to enforce unprecedented lockdown measures to curb the spread of novel virus severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). As of 31st December 2020, the virus has killed more than 1.8 million people worldwide, causing spiking fears, anxiety, and state of panic which result to various well-being and socioeconomic concerns among human population (1). Due to its substantial impact worldwide, new research on the psychological, behavioral, interpersonal, and clinical implications toward high-risk population and different contexts are imperative (2). On 25th January 2020, Malaysia had the first three positive cases of COVID-19. On 16th March 2020, Malaysia's Prime Minister has officially announced the unprecedented Movement Controlled Order (MCO), in response to the pandemic. The order promulgates restriction of social activities under the Prevention and Control of Infectious Diseases Act 1988 and the Police Act 1967. During the MCO period, only essential businesses were allowed to operate while most service sectors including schools and higher institutions suspended all physical activities. Concurrent with the steady increase of daily cases, the full MCO implementation has been extended twice, accumulating to a total of 6 weeks since the 1st date of enforcement has taken place.

A rapid review of previous outbreaks suggests that a state of isolation or restricted access measures has severe effects on individual psychological condition such as posttraumatic stress symptoms, confusion, and anger caused by various conditions such as fears of infection, frustration, boredom, inadequate supplies or information, financial loss, and stigma (3). Likewise, recent studies during the COVID-19 pandemic have also provide evidences of indirect adverse mental health impact of the virus (4, 5). Early evidence suggests that the impact of COVID-19 is beyond massive contraction of global economic activities,

similarly pointing to the degrading quality in health and well-being (6). While this will leave no sector in any country unaffected, the socioeconomic impact in all education sectors from preschool to tertiary education has been reported (7).

Young adults and educated individuals are particularly found to be more vulnerable to mental distress based on recent studies (8, 9). In addition, the conditions of disrupted daily life and delays in academic activities were positively linked to the declining of students' mental health condition (10), rising unhappiness, and conflict (11). However, despite serious attention given to this topic, there has been a lack of consensus drawing on university student population with existing data skewed toward certain countries. The unprecedented period of pandemic and restriction order has posed a new challenge toward universities. Many universities took the approach to resume academic activities under remote or online teaching methods while those with lacking resources or preparedness were advised to delay the semester. Studies from previous outbreaks have shown that university students are vulnerable to psychological problems (12–14). There are various factors contributing to the deterioration of student psychological well-being in universities such as fear of dormitory evacuation, event cancellation such as study exchange or uncertainty to graduate and fear of losing future job (15, 16). In addition, factors such as major changes in students' routine and daily life, delayed academic activities, and concern over financial struggle and economic fluctuation were also mentioned which overall might exacerbate the students' psychological condition (10).

Given the sudden consequences (such as online teaching or last-minute change in assessment method) this population is facing in complying with the pandemic control efforts, there is a need to investigate the extent to which the state of the pandemic has affected their negative emotional symptoms, happiness, and work-life balance. This study aims to achieve three objectives (a) to identify the state of negative emotional symptoms, happiness, and work-life balance among university students during the

second and third MCO phases; (b) to compare the state of negative emotional symptoms, happiness, and work-life balance among university students during the second and third MCO phases based on demographic factors; and (c) to investigate the risk and protective factors that can predict the state of negative emotional systems among Malaysian university students. This will serve as an important evidence to inform educational policy and future health promotion interventions for the university students in Malaysia.

## MATERIALS AND METHODS

This study utilized a cross-sectional design using Qualtrics online survey to collect data. Samples were recruited among public and private university students in Malaysia using snowball sampling. Data collection took place within 9 days from 15th April 2020 and ended on 23rd April 2020 when Malaysia was at its second and third phases of MCO. A total of 1,458 responses were retrieved; however, 453 responses were found incomplete making a final 1,005 usable responses. A link to the survey invitation was sent and shared through various social media platforms such as Facebook, WhatsApp, Twitter, and e-mail invitations. The survey was designed using dual languages of Bahasa Malaysia and English. Students in any public or private universities in Malaysia at the time of the study and with no history of psychiatric/mental disorders were eligible to participate.

### Ethical Consideration and Data Collection Procedure

This study has received an ethical evaluation from the Faculty of Arts and Social Sciences, University of Nottingham Malaysia Campus ethics committee (Approval number: FASS2020-0008/DOAP/SKH). A consent form was included in the first page of the survey informing the nature of study, voluntary, and withdrawal terms.

The link or QR code directed potential participants to the research information page and the next consent page. This consent form made clear the commitments and expectations relating to the project (commitments to anonymity and confidentiality, details about uses of data, etc.). The consent form page emphasized a range of issues for which consent was sought, and each participant was asked to indicate their support for each one. All participants were also asked to provide explicit consent by typing "I AGREE" or "SAYA SETUJU."

### Instruments

*Depression, Anxiety, and Stress Scale-21 (DASS-21)* (17). Negative emotional symptoms were assessed using 21-item DASS-21. It consists of depression, anxiety, and stress dimensions with seven items representing each. All items were rated using the scale of 0 to 4—0 (did not apply to me at all), (1) applied to me to some degree or some of the time, (2) applied to me to a considerable degree or a good part of the time, and (3) applied to me very much, or most of the time. Score was calculated using total score multiplied by 2 and further categorized into normal, mild, moderate, severe, or extremely severe levels. Our analyses showed that this scale has good internal consistency using Cronbach's

alpha. The Malay version of DASS-21 scored 0.951 while the English version scored 0.940. The DASS-21 has also been used in previous studies during the COVID-19 pandemic (4, 5, 18).

*Oxford Happiness Questionnaire (OHQ)* (19). The 29-item OHQ was used to measure students' happiness. All items were rated using a 6-point Likert scale ranging from 1 (strongly disagree) to 6 (strongly agree). Our analysis recorded good Cronbach's alpha value with the Malay version scoring 0.723 while the English version scoring 0.827.

*Work-family Conflict Scale (WFC)* (20). Work-life balance was measured using a 10-items WFC scale consisting of two subdimensions of work-to-family and family-to-work conflict. The scale was primarily developed for working population. However, as this juncture shows no relevant scale to measure university student's work-related activities (assignment, logbook, lab work, etc.), this scale is therefore used by explaining to the respondents to relate the items with their university's work. For this scale, the Cronbach's alpha is also good with the Malay version recording 0.932 while the English version scored 0.946.

### Statistical Analysis

Data analysis was performed using IBM Statistical Package for Social Science (SPSS) version 25 and AMOS version 26 employing both descriptive and inferential statistics. *T*-test and ANOVA analysis were performed for comparing means between groups according to demographic factors. Meanwhile, multivariate logistic regression analysis was performed to assess potential risk and protective factors for the incidence of severe depression, anxiety, and stress symptoms among participants. Results were presented using odds ratios (ORs) and bias corrected (BC) 95% confidence intervals. Path analysis was performed to examine the link between constructs of the study by observing beta estimates ( $\beta$ ).

### Data Assumptions

Multicollinearity and normality assumptions were assessed using skewness, kurtosis, and Q-Q plot. Following the suggestion by Garson (21), data was meeting the range for acceptable with skewness and kurtosis with  $\pm 2$  for skewness and  $\pm 3$  for kurtosis with a straight diagonal line for Q-Q plot observed.

## RESULTS

### Demographic Profile, Location, and Status at the Period of Lockdown

**Table 1** presents the descriptive characteristics of our participants. In summary, the majority of the respondents were female with 75.5% ( $n = 759$ ), while male participants only made up a total of 24.5% ( $n = 246$ ) from the entire population. Most respondents ( $n = 523$ ) were between 17 and 22 years old. Only 6% were aged 35 years and above ( $n = 60$ ). Results indicated Malay ethnicity representing almost a three-quarter ( $n = 746$ , 74.3%) of the overall population in this study. Public university students recorded 70.2% ( $n = 706$ ), meanwhile only 29.8% were from private universities ( $n = 299$ ).

At the point of data collection, a total of 36.0% of our respondents were located in the central region ( $n = 362$ ), 11.1%

**TABLE 1** | Respondents' demographic characteristics ( $N = 1,005$ ).

in the east coast ( $n = 112$ ), a total of 13.8% were located in the northern region ( $n = 139$ ), following 32.5% in the southern region ( $n = 327$ ). Those in East Malaysia and outside Malaysia

were represented by 5.7% ( $n = 57$ ) and 0.8% ( $n = 8$ ), respectively. Information for the study program was reclustered into two categories of technical and non-technical programs as defined by the Ministry of Higher Education Malaysia (22). For this, a total of 39.9% were from technical programs ( $n = 401$ ), meanwhile, 58.7% ( $n = 590$ ) were enrolled in non-technical programs. A very small percentage of 1.4% chose not to state their program. Lastly, more than half of our respondents ( $n = 603$ , 60%) were currently at their hometown, 15.0% ( $n = 151$ ) were on campus, meanwhile 18.2 stayed outside campus ( $n = 183$ ).

## Students Levels of Negative Emotional Symptoms, Happiness, and Work-Family Conflict During the Period of COVID-19 Lockdown

Tables 2–4 summarize negative emotional symptoms, happiness, and work-family conflict levels among our respondents. Descriptive statistics were analyzed using mean and frequency in the SPSS. In summary, the result suggests that the majority of students scored normal to mild for stress, anxiety, and depression levels. A total of 7.9, 8.0, and 8.4% scored severe stress, anxiety, and depression levels. This was followed by 2.8, 14.8, and 10.6% who scored extremely severe stress, anxiety, and depression levels (please refer to Table 2). Combining moderate to extremely severe levels altogether, this study found a total percentage of 22.0% of students suffering from stress, 34.3% from anxiety, and 37.3% from depression symptoms.

Table 3 indicated that half of the participating students scored from “rather happy” and “very happy” for happiness. Few students accounted for 11.6% indicating that they were unhappy or somewhat unhappy, 38.4% of our respondents were not particularly happy or unhappy making a total of 50.0% for these three categories.

Meanwhile, results in Table 4 suggested that the majority of students were experiencing low to moderate levels of work-to-family conflict and family-to-work. Those who experienced moderate to extremely high levels of work-to-family conflict accounted for 50.4% from the overall percentage for work-to-family conflict and 39.2% for family-to-work conflict.

## Differences in Students' Level of Negative Emotional Symptoms, Health, Happiness, and Work-Family Conflict Based on Demographic Factors

*T*-test and one-way ANOVA were performed to assess differences in students' level of negative emotional symptoms, happiness, and work-family conflict during the lockdown period based on demographic profiles. Overall test and *post-hoc* results in Tables 5, 6 revealed that there were significant differences in the DASS-S, DASS-A, DASS-D, happiness, W-FC, and F-WC levels across different demographic factors. Detailed results indicated differences in terms of DASS-S mean level for age, location, university type, and ethnicity with the  $p < 0.05$ . Specifically, students from the northern region ( $\mu = 1.679$ ,  $p < 0.001$ ) had lower stress symptoms compared with those in

**TABLE 2 |** Stress, anxiety and depression symptoms severity categorization ( $N = 1,005$ ).

	Normal		Mild		Moderate		Severe		Extremely severe	
	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%
DASS-S	664	66.1	120	11.9	114	11.3	79	7.9	28	2.8
DASS-A	498	49.6	162	16.1	116	11.5	80	8.0	149	14.8
DASS-D	487	48.5	143	14.2	184	18.3	84	8.4	107	10.6

*f*, frequency; %, percentage; DASS-S, stress; DASS-A, anxiety; DASS-D, depression.

<sup>a</sup>Scoring is based on a manual published by (23). After multiplying the scores by 2, the total score was categorized into five; normal, mild, moderate, severe, or extremely severe. Depression was scored with a total score from 0 to 9 for normal, 10 to 13 for mild, 14 to 20 for moderate, 21 to 27 for severe depression, and 28 to 42 for extremely severe depression. Anxiety was calculated based on scores 0–7 normal, 8–9 for mild, 10–14 for moderate, 15–19 for severe, and 20–42 for extremely severe. Lastly, stress was scored from 0 to 14 for normal, 15 to 18 for mild, 19 to 25 for moderate, 26 to 33 for severe, and 34 to 42 for extremely severe.

**TABLE 3 |** Happiness total score categorization ( $N = 1,005$ ).

	Not happy		Somewhat unhappy		Not particularly happy or unhappy		Rather happy		Very happy	
	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%
Happiness OHQ	9	0.90	108	10.7	386	38.4	421	41.9	81	8.1

Not happy score is between 0 and 58, somewhat happy score is between 59 and 87, not particularly happy or unhappy score is between 88 and 116, rather happy is between 117 and 145, very happy score is between 146 and 173, and too happy score is 174.

*f*, frequency; %, percentage.

**TABLE 4 |** Work-family conflict and family-work conflict total score categorization ( $N = 1,005$ ).

	Very low		Low		Moderate <sup>a</sup>		High <sup>a</sup>		Extremely high <sup>a</sup>	
	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%	<i>f</i>	%
W-FC	102	10.1	396	39.4	302	30.0	148	14.7	57	5.7
F-WC	173	17.2	438	43.6	222	22.1	125	12.4	47	4.7

*f*, frequency; %, percentage; W-FC, work-to-family conflict; F-WC, family-to-work conflict.

<sup>a</sup>Moderate-extremely high defined as W-FC  $\geq 16$ , F-WC  $\geq 16$ . Scoring: 0–5 for very low, 6–10 for low, 11–15 for moderate, 16–20 for high, and 21–25 for very high.

the East Coast ( $\mu = 1.936$ ,  $p < 0.001$ ), central regions ( $\mu = 1.917$ ,  $p < 0.001$ ), and outside the country ( $\mu = 2.298$ ,  $p < 0.001$ ).

For DASS-A, findings indicated that a total of four demographic factors were significant. In detail, private university students ( $\mu = 1.676$ ,  $p < 0.001$ ) generally had a higher anxiety level compared with the public university students ( $\mu = 1.609$ ,  $p < 0.001$ ). Younger students within the age bracket between 17 and 22 years old ( $\mu = 1.667$ ,  $p < 0.001$ ) and 23 and 28 years old ( $\mu = 1.624$ ,  $p < 0.001$ ) had higher symptoms of anxiety compared with more mature students aged 35 and above ( $\mu = 1.377$ ,  $p < 0.001$ ). Students' anxiety levels were also different based on locations where those from East Malaysia region displayed lower anxiety symptoms ( $\mu = 1.386$ ,  $p < 0.001$ ) compared to other regions. Moving on, students' levels of anxiety were different based on risk to contagion level and ethnicity status. Surprisingly, those in the moderate risk area were experiencing higher anxiety symptoms ( $\mu = 1.765$ ,  $p < 0.05$ ) compared with those in the high-risk area ( $\mu = 1.608$ ,  $p < 0.05$ ).

Meanwhile, for DASS-D, depression levels were different based on age and location. Older students aged 35 years old and

above were found to report lower levels of depression ( $\mu = 1.500$ ,  $p < 0.001$ ) compared to younger students aged between 17 and 28 years old ( $\mu = 1.667$ ,  $p < 0.001$ ;  $\mu = 1.624$ ,  $p < 0.001$ ). We also found that students in East Malaysia region were experiencing lesser depression symptoms ( $\mu = 1.681$ ,  $p < 0.001$ ) compared with students in other regions.

Three factors were found significant when comparing students' happiness levels. First, older students tend to be happier (29–34 years old:  $\mu = 4.508$ ,  $p < 0.001$ ; 35 years old and above:  $\mu = 4.590$ ,  $p < 0.001$ ) compared with younger students (19–22 years old:  $\mu = 4.102$ ,  $p < 0.001$ ; 23–28 years old:  $\mu = 4.172$ ,  $p < 0.001$ ). Second, students in the East Malaysia ( $\mu = 4.383$ ,  $p < 0.01$ ) and Northern region ( $\mu = 4.354$ ,  $p < 0.01$ ) tend to be happier than those in other regions. Third, Malay ethnicity recorded highest happiness levels ( $\mu = 2.275$ ,  $p < 0.001$ ) compared with other ethnicities.

Meanwhile, for both work-to-family and family-to-work conflict, only location and ethnicity was found to contribute to significant differences in terms of levels. Specifically, students from the East Coast region recorded the highest W-FC ( $\mu = 2.463$ ,  $p < 0.01$ ) and F-WC ( $\mu = 2.321$ ,  $p < 0.01$ ) compared

to other regions. Moreover Malay students recorded the highest for both W-FC ( $\mu = 2.376, p < 0.01$ ) and F-WC ( $\mu = 2.173, p < 0.01$ ) compared with other ethnicities.

### Risk and Protective Factors of Students' Level of Negative Emotional Symptoms During the Period of COVID-19 Lockdown

Multivariate logistic regression was performed using the Enter method to analyze students' risk factors to develop severe to extremely severe level of depression, anxiety, and stress symptoms. A summary of the results is presented in Table 7. Our overall model was significant, suggesting a good fit between data. A total of six predictors were tested: age, level of study, risk to contagion, happiness, work-to-family conflict, and family-to-work conflict. The dependent variables were clustered into two categories. "Zero" referring to a baseline group or cases with normal to moderate levels of negative emotional symptoms while "1" is the observed group referring to cases with severe to extremely severe levels of negative emotional symptoms. The results suggested that demographic factors of age, level of study, and risk of contagion did not predict the odds of occurrence severe or extremely severe stress, anxiety, and depression symptoms. Happiness was found as a protective factor, suggesting that a greater happiness score lowers the odds of experiencing severe to extreme stress (OR = 0.240, 95% CI: 0.180, 0.321), anxiety (OR = 0.336, 95% CI: 0.273, 0.414), and depression (OR = 0.121, 95% CI: 0.088, 0.165). Meanwhile, both work-to-family conflict and family-to-work conflict are found as risk factors for developing severe to extreme levels of different negative emotional symptoms. Detailed results suggest that a higher score of work-to-family conflict increases 1.45 times the odds of suffering from severe to extremely severe anxiety symptoms (OR = 1.453, 95% CI: 1.161, 1.818) while a greater score of family-to-work conflict increases the odds of experiencing severe to extremely severe stress and anxiety symptoms by 1.47 times (OR = 1.468, 95% CI: 1.109, 1.943) and 1.32 times (OR = 1.317, 95% CI: 1.059, 1.683) respectively.

### The Link Between Negative Emotional Symptoms, Happiness, and Work-Family Constructs

To further examine the linkages between constructs in this study, we performed path analysis a subset of SEM technique using AMOS software which overall finding is illustrated in Figure 1. Result suggests that all paths in this study are found significant. Mainly, the increase in happiness level is linked to lower stress ( $\beta = -0.521, p < 0.001$ ), anxiety ( $\beta = -0.387, p < 0.001$ ), and depression ( $\beta = -0.666, p < 0.001$ ) symptoms. Meanwhile, both high work-to-family and family-to-work conflicts are linked to higher stress (W-FC:  $\beta = 0.074, p = 0.036$ ; F-WC:  $\beta = 0.162, p < 0.001$ ), anxiety (W-FC:  $\beta = 0.110, p = 0.005$ ; F-WC:  $\beta = 0.115, p = 0.004$ ), and depression symptoms (W-FC:  $\beta = 0.071, p = 0.024$ ; F-WC:  $\beta = 0.094, p = 0.003$ ).

## DISCUSSION

### Students' Levels of Negative Emotional Symptoms, Happiness, and Work-Family Conflict During the Period of COVID-19 Lockdown

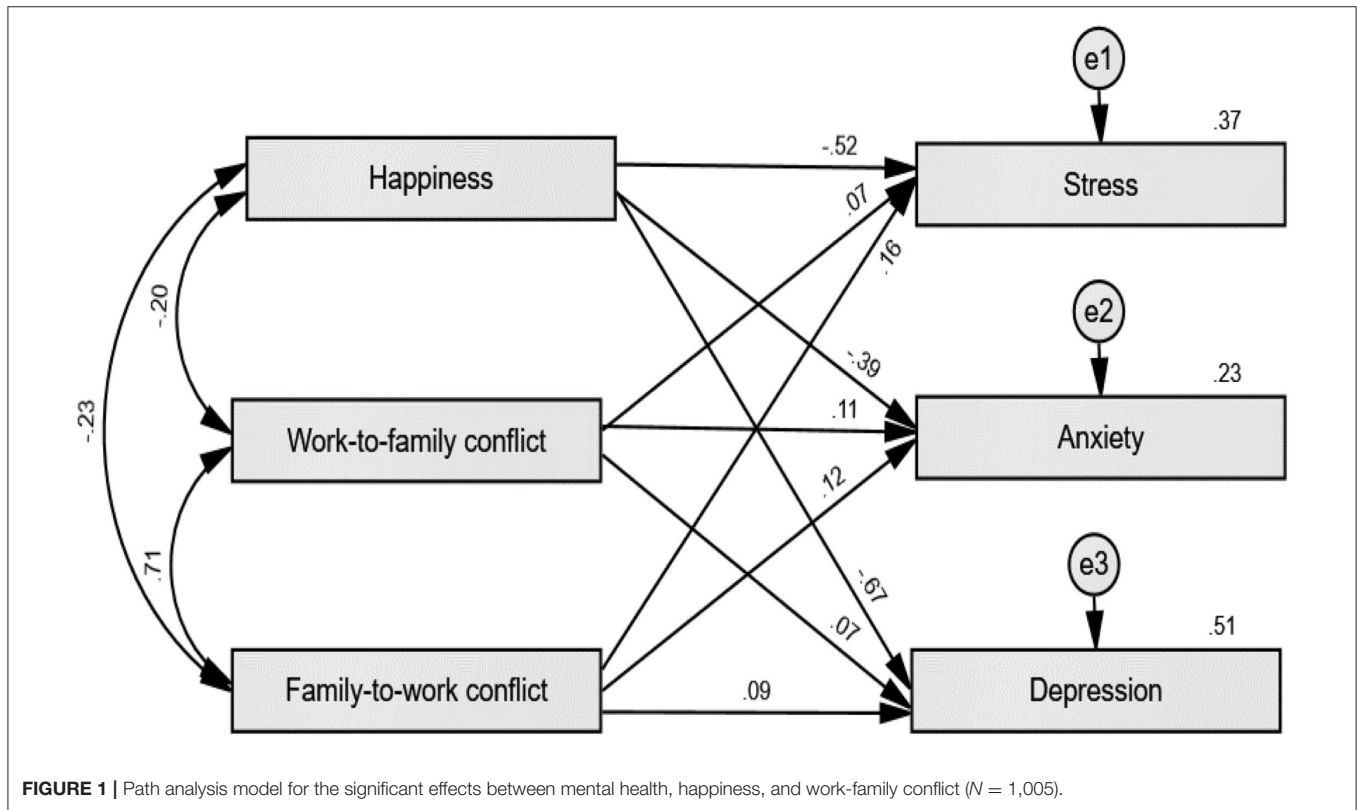

The implementation of the first MCO in Malaysia was generally found to be effective for curbing the spread of COVID-19; however, less is known on how it affected the psychological outcomes of university students. In terms of negative emotional symptoms, it appears that the majority of students experience normal level of stress symptoms. However, a major cause of concern was that nearly a quarter of students experience severe to extremely severe symptoms of anxiety and depression. Notably, nearly 40% of the students experience moderate to extremely severe symptoms of anxiety and depression. In comparison with a study conducted immediately after the COVID-19 outbreak in China, 16.5% reported moderate to severe depressive symptoms and 28.8% reported moderate to severe anxiety symptoms (24). Our findings to some extent are consistent with other studies that reported that outbreaks may trigger negative emotions either for COVID-19 (25) and SARS outbreaks (26, 27). This highlights the urgent need to cater to the mental health needs of the students to prevent further escalation without appropriate early interventions. Despite the alarming level of negative emotional symptoms, half of the students rated their happiness level as "rather happy" or "very happy." Our findings highlight further evidence that happiness can be maintained despite the fluctuating nature of our positive and negative mood (17).

This study also extends the understanding of students' state of work-family conflict during the period of MCO. Despite the lack of discussion on this notion among this population (11), our findings established compelling evidence that students are likewise experiencing interference of work and life conflict alike the working population. Work-family conflict refers to pressure from one area of life that negatively affects the other (19). An alarming rate of 50.4 and 39.2% of our total respondents were found to be experiencing high to very high levels of W-FC and F-WC which is significantly higher than average levels reported in the past research (11). This signifies that unconducive environment due to MCO carries certain negative implications to the students' everyday life. Having to stay at home with family members or to be confined in restricted university accommodations for a longer period may contribute to a different obstacle in their everyday life. Besides, the lack of resources and immense changes in terms of assessment might contribute to the conflict occurrences. Findings suggest that more students are experiencing higher work-to-family conflict compared with family-to-work conflict. In line with past research (11, 20), work behavior inflicts more damage to the family aspect, rather than the vice versa. Hence, engaging and spending time in academic-related activities such as online learning, assignment, and other related activities are perceived as a greater source of conflict during the MCO period.

### Differences in Students' Level of Negative Emotional Symptoms, Happiness, and Work-Family Conflict Based on Demographic Factors

Further analysis indicated that the level of stress, anxiety, and depression were significantly different according to age

and geographic location. Younger students experienced more stress, anxiety, and depression symptoms compared with older ones. Research on the wider youth population conducted during the COVID-19 outbreak found younger college and school students reported higher levels of psychological distress compared with older students (8). Our study, however, does not record statistically significant different levels of symptoms

according to study level (i.e., diploma, degree, masters, etc.) with consideration that the proportion of undergraduate degree students far exceeded the others. Those in central locations were more depressed, while those in the east coast region were more stressed and anxious. While the risk of contagion varies within specific locations in the central region, it can be said that the central region in Malaysia is more densely populated compared with other regions with more number of positive COVID-19 cases reported in the central region.

There is also a significant difference and higher stress and anxiety symptoms among private university students compared with public university students. In general, most public universities in Malaysia are equipped with more comprehensive facilities in offering support to the students. Undeniably, attention to all students regardless of background is imperative, and our data highlights the need for more support for those in the private universities. Anxiety symptoms also differed according to the risk of contagion of the different locations. Unsurprisingly, much lower symptoms were recorded in low-risk regions or the “green zones.” However, slightly higher anxiety symptoms were recorded in moderate-risk regions compared with high-risk regions. A possible explanation for this is that the high-risk region may already be on red alert whereas moderate-risk regions may subdue its possible negative implications causing uncertainties. In essence, anxiety may also develop due to uncertainties of possible threats which compromises our ability to avoid or mitigate its negative implications (28).

Our data also shows that older students tend to be happier than younger students during the COVID-19 lockdown. Previous studies have reported that global happiness of university students follows an inverted parabola pattern in which happiness gradually increases as students aged but a sudden drop is observed with older students (29–31). It should be highlighted that nearly 90% of our respondents were between 17 and 28 years old that was consistent with the inverted parabola pattern. On the other hand, our findings show that the increment continues for older students despite the significantly underrepresented group of older students. Moreover, students’ happiness levels also varied based on location. Those in the central region recorded lowest happiness level, followed by those who are currently situated in the east coast and southern regions. These findings suggest that students located at the central region were least happy compared with the rest of the population, and these might be due to several plausible explanations. At times where this study was conducted, the central region was the most badly affected area due to COVID-19 with more than half of the subregions declared as “red” or high-risk zones. Dealing with very strict rules and such limited access to facilities might contribute to their slightly lower happiness level compared with the rest.

Meanwhile, there was a significant difference in terms of means level based on the type of university, location, and ethnicity for the experience of work-family conflict. Public university students, in particular, were found to record higher W-FC level compared with those from private universities.

Besides, the finding indicates that those in the east coast and southern region to report a higher level of W-FC compared with the rest. Malay ethnicity experienced higher W-FC levels compared with Indian and other ethnic groups. While it is difficult to provide a meaningful explanation to some of these findings, these patterns give some valuable insight on conflict experience based on demographic factors. It was argued that students who received greater support from the university and with higher satisfaction were likely to experience lower between domain conflict (32). This signals that gaps might exist between strategy and level of support implementation given by public and private university to students during the MCO period which may contribute to such differences. It highlights a pivotal point for policy makers or researchers to focus on a specific ethnic group, Malay which is found more vulnerable to experiencing higher between domains conflict.

### **Risk and Protective Factors of Students’ Level of Negative Emotional Symptoms During the Period of COVID-19 Lockdown**

Our findings indicated that students with higher levels of happiness have decreased probability to have severe or extremely severe symptoms of stress, anxiety, and depression. Such a finding was also aligned in the path analysis, whereby we found evidence on the negative linear relationship between happiness with the three mental health constructs. Likewise, a large-scale cross-sectional study on 2,383 university students in Korea whereby happiness is associated with lower risk of depression symptoms (33). For decades, the field of clinical psychology has primarily focused on problems and deficits. In recent years, however, positive factors of psychological well-being pioneered by Martin Seligman have been starting to receive wide attention among researchers (34). In essence, our findings build on the fact that while negative symptoms may precipitate negative emotional symptoms, positive aspects such as happiness can be a protective factor for negative emotional symptoms among university students. Importantly, our evidence establishes a strong link between low happiness level with higher depression level, which suggests the importance of improving student’s subjective experience as one of the focal points to improve their mental health. Consistent with this, the directional nature can be two ways as once highlighted by Richard Layard, the coeditor of the World Happiness Report; “Better treatment for mental health would improve happiness directly; and improving happiness in other ways would reduce the frequency of mental illness” (35).

On the negative note, this study identifies work-family conflict and family-work conflict as potential risk factors for developing severe or extremely severe anxiety and stress symptoms. This finding aligns with our path analysis result which suggested positive links between work-family conflict with stress, anxiety, and depression. In line with a previous study conducted in Minia, Upper Egypt, W-FC was associated with an increase in the probability of developing severe anxiety symptoms (36). Moreover, the likeliness of students developing severe stress

and anxiety is higher following the increasing score of F-WC. Following the concept of work-family conflict as a form of inter-role conflicts, this study provides support from the student's context that work-family and family-work conflicts may contribute to stress and anxiety. It also stresses the potential risk of students' everyday environment and their life integration practice during unprecedented times of COVID-19 as an area that needs serious attention. It is evident from past research that overall educational experience plays a great role in eliciting between domains conflict (32), henceforth monitoring such occurrence will reduce the risk of negative emotional symptoms among students' population.

## IMPLICATIONS AND RECOMMENDATIONS

In this section, implication and recommendation of this study will be emphasized by using the Strengths, Weaknesses, Opportunities, and Threats (SWOT) strategies.

### Strengths

Most institutions have their own vision planning and during this time, challenges should complement strategic planning based on current resources. Most universities do have facilities to manage financial structure, academic curriculum, and psychosocial support. Therefore, they need a strategic plan that can benefit all parties involved in universities. Enhance the role of psychosocial support not only among students but also their families and all university staff to ease the burden of public health care. Online psychological interventions such as mindfulness-based therapy and cognitive behavior therapy were found to be helpful during the COVID-19 pandemic (37). University management could offer structured support systems in the areas of academic, finance, and counseling (both career and psychological health). Hence, it is of prominent importance that universities establish guidelines for virtual services that include all systems such as counseling, lecture, enrolment, and industrial collaboration. If online counseling is to be implemented by universities, a proper guideline is also needed considering privacy, confidentiality, and professional ethics besides the emphasis on the accessibility and availability of technology for students from varied locations.

### Weaknesses

Clearly, enrolment of domestic and international students will be reduced and on-campus tuition will not begin until 2021 resulting to the financial structure being affected. University management, lecturers, and research supervisors should change old practice to suit new norms together to ease the needs of students. This aspect is essential not only to understand academic challenges but also work and family conflict that may be experienced by students while also recognizing the challenges they face such as work from home, children's challenges, and other factors. These two issues will continue to be part of weaknesses if people are not flexible in adjusting to changes that are deemed as necessary.

### Opportunities

Due to the above weaknesses, vision planning will coexist and complement strategic planning. For instance, private and small colleges and universities can collaborate with other institutions. The academic structure may combine the best of both direct and online learning approaches. The recruitment activities throughout the year will allow applicants more flexibility in the selection and enrolment of colleges and universities. New business models and financing options will bring stability to the "bottom line." All universities should be encouraged for cooperation rather than competition to ensure both parties (i.e., universities and ministries; students and family) can benefit behind this pandemic. Replace competition with collaboration between colleges, private universities, and governments that have had to postpone operations or even shut down due to declining enrolment and student income. Universities that have the potential to be financially viable can offer intellectual or material collation so that the impact of the virus is not to cease the operation of educational institutions but to revitalize and strengthen the education system forward.

In terms of offering psychosocial services and support such as assessment and intervention (counseling, psychology, and psychiatry), professionals in these fields need to not only double their efforts in the traditional practice locations but also facilitate the use of virtual technology beyond logistics restrictions to provide appropriate services to students irrespective of their physical locations. This is even more imperative considering the high number of referral cases received by the public health services for the assessment and interventions of psychological issues in Malaysia (38). Programs utilizing psychologically positive methods can also be implemented for those affected by this COVID-19 pandemic to enhance aspects of happiness, gratitude, and emotional regulation. For students with diagnosis of mental illness or even with early signs of disorders, serious attention should be given so that the consequence will not worsen.

### Threats

COVID-19 pandemic accelerates the end of the traditional semester-based system for college enrolment, progress, and graduation. Some colleges and universities may be forced to close down. If the academic year is restructured, then the recruitment year must be restructured. An effective method of communication is important to ensure future students, graduates, and their parents are well-informed about any changes to be made. New business models and financing options shall be introduced to encourage students to continue their education without adding more burden to their families. The amount of annual/semester fees and other required fees should be reconsidered by the universities accordingly. Economic vulnerabilities may be one of the reasons for students' reluctance to seek help if they experience COVID-19 symptoms. These imply a need for involving the university clinics and health services as local health gatekeepers who are the first point of detecting and reporting of suspected COVID-19 cases (39), as well as a channel where accurate information regarding COVID-19, protective equipment, and intervention packages

can be delivered (40). Having COVID-19 testing centers in the universities are also recommended (39).

In sum, the psychological impact of the COVID-19 pandemic allows fresh opportunities for all parties to improve current financial management weaknesses, advance higher education curricula, enhance online learning opportunities, and most importantly improve communication between students, families, and universities to collaborate for the sake of good mental health and future prospect.

## LIMITATIONS AND FUTURE RESEARCH

This study has several limitations. In view of the MCO restrictions, we employed the non-probability snowball sampling method, therefore the findings do not reflect the overall patterns of negative emotional symptoms, happiness, and work-life balance and are not generalizable to the wide university student population in Malaysia. Moreover, our study also did not investigate possible confounders such as electronic device availability, Internet accessibility, premorbid personality, and coping style that could have an influence toward the study results. In addition, since this study was conducted during specific MCO period, thus findings are subjected to the unique circumstance of when this study took place. It cannot however be used to understand post-MCO period behavior. Therefore, future researchers might want to conduct studies investigating

fluctuation in terms of emotional and behavioral symptoms between the lockdown transition periods.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Faculty of Arts and Social Sciences, University of Nottingham Malaysia Campus ethics committee (Approval number: FASS2020-0008/DOAP/SKH). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

WMAWMY and SKZB contributed to the conception of the study, contributed significantly to analysis, manuscript preparation, performed the data analyses, and wrote the manuscript draft. SAP and FM helped modify the manuscript. WMAWMY, SKZB, SAP, and FM contributed to the interpretation and discussion of the results of the analysis. All authors contributed to the article and approved the submitted version.

**Objective:** The objective of our current research is to compare the different psychological interventions and distinguish the most effective way to treat psychological crisis according to different clinical manifestations in people affected by coronavirus disease 2019 (COVID-19). No previous systematic review has provided a comprehensive overview by performing a Bayesian network meta-analysis of this current topic.

**Method:** A systematic review and a Bayesian network meta-analysis were conducted on randomized controlled trials (RCTs), non-RCTs, case-control studies, self-controlled case series (SCCS), cohort studies, and cross-sectional studies of all the available interventions for psychological crisis in people affected by COVID-19. We searched the electronic databases EMBASE, PubMed, Web of Science, PsycINFO, and Cochrane Library, as well as the Chinese databases such as Sinomed, Chinese Biomedicine Literature (CBM), Chinese Scientific Journal Database (VIP), WanFang Database, and China National Knowledge Infrastructure (CNKI), from 2019 to April 30, 2020. The main outcomes were self-rating anxiety scale (SAS), self-rating depression scale (SDS), patient health questionnaire (PHQ-9), and symptom checklist (SCL-90). The study is registered with Inplasy, number 202050076.

**Result:** Sixteen self-controlled case series (SCCS) comprising 1,147 participants compared five different psychological interventions with four different measurement scales were included in this study. For effectiveness, all the psychological therapies were significantly more effective than before intervention. Our results showed that supportive therapy (ST), which is adjusted to the COVID-19-related mental crisis, is the best treatment compared with behavioral therapy (BT), nursing-based psychological

therapy (NBPT), traditional Chinese medicine therapy (TCMT), and COVID-19-related standard training (CRST) at reducing the anxiety-related symptoms assessed by SAS. When measured by SDS, BT was better than ST and NBPT treatment for reducing the depression symptoms. And ST was better than BT and ST+BT as assessed by PHQ-9. In the end, the last network meta-analysis indicated that NBPT was more effective than ST by the measurement of SCL-90.

**Conclusion:** Our research suggested the potential effectiveness of psychological interventions for decreasing psychological crisis in people affected by COVID-19 and try to introduce the best effective treatment options for clinical practice according to the clinical manifestations of psychological problems, but further confirmation from high-quality RCTs is needed.

**Keywords:** psychological intervention, COVID-19, affected people, psychological crisis, network meta-analysis

## INTRODUCTION

The acute respiratory infectious disease caused by the outbreak of coronavirus disease 2019 (COVID-19) spread quickly to all parts of the world. The World Health Organization (WHO) points out that the COVID-19 is an international public health emergency with the highest mortality rate among the new-onset infectious diseases (Sohrabi et al., 2020). The outbreak occurred during the Chinese New Year. The high mobility of the population is very conducive to the spread of the virus, resulting in a rapid increase in the number of affected people, which poses a great threat to human health, resulting in extremely tight medical resources and immense psychological pressure on both medical staff and patients (Blake et al., 2020; Talevi et al., 2020).

Due to the impact of the epidemic, many changes have taken place in people's daily lives. Life seems to be filled with information related to the epidemic. There has also been a panic reaction of irrationally hoarding food, snapping up masks, and disinfecting supplies. Many studies have found that COVID-19 patients and medical staff are more prone to mental disorders than the general population, such as feeling uneasy, worried, fear, confused, and helpless; insomnia; depression; and other psychological crises (Petzold et al., 2020; Wu and Zhang, 2020).

Psychological intervention is aimed to reduce the risk of acute psychological crisis and stabilize or reduce the direct and serious consequences of psychological crisis on the individual, thereby promoting the individuals to recover from the crisis. After the outbreak, whether or not to take correct measures in a timely manner is an important factor in rehabilitation. We believe that actively carrying out mental health work on such people can reduce the potential and long-term impact on the mind.

At present, Internet information is convenient and well-developed; various stress manuals, methods of psychological intervention (including professional intervention and self-intervention), video, audio, and WeChat articles are overwhelming. Information overload makes many effective psychological intervention methods submerged in a large amount of information. And which psychological intervention is better is still controversial. Therefore, finding effective psychological intervention is particularly important. Based on this, the Bayesian method is used here to analyze the

therapeutic effects of different psychological interventions and to explore the best psychological intervention methods under the COVID-19 epidemic.

We compared five different psychological interventions in this research. First, supportive therapy (ST) is a commonly used and well-developed psychological intervention with a long history, and the studies we included in this article were adjusted according to the particularity of the COVID-19 epidemic. Second, BT is another commonly used non-pharmacological application defined as behavior-change intervention, including exercise or changes in daily activity to help deal with the psychological problems. Third, traditional Chinese medicine therapy (TCMT) is a psychological adjustment method based on traditional Chinese medicine theory and modern psychology, such as acupoint-plucking emotional freedom method (Tian, 2014). Next, COVID-19-related standard training (CRST) refers to the training of medical expertise in the guidelines related to the COVID-19, as well as learning to deal with psychological crisis caused by COVID-19. The last one, nursing-based psychological therapy (NBPT), is a unified nursing process with characteristics formulated according to the COVID-19 treatment plan, including breath training and psychological evaluation and guidance. We hope to provide scientific and effective psychological intervention methods for maintaining the mental health of people affected by COVID-19.

## METHODS

We conducted this study according to the Cochrane Handbook for the Systematic Review of Interventions (see details at <http://training.cochrane.org/handbook>), and reporting was in line with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) extension statement for network meta-analyses (Liberati et al., 2009). Included studies were classified according to the types of psychological interventions.

## Search Strategy

We searched the electronic databases EMBASE, PubMed, Web of Science, PsycINFO, and Cochrane Library, as well as Chinese databases such as Sinomed, Chinese Biomedicine Literature

(CBM), Chinese Scientific Journal Database (VIP), WanFang Database, and China National Knowledge Infrastructure (CNKI), from 2019 to April 30, 2020. Searches were not restricted by language. We aimed to compare all psychological interventions used for psychological crisis in people affected by COVID-19 (see **Supplementary Figure 1** for full search terms).

## Study Selection

### Participants

Psychological crisis was assessed in people affected by COVID-19, which includes confirmed patients, patients with suspected infection, quarantined relatives, and other patients who have a high risk of infection due to other diseases that have to be treated in the hospital, as well as caregivers and health-care professionals, such as doctors, nurses, and health-related administrators.

### Interventions

All types of psychological interventions were included as long as the explicit aim was to prevent anxiety, depression, and fear of any other type of psychological crisis.

### Comparisons

Any type of psychological treatments was compared with each other or with other control groups (placebo, blank, and usual care) who were eligible.

### Outcomes

At least one outcome reported psychological symptoms. The primary outcomes were self-rating anxiety scale (SAS), self-rating depression scale (SDS), patient health questionnaire (PHQ-9), and the symptom checklist (SCL-90), which were also analyzed by a network meta-analysis.

### Study Design

Randomized controlled trials (RCTs), non-RCTs, case-control studies, self-controlled case series (SCCS), cohort studies, and cross-sectional studies were all included.

### Exclusion Criteria

(1) The same patients were enrolled in different articles; (2) duplicate reports, conferences, observational studies (prospective and retrospective), review articles, nonhuman studies, studies with incorrect comparator, and case reports were strictly excluded.

## Data Extraction and Quality Assessment

Two investigators (YY and SWH) independently selected the studies. The extractions of the relevant information from the included trials were extracted with a predetermined data extraction sheet (**Table 1**). The risk of bias assessments was performed at the outcome measure level during data collection. And different types of tool were used according to the different study designs. Any disagreements were resolved through discussion. When they could not reach a consensus, the final decision regarding each question was made by other investigators (HBL) within the review team.

## Statistical Analysis

First, we summarized and analyzed the baseline data and outcomes of involved studies' characteristics. Accordingly, mean differences (MDs) for continuous outcomes with 95% credible intervals (CrIs) were selected to reflect the assessments.

We conducted two types of meta-analyses. First, we conducted traditional pairwise meta-analyses using a random-effects model, through which the heterogeneities and publication biases among the trials were well anticipated before the Bayesian network meta-analysis. The analysis above evaluated the heterogeneities by the  $I^2$  statistic and judged the publication biases using funnel plots, and all the processes were performed in RevMan version 5.3.

A Bayesian network meta-analysis was conducted by using Aggregate Data Drug Information System (ADDIS, version 1.16.8). This software is based on the Bayesian framework and the Markov chain Monte Carlo method, which can evaluate *a priori* and process research data. The  $I^2$  statistic will be used to assess levels of the heterogeneity. Fixed-effects models will be used if the  $I^2$  value is 0.05, indicating good consistency. Iteration number will be set to 50,000; and the first 10,000 iterations for annealing will be set up to eliminate influences of the initial value. For indirect comparison, continuous outcomes will be calculated as standardized mean differences (SMDs), and binary outcomes will be calculated as ORs. Both types of effect sizes will be presented with 95% CrIs, and values of  $p < 0.05$  will be regarded as statistically significant. The analysis of the network plot will show the evidence supporting the relationship between the included studies. Also, the result figures and network meta-analysis graphs will be provided.

## RESULTS

### Study Identification and Selection

In total, 6,194 citations published between 2019 and April 30, 2020, were identified by the search. **Figure 1** shows the process of study selection. Eventually, 16 unique researches involving 1,147 unique patients were eligible for further analyses. The baseline characteristics of the studies were also extracted (**Table 1**).

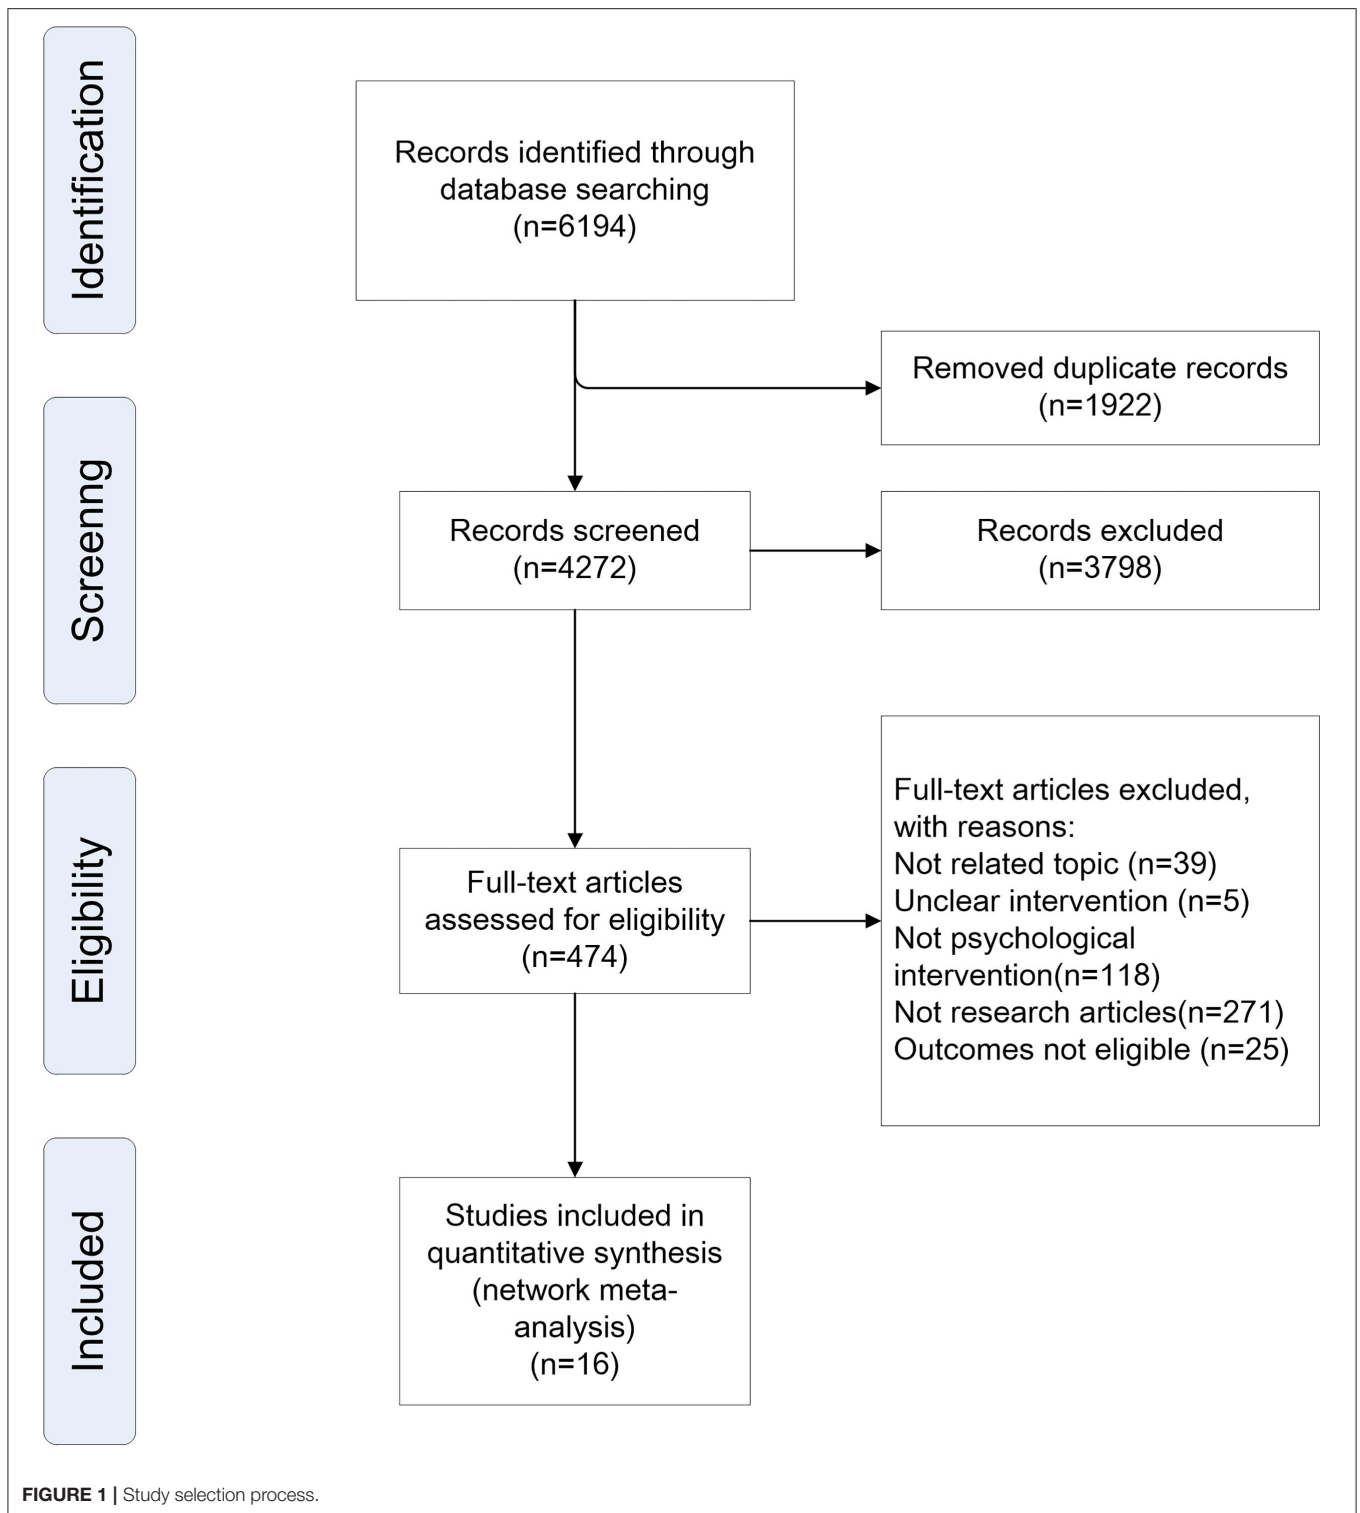

### Quality Assessment of Included Studies

Due to the particularity of COVID-19, it is difficult to conduct RCT research as far. After final screening, all the experiments included in this systematic review are SCCS (nonrandomized) without any RCTs. So we utilized the Newcastle-Ottawa scale (NOS) with a slightly adapted version to match the needs of this study to evaluate the quality of SCCS studies ([http://www.ohri.ca/programs/clinical\\_epidemiology/oxford.asp](http://www.ohri.ca/programs/clinical_epidemiology/oxford.asp)). The quality of the studies was evaluated by examining three items: patient selection, comparability of groups, and assessment of outcome. Studies were graded on an ordinal star scoring scale, with higher scores representing studies of higher quality. A study can be awarded a maximum of one star for each numbered item within the selection and exposure categories, and a maximum of two stars can be given for the comparability. The quality of each study was

**TABLE 1** | Baseline of included studies.

Year	First author	Location	Participants	Mean age in years	Sex	Intervention	Main outcomes	Final sample size	Duration

TCMT, traditional Chinese medicine therapy; SAS, self-rating anxiety scale; CRST, coronavirus disease 2019-related standard training; NBPT, nursing-based psychological therapy; SDS, self-rating depression scale; BT, behavioral therapy; SF-36, 36-Item Short Form Health Survey; PHQ-9, patient health questionnaire; ST, supportive therapy; SCL-90, symptom checklist; GAD-7, General Anxiety Disorder-7; PSQI, Pittsburgh Sleep Quality Index.

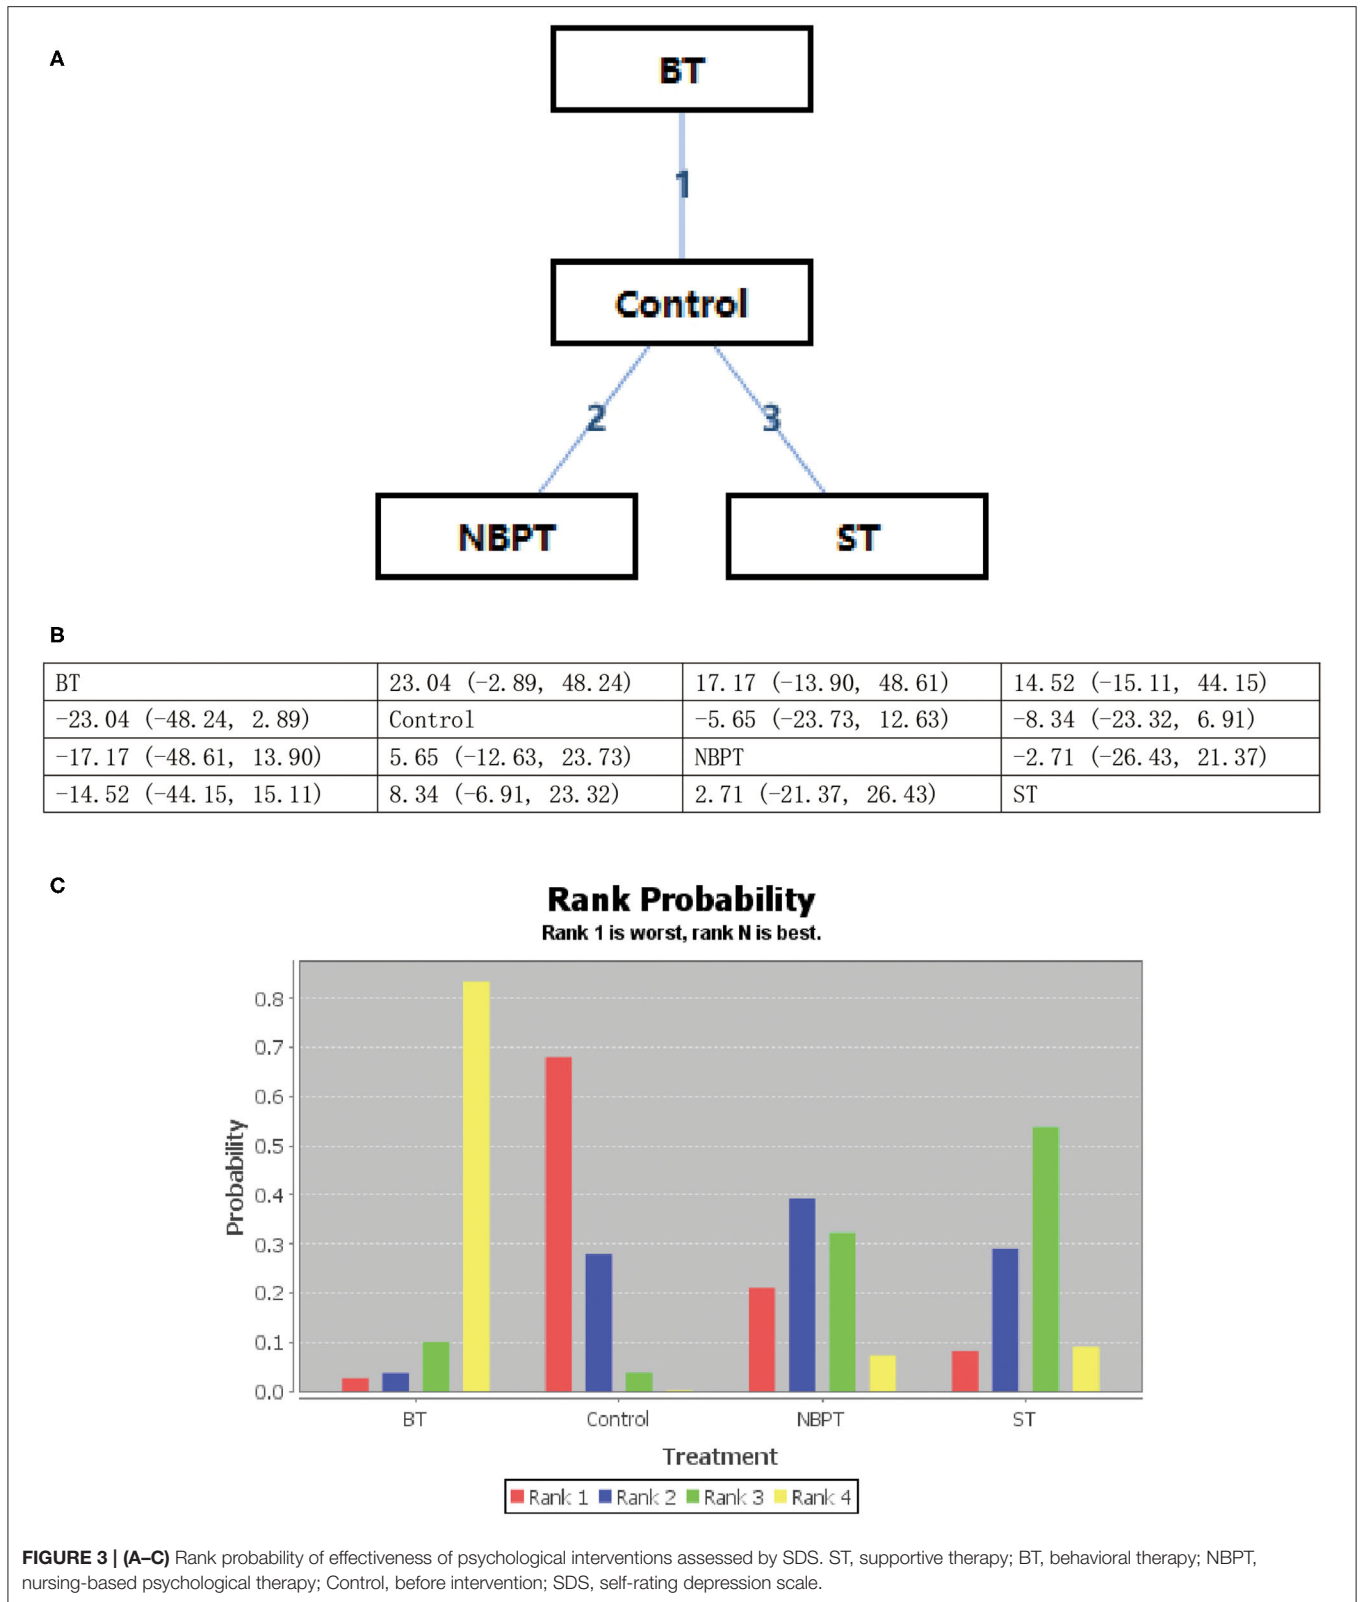

graded as either low quality (0–5) or high quality (6–9). The bias introduced in the studies included in this research was mainly attributed to the lack of community controls. The results of the risk of bias assessments for the SCCS studies are presented in **Supplementary Figure 2**.

### Meta-Analyses

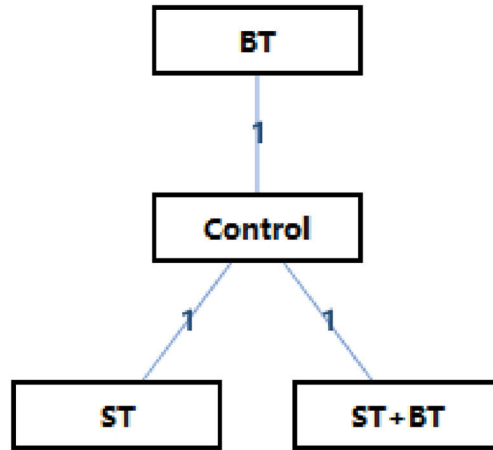

There were a total of four network meta-analyses performed to compare and rank the included psychological interventions in four different psychological scales. The network of eligible comparisons for effectiveness

**A**

**B**

BT	5.03 (-3.74, 13.24)	-1.81 (-13.87, 10.50)	3.58 (-8.58, 16.12)
-5.03 (-13.24, 3.74)	Control	-6.85 (-15.29, 1.93)	-1.44 (-9.94, 7.27)
1.81 (-10.50, 13.87)	6.85 (-1.93, 15.29)	ST	5.40 (-6.95, 17.42)
-3.58 (-16.12, 8.58)	1.44 (-7.27, 9.94)	-5.40 (-17.42, 6.95)	ST+BT

**C**

**FIGURE 4 | (A–C)** Rank probability of effectiveness of psychological interventions assessed by PHQ-9. ST, supportive therapy; BT, behavioral therapy; ST+BT, combination of supportive therapy and behavioral therapy; Control, before intervention; PHQ-9, patient health questionnaire.

consisted of 16 studies and 5 treatments. The consistency model was selected for the subsequent network analyses. Meanwhile, the inconsistency model was used to test consistency.

All psychological interventions were more beneficial than the control condition, but the best interventions on different scales are not completely consistent; also the rankings are also inconsistent. The results of our study indicated that ST was significantly more effective than the other treatments for reducing anxiety symptoms in SAS. Then the ranking is BT, NBPT, TCMT, and CRST. The ranking probability of treatments is presented in **Figure 2**. The second network meta-analysis was run to assess the most effective psychological interventions in SDS. We can see that BT was the best, followed by ST and NBPT. The specific network is presented in **Figure 3**. In terms of effectiveness in PHQ-9, group ST (SMD, 1.81; 95%CI 10.50, 13.87) were more effective than group BT. But interestingly, group ST+BT was the least effective one. The specific network is presented in **Figure 4**. In the final network meta-analysis, which was conducted to assess the effectiveness in SCL-90, only two kinds of psychological interventions (NBPT and ST) were included. They were both significantly more effective than before the intervention. And NBPT showed significantly more benefit than ST condition (SMD, 16.60; 95%CI, -85.23, 120.06) (**Figure 5**). **Supplementary Figure 3** shows the results of pair-wise meta-analyses of compliance for each intervention.

## DISCUSSION

This network meta-analysis included all available studies from 2019 to April 30, 2020, to analyze the effectiveness of psychological interventions for psychological crisis in people affected by COVID-19. After careful screening, a total of 16 articles were included in the study. Because of the rapid development of the epidemic, there are few published RCTs. Although all the studies were case studies and data of randomized controlled studies were lacking, most of our results had relatively high quality in terms of the NOS, and there was no obvious publication bias.

We can see that, in this study, the ranking of various interventions in different psychological scales was inconsistent, which indicated that different interventions may have different therapeutic effects on psychological problems. The ranking probability was primarily tied to direct and indirect effects that might provide robust evidence to support the results. Therefore, most of our conclusions were based on the ranking probability. But what can be found is that these interventions can effectively reduce the psychological crisis compared with before the intervention. First, there were five kinds of psychotherapies (ST, BT, NBPT, TCMT, and CRST) included in this network analysis that was assessed by SAS. Among them, ST showed a better effectiveness in the management of anxiety symptoms. ST is a commonly used and well-developed psychological intervention with a long history. The experiments we included in the study that used ST as a treatment were adjusted

according to the particularity of the epidemic. They also showed significance in improving mental health assessed by PHQ-9 when compared with BT, or even the combination of ST and BT. However, these results may have been related to sample size. Then, based on our results, we found out that the most effective intervention for psychological crisis especially the depression symptoms according to the SDS test was BT, which is another commonly used non-pharmacological application defined as behavior-change intervention, including exercise or changes in daily activity to help deal with the psychological problems. And ST and NBPT were the second and third in reducing depression feelings as assessed by SDS. The last network meta-analysis only included two kinds of psychological interventions (NBPT and ST). And we found that NBPT was better than ST when measured by SCL-90. We did not standardize different measurement scales when conducting this network analysis, because each evaluation tool has special characteristics and focuses on different clinical manifestations of psychological problems. Therefore, it may be valuable to distinguish the clinical manifestations of psychological problems and adopt the best effective treatment options accordingly.

Due to the lack of understanding of COVID-19 in the first place, it is difficult to form a complete routine work process in a short period of time. Inadequate medical resources, insufficient medical protection and treatment measures, and the high infectivity of the virus have led to a sharp increase in the number of patients and a high mortality rate. As a result, the frontline medical staff and COVID-19 patients are suffering from psychological crisis to varying degrees (Huang and Zhao, 2020). It is easy to feel helpless and insecure and even to experience psychological problems such as anxiety, insomnia, fear, panic, blind disinfection, disappointment, irritability, aggressive behavior, and blind optimism (Duan and Zhu, 2020). Therefore, timely and effective psychological interventions can play a positive role in protecting the patients' physical and mental health (O'Donoghue et al., 2020). However, which intervention can better treat the psychological crisis has not been studied. Therefore, the results of this article are very meaningful.

## CONCLUSIONS

This research first evaluated the effectiveness of multiple psychological interventions for psychological crisis in people affected by COVID-19 *via* a Bayesian network meta-analysis and suggested potential benefit of psychological interventions for mental disorders caused by COVID-19 among all the affected people. Comprehensive analysis of the results indicated that ST was the most commonly used therapy and showed a better performance in all the measurement scales, with SAS and PHQ-9 in the first place and SCL-90 and SDS in the second. According to different assessment outcomes, ST, BT, and NBPT might be recommended for the COVID-19-affected people as their first-line treatment for managing psychological crisis. However, due to the limitations of case series studies, there is still a need for

a larger sample size, especially high-quality RCTs and advanced analytic strategies in the future to confirm such conclusions.

## Strengths and Limitations

First, this is the first Bayesian network meta-analysis that comprehensively summarized all available evidences on the effectiveness of different psychological interventions in the treatment of psychological crisis during the COVID-19 pandemic. Second, it objectively recommended the best effective treatment options according to the clinical manifestations of psychological problems for people affected by COVID-19.

However, there were still some limitations included in this study: (1) all the included studies were case series. However, due to the rapid popularity of COVID-19, RCT or prospective studies have not been possible so far. (2) Although the language restriction was set as English and Chinese, we failed to include qualified English literature. However, as far as we know, there have been no reports of ethnic differences in the pathogenesis of COVID-19 so far. (3) We did not conduct subgroup analysis. (4) Due to the non-closed loop and few publications, the effectiveness of certain interventions may be exaggerated. (5) The ADDIS software is simple and convenient to operate, but it cannot be freely programmed, which may have some limits.

In March 2020, the World Health Organization announced the Covid-19 outbreak a pandemic and restrictive measures were enacted by the Governments to fight the spread of the virus. In Italy, these measures included a nationwide lockdown, with limited exceptions including grocery shopping, certain work activities, and healthcare. Consistently with findings from previous studies investigating the psychological impact of similar pandemics [e.g., Severe Acute Respiratory Syndrome (SARS)], there is evidence that Covid-19 is associated with negative mental health outcomes. Given this background, we conducted a cross-sectional study aimed at investigating the impact of the Covid-19 pandemic and the subsequent restrictive measures imposed by the Government on the psychological health of Italian men and women aged =18 years and living in Lombardy, one of the worst-hit regions. The study also aimed at identifying what factors are associated with specific psychological outcomes. Thus, we developed an online survey that included a researcher-made questionnaire to collect sociodemographic, household, general health, and pandemic-related information. The Generalized Anxiety Disorder-7, the Patient Health Questionnaire-9 and the Perceived Stress Scale were used to assess anxiety, depression, and perceived stress, respectively. We found that younger age, greater concerns about the pandemic, female gender, being unmarried, not having children, and being a student were associated with worse psychological health. These findings may provide further insight into the risk factors associated with negative psychological outcomes during the current pandemic, with identification of vulnerable groups. This body of evidence may help professionals implement targeted psychosocial treatment and prevention programs.

## INTRODUCTION

Since December 2019, when the first cases were reported in the city of Wuhan, China, the Covid-19 outbreak has spread worldwide, facilitated by the contagiousness of asymptomatic individuals, as well as by international travels (Matias et al., 2020; Vigo et al., 2020). In the morning of 12 March 2020, with more than 20,000 confirmed cases and almost 1,000 deaths in Europe, the World Health Organization (WHO) announced the Covid-19 outbreak a

pandemic<sup>1</sup>. Different types of restrictive measures were enacted by the Governments to contain the spread of the disease. In Italy, these measures involved a nationwide lockdown from 9 March to 4 May 2020, with exceptions allowed only for medical reasons and for necessities like grocery shopping and work.

The negative psychological impact of similar pandemics [such as Severe Acute Respiratory Syndrome (SARS), Ebola, the 2009–2010 H1N1 influenza, Middle East Respiratory Syndrome (MERS), and equine influenza] has been highlighted in previous studies, whose findings were recently summarized by Brooks et al. (2020). In their rapid literature review, the authors included 24 studies reporting evidence on the psychological consequences of quarantine, which entails an overall high prevalence of psychological distress, sense of isolation, anxiety, mood disorders, insomnia, anger and frustration, and even post-traumatic stress disorder (Brooks et al., 2020). Besides the fact that viral outbreaks represent a severe threat to people's lives, the adverse psychological effects of pandemics such as Covid-19 also derive from the consequent economic crisis, with millions of people left out of work or at risk of losing their job (Vigo et al., 2020). For all these reasons, the psychological burden of pandemics has been referred to as a “parallel epidemic” (Yao et al., 2020).

In a study focused on the immediate psychological reactions displayed by the Chinese population during the initial stage of the Covid-19 outbreak (Wang C. et al., 2020), 54% of 1,210 respondents rated the psychological impact of the situation as moderate or severe, with depressive and anxiety symptoms reported by 16 and 29% of participants, respectively. Moreover, 75% of the participants were worried about their family members contracting the disease and were satisfied with the available health information. Risk factors associated with worse psychological conditions were female gender, student status, presence of physical symptoms such as myalgia, dizziness, coryza, and overall poor self-related health status, while appropriate preventive measures (such as hand washing and wearing a mask) and detailed health information were associated with better psychological outcomes.

In another study (Wang H. et al., 2020), younger, unmarried individuals, with poor social support, reported higher psychological distress than the rest of the sample. People with pre-existing physical and mental disorders (including substance abuse) represent a particularly vulnerable group due to the psychological burden of the pandemic, as well as to disruptions in their care (Vigo et al., 2020). Exposure to Covid-19 news can also influence the psychological impact of the disease by increasing stress and depressive symptoms, especially in individuals who report a high perceived vulnerability to the virus (Olagoke et al., 2020; Yao et al., 2020).

Given this background, more research is needed to further clarify the psychological impact of Covid-19, including risk and protective factors. In this regard, this study aims to examine the psychological consequences of the pandemic in Lombardy, the worst-hit Italian region (Odone et al., 2020). Specifically, our goal was to investigate the association between sociodemographic, household, general health, beliefs and concerns about the

pandemic, and the psychological health of the community, with a specific focus on anxiety and depressive symptoms, and perceived stress.

## MATERIALS AND METHODS

The study used a cross-sectional design, with data collected from 13 April to 10 May 2020 using an online survey that was delivered through the Qualtrics suite (Qualtrics, Provo, UT). Participants were recruited using a snowball sampling procedure, which also involved posting the invitation to participate in the research on social media. We included only participants aged  $\geq 18$  years, resident in Lombardy, and fluent in Italian. The study was approved by the Ethics Commission of the Department of Psychology of Università Cattolica del Sacro Cuore. Before completing the questionnaires, all participants provided electronic informed consent.

### Measures

A researcher-made questionnaire was developed to collect sociodemographic data (age, level of education, employment and marital status, and presence of children), household information (number of people in the same house, presence of pets, size of the house, and presence of garden or balcony), general health status (diagnosed physical or psychological conditions), and Covid-19 related information [Covid-19 diagnosis, concerns about the pandemic (e.g., “To what extent are you concerned about this pandemic?”; 1 = not at all, 4 = extremely), perceived risk for themselves and their significant others (e.g., “To what extent do you perceive yourself at risk due to the pandemic?”; 1 = low risk, 3 = high risk), fear of being infected or infecting others (e.g., “To what extent are you concerned about being infected by others?”; 1 = not at all, 5 = very much), and satisfaction with the information provided by public authorities (i.e., “To what extent are you satisfied with the quality of the information provided by public authorities?”; 1 = not at all, 5 = very much)]. The Italian version of three standardized self-report questionnaires was then used to assess participants' psychological health: (1) the *Generalized Anxiety Disorder-7* (GAD-7; Spitzer et al., 2006; Bruno et al., 2020); (2) the *Patient Health Questionnaire-9* (PHQ-9; Kroenke et al., 2001; Mazzotti et al., 2003); (3) the *Perceived Stress Scale* (PSS; Cohen, 1994; Mondo et al., 2019).

The GAD-7 is a 7-item measure that allows the rapid detection of generalized anxiety disorder (GAD). Participants are asked to rate on a 4-point Likert scale (0 = not at all; 3 = nearly every day) how often they have been bothered by anxiety symptoms in the past 2 weeks. The global score ranges from 0 to 21, with higher scores indicating greater GAD. Scores of 10 or higher indicate possible clinically significant conditions (Spitzer et al., 2006).

The PHQ-9 is a widely used 9-item questionnaire for the screening of depression in non-psychiatric settings. The PHQ-9 detects the presence of a wide range of depressive symptoms (such as anhedonia, depressed mood, trouble sleeping, tiredness, and even suicidal thoughts) based on their frequency in the last 2 weeks, which is rated on a 0–3 Likert scale (0 = not at all; 3 = nearly every day). The PHQ-9 total score ranges

**TABLE 2 |** Descriptive statistics of the scales.

	M (SD)	Median	Skewness		Kurtosis	
			Statistics	SE	Statistics	SE
GAD-7	6.52 (4.6)	6	1.284	0.137	1.279	0.272
PHQ-9	6.25 (4.3)	5	1.502	0.137	3.263	0.272
PSS-10	18.48 (3.0)	18	-0.614	0.139	3.799	0.277

from 0 to 27, with greater scores indicating worse psychological conditions. Similarly to the GAD-7, scores  $\geq 10$  indicate clinical cases (Gilbody et al., 2007).

The PSS is a 10-item questionnaire for assessing the perception of stress. Specifically, participants are asked to rate on a 0–4 Likert scale (0 = never; 4 = very often) how often they felt upset, nervous, unable to control and to cope with things in their life, angered, and overwhelmed, focusing on the last month. After reversing four positively stated items, all items are summed to obtain a total score that ranges between 0 and 40, with higher scores indicating greater perceived stress. Scores ranging from 0 to 13, 14 to 26, and 27 to 40 indicate low, moderate, and high stress, respectively (Cohen, 1994).

In this study, all these scales showed good internal consistency (Cronbach's  $\alpha$  was 0.894 for the GAD-7, 0.830 for the PHQ-9, and 0.925 for the PSS).

## Statistical Analyses

Once obtained the descriptive statistics, we examined whether the scores of the GAD-7, the PHQ-9, and the PSS-10 were normally distributed, considering skewness and kurtosis ( $-1/ + 1$  was established as the acceptable range for normality). Given that these variables were not normally distributed, and

**TABLE 3** | Spearman's correlations coefficients among continuous variables.

\*\* $P_s < 0.01$ ; \*\*\* $P_s < 0.001$ .

considering that our analytic strategy involved comparisons between unbalanced groups, statistical analyses were performed using a non-parametric approach. Specifically, relations between continuous variables (such as for instance age and psychological symptoms) were explored using Spearman's correlation. Group comparisons were conducted using the Mann-Whitney *U*-test or the Kruskal-Wallis *H*-test, as appropriate. Because our analytic strategy involved multiple comparisons,  $P_s < 0.01$  were considered statistically significant. All statistical analyses were performed using the software SPSS, version 25.

Statistical power was computed based on previous data collected by our Department (Pagnini et al., 2020) using a conservative approach, suggesting a correlation between worries and well-being around 0.182. Under these circumstances, a sample of 313 participants would allow a power of 0.90. The power analysis was conducted using the software G\*Power 3.1 (Faul et al., 2009).

## RESULTS

Our participants were 319 residents of Lombardy aged between 18 and 78 years old ( $M = 42.95$ ;  $SD = 16.85$ ). Most participants were women (81% vs. 19% of men). The characteristics of the sample based on the information collected using the researcher-made questionnaire (i.e., socio-demographic, household, health-related, and pandemic-related information) are reported in **Table 1**, while median, means and standard deviations for psychological health assessed using the GAD-7, the PHQ-9, and the PSS-10 are presented in **Table 2**. Considering the cut-offs of these three questionnaires, we found that 18.5% of the participants reported clinically significant anxiety, 17.6% had clinical depression (with 12.2% of participants having clinically significant symptoms of both anxiety and depression), while moderate levels of perceived stress were reported by most participants (96%).

Correlations between variables are shown in **Table 3**. We found that younger age was associated with higher anxiety, depression, and perceived stress ( $P_s < 0.001$ ). In addition, the more our participants were worried about the pandemic and concerned about being infected by others, the greater were their symptoms of anxiety ( $P_s < 0.001$ ).

Mann-Whitney *U*-test and Kruskal-Wallis test analyses revealed several statistically significant differences among participants as regards psychological health. Specifically, compared with men, women reported higher levels of anxiety ( $U = 10.663$ ;  $P < 0.001$ ) and depressive symptoms ( $U = 10.841$ ;  $P < 0.001$ ). Furthermore, group differences related to marital status were detected for all psychological health outcomes, such that unmarried participants reported greater symptoms of anxiety ( $H = 15.358$ ;  $P = 0.002$ ) and depression ( $H = 21.146$ ;  $P < 0.001$ ), and higher perceived stress ( $H = 17.378$ ;  $P = 0.001$ ) than married or cohabitating couples. Participants who reported having children showed lower anxiety ( $U = 9.688$ ;  $P < 0.001$ ) and depression ( $U = 9.283$ ;  $P < 0.001$ ), as well as less perceived stress ( $U = 9.362$ ;  $P = 0.001$ ) than participants without children.

In addition, considering participants' occupational status, significant group differences emerged on depressive symptoms ( $H = 21.128$ ;  $P = 0.004$ ) and perceived stress ( $H = 25.638$ ;  $P = 0.001$ ). Specifically, retired people reported the lowest levels of depressive symptoms followed by self-employed individuals, whilst the highest levels of depressive symptoms were detected among students with a part-time job. Considering perceived stress, the lowest levels were reported by retired participants and the highest levels by students and students with a part-time job.

Household characteristics (such as having pets, having a balcony or a garden) did not affect psychological outcomes. No significant effects were found when we examined the associations between other Covid-19 related information (such as being diagnosed with Covid-19 and having lost a loved one due to the disease), general health status, and psychological health.

## DISCUSSION AND CONCLUSION

We examined the impact of the Covid-19 outbreak on the psychological health (anxiety and depressive symptoms, and perceived stress) of individuals living in Lombardy, one of the worst hit Italian regions. Specifically, the study was conducted during the final period of the lockdown (i.e., 1 month and a half since the beginning of the pandemic), in which very restrictive measures (including confinement) were enacted by the Government to contain the spread of the virus. Our goal was not only to examine the psychological conditions of the community, but also to identify what factors were related to

negative psychological outcomes of such a critical situation, focusing on socio-demographic and housing factors, Covid-19 related aspects, and general health status.

Our findings confirmed that, when the study was conducted, people who lived in Lombardy were worried about Covid-19 (with 92.4% of participants reporting to be from moderate to extremely worried about the pandemic), which confirms results from other Italian studies suggesting that the concerns of the community are associated with the geographical proximity to the center of the pandemic (Pagnini et al., 2020). Moreover, in our research, participants' worries related to Covid-19 (including concerns about being infected by others) were associated with worsened psychological conditions, which corroborates the conclusions of other studies highlighting the negative emotional consequences of the current pandemic (Eisazadeh et al., 2020). Women, unmarried individuals, and students were the most affected groups, with poorer psychological outcomes than the rest of the sample. Overall, the general high levels of concern found in our participants can be partially explained by the fact that most of the respondents (81%) were females. In this regard, a study by Gerhold (2020) showed that women are more likely to be worried about the pandemic than men.

Surprisingly, participants' younger age was associated with greater worries about the pandemic. This is interesting, especially if one considers that younger people reported worsened psychological conditions in other Covid-19 studies (e.g., Wang H. et al., 2020) and that, based on our findings, students were more distressed than other groups. In this regard, the uncertainty related to the sudden, unexpected transition to distance learning, and concerns about the future (including procedures for assignments and evaluations; see Sahu, 2020) might have played an important role, with negative effects on the psychological health of this younger subgroup of people. It should also be considered that young people may be overrepresented in the other distressed categories identified in our study (unmarried people, people without children, and students). Taken together, our findings suggest that assessing people's worries and risk perception is important, since these subjective aspects may significantly impact on their psychological conditions and behaviors, also related to the adoption of correct preventive strategies (Khosravi, 2020).

In this study, we also examined the role of housing conditions, with the hypothesis that these factors might have affected the individuals' psychological health during the lockdown. Surprisingly we did not find any significant effect of housing characteristics, such as house size, having a balcony or a garden. Indeed, there is need for more research to further understand what type of household situations are associated with mental health outcomes when people are confined to their homes during pandemics. This is particularly important considering that other Covid-19 outbreaks are expected in the next future.

Our data suggest that social isolation negatively affects the psychological health of the community, especially among young unmarried individuals without children. As underlined in other studies, people who are more socially connected live longer and healthier than isolated individuals (Umberson and Montez, 2010). In this regard, social support

can contribute to increase self-monitor and self-control (Pilcher and Bryant, 2016), which represent important resources while coping with stressful situations. At the same time, conjoint efforts to cope with a stressor as a couple may lead to enhanced couple satisfaction (Molgora et al., 2019). On the other hand, forced cohabitation and greater levels of stress due to the pandemic may increase the risk of domestic violence and abuse (Barbara et al., 2020; Bradbury-Jones and Isham, 2020). This issue is very important and requires further research. Despite the significant number of studies conducted during the Covid-19 outbreak, there is still a gap in the literature regarding how couples and families cope with this stressful situation. Our findings, combined with those from other studies (Saita et al., 2016), suggest that promoting couple adaptive behavioral and emotional coping strategies (i.e., positive dyadic coping) may be particularly useful in situations that entail dealing with a disease (including the threat of a disease, for those who have not been infected by Covid-19).

Besides the interesting findings reported in this article, our study presents several limitations. First, our sample is not fully representative of the general population due to self-selection bias, since most participants were female. Second, the cross-sectional nature of the research design did not allow to investigate adjustment trajectories over time, which is very important, given the rapid changes of the situation.

Despite these limitations, our study contributed to clarify the short-term psychological impact of the disease by identifying individual characteristics associated with more negative psychological outcomes. Therefore, our findings may offer interesting suggestions for future studies and interventions aimed at promoting the psychological health of the community during pandemics.

# Associations Between Childhood Abuse and COVID-19 Hyperarousal in Adulthood: The Role of Social Environment

Neha A. John-Henderson<sup>1\*</sup>, Cory J. Counts<sup>1</sup> and Annie T. Ginty<sup>2</sup>

<sup>1</sup> Department of Psychology, College of Letters and Science, Montana State University, Bozeman, MT, United States,

<sup>2</sup> Department of Psychology and Neuroscience, College of Arts & Sciences, Baylor University, Waco, TX, United States

**Background:** Childhood abuse increases risk for high levels of distress in response to future stressors. Interpersonal social support is protective for health, particularly during stress, and may be particularly beneficial for individuals who experienced childhood abuse.

**Objective:** Investigate whether childhood abuse predicts levels of posttraumatic stress disorder (PTSD) symptoms related to the COVID-19 pandemic, and test whether the perceived availability of social companionship preceding the pandemic moderates this relationship.

**Methods:** During Phase 1, adults ( $N = 120$ ; Age  $M[SD] = 19.4 [0.94]$ ) completed a retrospective measure of childhood adversity along with a measure of perceived availability of opportunities for social engagement immediately preceding the pandemic. Two weeks after the COVID-19 pandemic declaration, participants completed the Impact of Event Scale-Revised (IES-R) with respect to the pandemic. Hierarchical linear regression analyses examined the interaction between childhood abuse and the perceived availability of social companionship preceding the pandemic as a predictor of PTSD symptoms.

**Results:** Adjusting for covariates, the interaction between childhood abuse and perceived availability of others to engage with before the onset of the pandemic was a significant predictor of IES-hyperarousal ( $\beta = -0.19$ ,  $t = -2.06$ ,  $p = 0.04$ ,  $\Delta R^2 = 0.032$ , CI:  $[-0.31$  to  $-0.01]$ ).

**Conclusion:** Levels of perceived opportunities for social companionship before the pandemic associates with levels of hyperarousal related to the pandemic, particularly for individuals who experienced high levels of childhood abuse. More research is needed to understand how to mitigate the higher levels of distress related to the pandemic for these individuals in order to reduce risk for future psychiatric disorders.

**Keywords:** childhood abuse, hyperarousal, social support, COVID-19, PTSD, adults

## INTRODUCTION

A robust body of work highlights the long lasting implications of childhood abuse for health-relevant behaviors and outcomes into adulthood (e.g., Springer et al., 2003; Maniglio, 2009; De Bellis and Zisk, 2014; Beilharz et al., 2020). For example, trauma and abuse during childhood are risk factors for psychological distress and psychiatric disorders in adulthood (Duncan et al., 1996; Yehuda et al., 2001; Min et al., 2007; Shonkoff et al., 2009; Rogosch et al., 2011; Edwards et al., 2014; Nemeroff, 2016). It is theorized that in response to early life stress, the brain coordinates and regulates behaviors and physiological responses to stress in order to help the individual adapt to the demands of their environment (Hostinar and Gunnar, 2013). The experience of abuse is embedded into the regulation of stress systems in a way that shapes responses to future stressors (Berens et al., 2017).

While it is well known that a single stressor or stressful event can produce an ongoing cascade of event-related pathology, stressful events impact individuals differently (Lewis, 1992; Meaney et al., 1993; Bowman, 1997; Kirschbaum et al., 2008). For some individuals, their response to the stressor could result in a diagnosis of posttraumatic stress disorder (PTSD) or subclinical symptomatology. Previous work indicates that childhood abuse is one factor which sensitizes individuals to future stressful events (Harkness et al., 2006; McLaughlin et al., 2010; Gouin et al., 2012; Nakai et al., 2014; Shapero et al., 2014; Asselmann et al., 2018). For example, in children who have experienced a natural disaster, previous exposure to trauma is an important predictor of post-disaster traumatic stress (Neuner et al., 2006). Separately, in veterans, reports of childhood abuse were higher in veterans with combat related PTSD compared to rates of PTSD in veterans who did not have combat-related PTSD, a relationship that was independent of levels of combat exposure (Bremner et al., 1993). Furthermore, a separate investigation found that childhood abuse changes psychological responses to future trauma, with greater reports of childhood abuse associating with higher levels of shame following the experience of a violent crime (Andrews et al., 2000). Together these findings provide compelling evidence that the experience of childhood abuse shapes the way in which individuals respond to future traumas or stressors.

A separate body of research links perceptions of social support to a variety of health outcomes (Cohen and Syme, 1985; Theorell et al., 1995; Brady and Helgeson, 1999; Wang et al., 2003; Uchino, 2006, 2009; Reblin and Uchino, 2008; Taylor, 2011). A perceived lack of social support and companionship can exacerbate illness and has been identified as a risk factor for poor psychological well-being (Avison and Gotlib, 1994; Cohen et al., 1997). According to the stress buffering hypothesis (Cohen and Wills, 1985), interpersonal social support can have a positive impact on health through preventing or dampening stress responses. For example, following a natural disaster, perceived social support was found to moderate the stressor–distress relationship, with individuals who reported lower levels of social support reporting more disaster related distress (Arnberg et al., 2012). Separately, previous findings indicate that social support and resources may be particularly important in the

context of stress or adversity (John-Henderson et al., 2015), and in a prospective investigation, social support was found to mediate and moderate long-term consequences of childhood maltreatment (Sperry and Widom, 2013). Levels of interpersonal support and social engagement prior to a stressful event, may be particularly important in shaping psychopathology during uncertain times, and may be most important for individuals who have experienced early life trauma.

Based on previous work, infectious disease outbreaks elicit psychological responses (Sim et al., 2010; Shah et al., 2020; Xiang et al., 2020). The uncertainty which characterizes these outbreaks can contribute to increased levels of distress and PTSD symptoms (Cheng and Cheung, 2005; Lee et al., 2018). However, similar to other stressors, the nature of these psychological responses can vary significantly across individuals (Lau et al., 2007; Williams et al., 2012). On March 11, 2020, the novel coronavirus disease (COVID-19) was labeled as a pandemic and was acknowledged as a national emergency in the United States 6 days later. In an effort to reduce the spread of infection, recommendations were issued to stay home and socially distance, prompting individuals to make drastic changes to their daily lives and social environments. In general, previous work indicates that social companionship or the perceived availability of others to socially engage with is a predictor of physical and mental health (Seeman, 1996; Hale et al., 2005; Ang, 2018). However, it is unknown whether these perceptions would affect levels of distress in the context of a pandemic.

Merging these bodies of work, we hypothesize that childhood abuse may predict greater distress symptoms at the onset of the COVID-19 pandemic, in particular for those individuals who reported low levels of interpersonal support preceding the pandemic. While there are many dimensions of social support, we chose to focus on interpersonal support as reflected by the perceived availability of persons with whom one could engage in activities, because this social resource may be particularly protective as individuals enter a period of time where opportunities for social engagement are limited. In the context of the COVID-19 pandemic, it is possible perceived social companionship before social distancing recommendations were implemented, shaped the degree to which the stressor and associated changes in the social environment affected subsequent mental health.

## METHODS

Participants ( $N = 120$ , 72% female; mean [standard deviation] age = 19.4 [0.94] years, age range 18–24 years; 69.3% White) were a subsample of an ongoing research study (total participants contacted from ongoing study  $N = 457$ ). Exclusion criteria of the original study included a history of cardiovascular disease or current illness/infection. The initial laboratory visit (Phase 1) took place in Central Texas between January 2019 and February 2020. During this phase demographics, reports of childhood abuse, and perceived availability of social engagement and companionship were measured. During the second part of the

study (Phase 2) participants resided in 22 different states during the follow-up. Participants completed questionnaires regarding pandemic related distress between March 26, 2020 and April 5, 2020. None of the participants had tested positive for COVID-19 and 87.5% of participants were living in a city/state that had a “shelter in place” order at the time of phase 2 completion. One participant was excluded due to incomplete data. All participants gave informed consent for both phases of the study. For Phase 1, participants were recruited through the university’s SONA system and received course credit. For Phase 2, all participants who completed Phase 1 were contacted and asked to take part in this second study. Participants who chose to take part were entered in a raffle to win one of 15, \$25 gift cards. The studies were approved by the university’s Institutional Review Board.

## Questionnaires Phase 1

Childhood abuse was measured with the 28-item version of the Childhood Trauma Questionnaire (CTQ; Bernstein and Fink, 1998). The CTQ short form is a self-report measure which encompasses experiences from 0 to 17 years of age. The CTQ has five subscales which measure emotional abuse, emotional neglect, physical abuse, physical neglect, and sexual abuse. Each item uses a five-point frequency of occurrence scale: (1) never true, (2) rarely true, (3) sometimes true, (4) often true, and (5) very often true. In previous work, the CTQ short form has been found to be reliable and valid ( $\alpha = 0.61 - 0.95$ ; Bernstein et al., 2003). Following previous work (McLaughlin et al., 2014) we calculated a threat score using subscales from the CTQ. Childhood threat has been associated with higher levels of future internalizing and externalizing symptoms (Miller et al., 2018) and high levels of psychological distress (Hughes et al., 2007; Llabre et al., 2015). The threat score consists of sum of the following subscales: physical abuse, sexual abuse, and emotional abuse. Cronbach’s alpha for the threat score in the present study was 0.617.

Interpersonal social support and resources were measured using the Interpersonal Support Evaluation List –Short version (ISEL-12; Cohen and Hoberman, 1983). The ISEL-12 is a self-report questionnaire with 12 statements regarding the perceived availability of social resources and support. We focused on the belonging subscale of the ISEL-12 which is meant to assess the

perceived availability of persons to engage in social activities with (Cohen et al., 1985). An example item from the belonging scale is, “If I wanted to have lunch with someone, I could easily find someone to join me.” Participants respond to each question using the following scale: 1 (*definitely false*), 2 (*probably false*), 3 (*probably true*), and 4 (*definitely true*). Higher scores on this measure reflect a perceived greater ability to engage with others in social activity before the pandemic. The belonging subscale demonstrated good internal consistency in this sample (Cronbach  $\alpha$ s > 0.790).

## Questionnaires Phase 2

Participants who had completed the larger study were sent an email on March 26, 2020 notifying them about the opportunity to participate in a follow-up study online. In this follow-up they completed the Impact of Events Scale-Revised (IES-R), which is used to assess subjective distress and PTSD symptomology for a specific event (Weiss and Marmar, 1997). In the present study, the life event was the COVID-19 coronavirus pandemic. The IES-R has three subscales, intrusion (e.g., intrusive cognitions, nightmares), avoidance (e.g., avoidance of feelings), and hyperarousal (e.g., anger, trouble concentrating). Item response anchors for this scale are: 0 (*not at all*), 1 (*a little bit*), 2 (*moderately*), 3 (*quite a bit*), and 4 (*extremely*). Each subscale score is computed as the mean item response of the subscale item. The IES-R subscales have good internal consistency in previous work (Craparo et al., 2013) and in this research (Cronbach  $\alpha$ s > 0.791).

## Statistical Analysis

All statistical analyses were conducted using SPSS (version 24; IBM, Armonk, NY). We first examined descriptive statistics and bivariate Pearson correlations between the CTQ threat score, ISEL-belonging scores, IES-R subscales (intrusion, avoidance, and hyperarousal), and demographics. Next, in three separate hierarchical linear regressions, adjusting for age, race, biological sex, and depressive symptoms, we examined whether childhood abuse interacts with perceived availability of others for social engagement preceding the pandemic to predict clusters of PTSD symptoms related to the COVID-19 pandemic. To identify specific values of CTQ threat for which the relationship between ISEL-belonging and IES-hyperarousal is statistically significant in this sample, we used the Johnson-Neyman technique (Rast et al., 2014).

## RESULTS

### Descriptive Statistics

One hundred and twenty participants completed both phases of the study. Participants had a mean (SD) HADS score of 4.25 (2.78) and a CTQ threat score of 19.70 (5.72) during phase 1 of the study. The mean (SD) parental occupational status was 5.94 (1.20). During phase 1 of the study, participants reported an ISEL belonging mean (SD) of 8.82 (2.51). During phase 2 of the study, participants reported mean (SD) scores for the following

**TABLE 1 |** Descriptive statistics.

	Mean (N = 120)	SD/%	Range
Age	19.40	0.94	18.11–24.50
Sex		72.4% (Female)	–
Race		69.3% (White)	–
Parental occupation status	5.94	1.20	2–7
Current depressive symptoms	4.25	2.78	0–32
Childhood threat score	19.70	5.72	15–52
ISEL belonging	8.82	2.51	3–14
IES-R hyperarousal	0.84	0.74	0–3.17

Parental occupation was coded as: 2 = unskilled, 3 = partly skilled, 4 = skilled manual, 5 = skilled non-manual, 6 = skilled managerial, and 7 = professional. ISEL: Interpersonal Support Evaluation List; IES-R: Impact of Events Scale-Revised.

**TABLE 2** | Bivariate correlations of interest variables.

Variable	1	2	3	4	5	6	7	8	9
1. Age	–								
2. Sex	–0.26**	–

Sex: 1 = male, 2 = female; SES: Socioeconomic status; ISEL: Interpersonal support Evaluation List; IES: Impact of Events Scale.

\*Correlation significant at the 0.05 level (two-tailed).

\*\*Correlation significant at the 0.01 level (two-tailed).

subscales of the IES-R: hyperarousal, 0.84 (0.74), intrusion 0.86 (0.73), and avoidance 1.14 (0.72). See **Table 1** for mean, standard deviation, and ranges of demographic information and descriptive statistics.

## Correlation Analyses

Higher levels of CTQ threat were moderately associated with lower socioeconomic status (SES) and higher depressive symptoms. Females had higher levels of ISEL-belonging. Additionally, there was a moderate association between higher levels of ISEL-belonging were associated with lower levels of depressive symptoms. There was a small association between higher IES-intrusion and IES-hyperarousal associated with being older, having more depressive symptoms at time 1. There was a small association between high CTQ threat was associated with higher scores on all three IES subscale. Lastly, there was a moderate to large association between all three subscales of the IES were related to one another with moderate to large effects. **Table 2** reports the full correlation matrix.

## Hierarchical Regressions

We conducted a series of hierarchical regression to test our main hypothesis. In block 1 we entered age (calculated from reported date of birth), race, biological sex, depressive symptoms, and parental occupation status along with the CTQ threat score and the ISEL-belonging subscale score. In block 2, we entered the interaction term for CTQ threat and ISEL-belonging. We examined whether this interaction term was a significant predictor of IES-intrusion, IES avoidance and IES hyperarousal. The interaction term was not a significant predictor of IES intrusion or IES avoidance ( $\beta = -0.064$ ,  $t = -0.70$ ,  $p = 0.48$  and  $\beta = -0.042$ ,  $t = -0.44$ ,  $p = 0.66$ , respectively). However, we found that the interaction between CTQ threat and ISEL-belonging was a significant predictor of IES hyperarousal ( $\beta = -0.19$ ,  $t = -2.06$ ,  $p = 0.04$ ,  $\Delta R^2 = 0.032$ , CI:  $[-0.31$  to  $-0.01]$ ). This regression model is reported in **Table 3**. Using the Johnson-Neyman technique (Rast et al., 2014), we found that the relationship between ISEL-belonging and IES-hyperarousal was statistically significant for participants who had CTQ threat

scores above 28.63 (possible range: 15–75, observed range: 15–52). Specifically, for individuals with high levels of childhood abuse, low levels of ISEL-belonging predicted higher levels of IES-hyperarousal.

## DISCUSSION

The findings reported here utilize data which were collected before the onset of the COVID-19 pandemic and data from a follow-up which took place during the weeks immediately following its classification as a national emergency in the United States. In a sample of 119 adults, we found that for individuals who reported experiencing high levels of childhood abuse, there was a significant relationship between perceived availability of social companionship preceding the pandemic and distress symptoms related to the pandemic. Specifically, these individuals had higher levels of hyperarousal symptoms related to the pandemic. This cluster of symptoms is characterized by constantly feeling on guard, having difficulty falling or staying asleep, feeling jumpy or easily startled, and feeling irritable.

Given that individuals who experience childhood abuse are known to be at greater risk for psychiatric disorders in adulthood compared to individuals who did not experience

**TABLE 3** | Predictors of IES-R Hyperarousal in hierarchical linear regression model.

	IES hyperarousal		
	$\beta$	$p$	$\Delta R^2$

childhood abuse (Duncan et al., 1996; Shonkoff et al., 2009; Rogosch et al., 2011; Nemeroff, 2016), it is important to understand the risk and protective factors which moderate the relationship between stressful events, PTSD symptoms and subsequent risk for PTSD for this population. Our findings suggest, in the context of the COVID-19 pandemic, high levels of perceived availability of social companionship preceding the pandemic is one such factor which may reduce subsequent risk. It is possible that efforts to increase opportunities for social engagement generally for this at-risk population may help to offset high levels of PTSD symptoms in response to stressful events. Further, during stressful events such as the ongoing COVID-19 pandemic, it is possible that efforts to increase social engagement, even if virtually due to social distancing recommendations, may help to manage their pandemic related distress.

The findings are in line with a body of work indicating a relationship between childhood trauma and risk for psychiatric disorders into adulthood (Widom, 1999; Copeland et al., 2007; Widom et al., 2007). Individuals who experience abuse during childhood exhibit chronically high levels of corticotropin releasing factor (CRF) as adults, which causes generalized arousal, anxiety and hypervigilance, all of which are symptoms of the PTSD hyperarousal cluster (Charney et al., 1993). While we do not measure CRF or other biological proteins which may contribute to observed hyperarousal symptoms, our findings indicate that the relationship between childhood maltreatment and this cluster of PTSD symptoms in response to stress may be moderated by one's social environment preceding the stressor. In light of this observation, it may be important to consider social environments more closely when assessing risk for PTSD following a stressor for this at-risk population.

The findings from this research could have clinical implications for the development of interventions which could benefit adults who experienced childhood abuse, specifically in the context of a life event such as the COVID-19 pandemic. Based on the pattern of observed findings, interventions which provide these adults with opportunities for social engagement could be useful in dampening distress levels related to the event. In the context of live events which make in-person social engagement challenging (e.g., the COVID-19 pandemic), social engagement

opportunities could be made available online or using social media platforms.

This research has important limitations. First, while the study is prospective, it is still correlational, and it remains possible that the pattern of our results are affected by a separate variable or construct (Christenfeld et al., 2004). However, the pattern of results we observed accounted for variables which may be related to our outcome variables including age, biological sex, ethnicity and depressive symptoms. Second, since the symptoms measured using the IES-R had not persisted over a period of a month, the participants in this sample do not meet diagnostic and statistical manual of mental disorders (DSM)-V criteria and the IES-R is not an official diagnostic criteria instrument for PTSD.

Overall, our findings provide initial evidence, that low levels of perceived availability of social companionship and opportunities for social engagement with others preceding a stressful event, may be a social risk factor for subsequent development of subclinical PTSD symptoms and potentially future PTSD diagnosis.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Baylor University Institutional Review Board. The participants provided their written and informed consent to participate in the study.

## AUTHOR CONTRIBUTIONS

AG designed the research study, collected the data, and participated in writing the manuscript. CC helped with the data analyses and preparation of findings for the manuscript. NJ-H analyzed the data and wrote the manuscript. All authors contributed to the article and approved the submitted version.

**Background:** The measures taken to contain the coronavirus disease 2019 (COVID-19) pandemic, such as the lockdown in Italy, do impact psychological health; yet, less is known about their effect on cognitive functioning. The transactional theory of stress predicts reciprocal influences between perceived stress and cognitive performance. However, the effects of a period of stress due to social isolation on spatial cognition and exploration have been little examined. The aim of the present study was to investigate the possible effects and impact of the COVID-19 pandemic on spatial cognition tasks, particularly those concerning spatial exploration, and the physiological leftward bias known as pseudoneglect. A right-hemisphere asymmetry for spatial attention processes crucially contributes to pseudoneglect. Other evidence indicates a predominantly right-hemisphere activity in stressful situations. We also analyzed the effects of lockdown on coping strategies, which typically show an opposite pattern of hemispheric asymmetry, favoring the left hemisphere. If so, then pseudoneglect should increase during the lockdown and be negatively correlated with the efficacy of coping strategies.

**Methods:** One week before the start of the lockdown due to COVID-19 in Italy (T1), we had collected data from a battery of behavioral tests including tasks of peri-personal spatial cognition. During the quarantine period, from late April to early May 2020 (T2), we repeated the testing sessions with a subgroup of the same participants (47 right-handed students, mean age = 20, SD = 1.33). At both testing sessions, participants performed digitized neuropsychological tests, including a Cancellation task, Radial Arm Maze task, and Raven's Advanced Progressive Matrices. Participants also completed a newly developed COVID-19 Student Stress Scale, based on transactional models of stress, and the Coping Orientation to Problems Experienced—New Italian Version (COPE-NIV) to assess coping orientation.

**Results:** The tendency to start cancellation from a left-sided item, to explore first a left-sided arm of the maze, and to choose erroneous response items on the left side of the page on Raven's matrices increased from T1 to T2. The degree of pseudoneglect

increment positively correlated with perceived stress and negatively correlated with Positive Attitude and Problem-Solving COPE-NIV subscales.

**Conclusion:** Lockdown-related stress may have contributed to increase leftward bias during quarantine through a greater activation of the right hemisphere. On the other hand, pseudoneglect was decreased for better coping participants, perhaps as a consequence of a more balanced hemispheric activity in these individuals.

**Keywords:** cognition, psychology, stress, pseudoneglect, coronavirus, quarantine, pandemic

## INTRODUCTION

Coronavirus disease 2019 (COVID-19) broke into a worldwide pandemic (World Health Organization, 2020) at the beginning of 2020. At the time of writing, there are more than 7.5 million confirmed cases throughout 215 countries, with more than 400,000 deaths. Italy was the first European Union (EU) country to be hit by a dramatic COVID-19 outbreak, with a quick and heavy impact on public physical and psychological health. Millions of people have experienced an abrupt change in their lives, due not only to the spreading of the illness but also to the measures put in place to prevent the contagion and limit the outbreak. On March 9, 2020, the Italian government imposed a national quarantine and several consequent lockdown restrictions, which ended on May 4, 2020, for some activities and on May 18, 2020, for others. Thus, the Italian quarantine lasted 70 days.

Brooks et al. (2020) examined previous research on the psychological impact of quarantine and reported a high prevalence of symptoms of psychological distress and disorder: especially low mood and irritability, but also emotional disturbance, depression, stress, insomnia, post-traumatic stress symptoms, etc. Moreover, they found that the effects of security measures due to a pandemic can affect not only short-term but also long-term psychological state (Brooks et al., 2020). Poor sleep quality, for example, can affect mental health (Gehrman et al., 2013; Franceschini et al., 2020) and alter emotional and cognitive functioning (Altena et al., 2020). As emphasized by the American Psychological Association (Novotney, 2020), social isolation can trigger several health risks. Feeling isolated can lead to poor sleep, poor cardiovascular health, depressive symptoms, and impaired executive function. These effects tend to impair the ability to stay focused, emotional control, retrieval of information, and the capacity to follow directions. Even brief periods of loneliness and isolation can have negative consequences on both physical and mental well-being (Cacioppo and Patrick, 2008).

Restrictions could affect different life domains among students, inducing specific perceived stressors related to academic studying, relationships with university colleagues, relationships with professors, social isolation, risk of contagion, relationships with relatives, and sexual life (Zurlo et al., 2020). Moreover, restrictions could also affect physical activity, socializing (except virtual social media), proper nutrition, and good quality of sleep. These restrictions were likely to result in increased stress and psychological disease (Mandolesi et al., 2018; Brooks et al., 2020; Zurlo et al., 2020) as well as in recourse to coping strategies

to deal with it. However, less is known about the potential impact of quarantine on spatial cognition, a heterogeneous set of processes incorporating spatial memory (Mandolesi et al., 2009b; Sorrentino et al., 2019), egocentric and allocentric representation and mapping abilities (Klatzky, 1998; Foti et al., 2020), and visuo-perceptive abilities, including spatial attention (Newcombe and Huttenlocher, 2007; Bartolomeo et al., 2012; Newcombe, 2018; Bartolomeo and Malkinson, 2019; Bartolomeo, 2020).

The transactional theory of stress predicts a reciprocal influence between perceived stress and cognitive performance and underlines the key role played by individual differences, such as coping strategies, in influencing this relationship (Lazarus and Folkman, 1984; Matthews et al., 2000). The individual adaptation process to a significant source of stress (such as the current COVID-19 pandemic lockdown) consists of appraisals of primary control (i.e., perceived possibilities to modify the situation to reduce its negative impact) and secondary control (i.e., perceived possibilities to modify the appraisal of circumstances to achieve a positive adjustment).

Thus, similar sources of stress may have a different subjective impact. Stress is a dynamic concept, depending on the constant interplay between individual and situational factors that reciprocally influence each other, and the potential efficacy of the different coping strategies adopted to deal with perceived stress and to enhance adjustment is strongly situation-specific and related to the interaction between the individuals and the situations (Zurlo et al., 2013, 2019). From this perspective, in particular, a perceived lack of controllability can lead to lower levels of performance (Matthews and Campbell, 2009).

Little is known about the effects of a period of stress (such as quarantine and social isolation) on spatial cognition. Animals being exposed to chronic stress show impaired exploratory behavior (Brydges et al., 2012; ter Horst et al., 2012; van der Kooij et al., 2018). Rats exposed to chronic stress in their early life show atypical leftward asymmetry in turning behavior (Mundorf et al., 2020). In particular, stress might play different roles at different stages of development: early exposition might lead to structural brain changes, whereas later exposition might modulate functional aspects (Berretz et al., 2020).

Gruzelier and Phelan (1991) found that stress was able to shift the hemispheric balance in a divided visual field lexical task toward the left visual field in a sample of medical students. Richardson and VanderKaay Tomasulo (2011) induced stress in human participants by using the frustrating Star Mirror Tracing Task and found slower spatial responses in a navigation task and a perspective taking task, as compared with non-stressed control

participants. However, Schwabe et al. (2007) found no evidence of an effect of stress on spatial learning, and Duncko et al. (2007) found improved performance on a virtual navigation task after hand immersion in ice water (cold pressor stress).

Directional spatial effects offer a possibility to quantify the effects of stress on spatial cognition. A basic, evolutionarily conserved pattern of asymmetry sees the right hemisphere taking control of responses to novel, unpredicted and potentially dangerous changes in the environment (Compton et al., 2000; Vallortigara and Versace, 2017; Bartolomeo and Malkinson, 2019). Another, well-known pattern of asymmetry favoring the human right hemisphere concerns the fronto-parietal brain networks important for orienting and control of spatial attention (Corbetta et al., 2008; Bartolomeo and Malkinson, 2019). A relative hyperactivity of right-hemisphere attention networks might push spatial attention leftward. This directional attention bias contributes to a small, physiological leftward bias in spatial processing (Toba et al., 2011), labeled pseudoneglect (Bowers and Heilman, 1980). Pseudoneglect can manifest itself during the bisection of horizontal lines, as a small leftward deviation of the subjective midpoint (Jewell and McCourt, 2000) or as a bias to start visual search from a left-sided item (Gigliotta et al., 2017).

Evidence on structural and functional brain asymmetries regarding attention networks and stress response (both involving the right hemisphere, see Ocklenburg et al., 2016; Zach et al., 2016; Gigliotta et al., 2017) led us to hypothesize a relation between stress and pseudoneglect. Specifically, two predictions were made: (1) higher level of stress should increase the magnitude of pseudoneglect and (2) effective coping strategies that may preferentially reduce right-hemisphere activation (Lindauer et al., 2008) should reflect in a lower magnitude of pseudoneglect. Just before the beginning of the COVID-19 lockdown, we had assessed visuospatial performances in a group of Italian university students. Thus, we had the unique opportunity to test our predictions by comparing students' performances before and during the lockdown.

## MATERIALS AND METHODS

### Participants

Throughout the month of February 2020, before the Italian lockdown, we conducted data collection sessions on personal spatial cognition tasks. The data collection ended on March 2, exactly 1 week before the start of the lockdown due to COVID-19 in Italy. We therefore decided to perform a second data collection with the same participants during the quarantine period. Specifically, the session lasted 2 weeks from late April to early May.

Before the beginning of the lockdown, 102 Psychology and Philosophy students (81 females) of the University of Naples Federico II aged between 18 and 26 years (mean = 19.5, SD = 1.5) voluntarily enrolled in the first experimental session. Selection criteria for participants' recruitment included normal or corrected-to-normal vision. Students were contacted later on during quarantine, and 55 out of 102 students agreed to participate in the second session. Seven out of 55 participants

were excluded because they reported left hand preference. Left-handers were excluded because of evidence of higher performance variability on visuospatial tasks (see, for example, Sampaio and Chokron, 1992) and of decreased pseudoneglect effects (Jewell and McCourt, 2000). One additional participant did not conclude the session because of technical problems. The final sample consisted of 47 right-handed students, aged between 18 and 24 years (mean = 20, SD = 1.33), 41 females and 6 males.

Written informed consent was obtained from all participants. The study was approved by the Local Ethics Committee of the University of Naples Federico II (protocol number: 12/2020) and was carried out in accordance with the Declaration of Helsinki.

## Measures

### Neuropsychological Tests

#### *Cancellation Task*

In the present study, we administered a digitized Cancellation task developed by Gigliotta et al. (2017). Each trial starts with participants touching (or clicking on) a green button located at the center of the screen. Participants are then presented with five round red stimuli randomly arranged on an electronic screen. They have to cancel all the stimuli as fast as possible with a stylus pen touch or a mouse click (depending on the user interface). The canceled item changes in color to a brighter nuance of red. Thirty trials were administered, with randomly different spatial disposition of targets.

#### *Radial Arm Maze Task*

The Radial Arm Maze (RAM; Olton and Samuelson, 1976) consists of a central area with identical radiating arms. It is extensively used to assess the spatial abilities of laboratory rodents and human participants (Overman et al., 1996; Mandolesi et al., 2009a,b; Foti et al., 2011, 2020). The aim is to recover rewards hidden at the end of each arm. Different strategies can be implemented (for example, visit a specific sequence of arms, adjacent, opposite, or alternating, etc.). We used a digitized version (Mandolesi and Gigliotta, submitted) whereby participants control a ladybug, positioned in the center of the labyrinth, along the arms to retrieve hidden ladybugs placed at the end of each arm. There were six trials, with a time limit of 60 s per trial. The number of arms gradually increased over trials from 3 to 8 arms. In the present work, we analyzed results from the 8-arm maze, the condition with the highest spatial resolution.

#### *Raven's Advanced Progressive Matrices*

The Raven's Advanced Progressive Matrices (APM; Raven et al., 1962) are used to assess non-verbal and "fluid" intelligence and require the direct analysis, construction, and integration of a series of visual items. Raven's matrices questions consist of visual geometric designs with a missing piece. Participants are asked to choose the missing piece between eight alternatives, arranged along four vertical columns disposed from the left to the right of the page below the test image. A digital version of the Raven's APM was administered in the present study, for which the matrices were transposed on Google Modules. Only set I (12 items with 8 possible responses) was administered.

Costa et al. (1969) administered the Raven's APM to patients suffering from left neglect after right-hemisphere damage and assessed the spatial side (left or right) of the error responses. The results showed that patients tended to erroneously choose right-sided items. Colombo et al. (1976) administered Raven's APM to patients with left and right brain injuries and found that patients tended to prefer ipsilesional candidate items. This position preference was especially evident in patients with right-hemisphere damage. This evidence, suggesting that spatial biases can influence performance on the Raven's APM, incited us to employ such a space-based assessment in the present setting.

## Questionnaires

### The COVID-19 Student Stress Questionnaire

The COVID-19 Student Stress Questionnaire (CSSQ; Zurlo et al., 2020) was specifically developed to assess university students' perceived stress during the COVID-19 pandemic lockdown. It consists of 7 items on a 5-point Likert scale ranging from 0 ("not at all stressful") to 4 ("extremely stressful"). For the purpose of instrument design, perceived stress was operationalized based on transactional models of stress (Lazarus and Folkman, 1984). Each item was developed to cover different domains that could have been subject to variations due to the COVID-19 pandemic lockdown and, therefore, that may be potentially perceived as sources of stress (i.e., risk of contagion; social isolation; relationship with relatives; relationship with colleagues; relationship with professors; academic studying; couple's relationship, intimacy, and sexual life). The scale provides a Global Stress score ranging from 0 to 28. The CSSQ was developed and tested in a sample of 514 Italian university students, and it was confirmed to be a valid and reliable measure. The Global Stress score revealed significant correlations, in the expected directions, with measures of Anxiety ( $r = 0.55$ ,  $p < 0.01$ ), Depression ( $r = 0.56$ ,  $p < 0.01$ ), and Somatization ( $r = 0.39$ ,  $p < 0.01$ ), as assessed by means of the Symptom Checklist-90—Revised (SCL-90-R; Prunas et al., 2010). The questionnaire revealed a satisfactory internal consistency (Cronbach's alpha = 0.71).

The results of the CSSQ scale validation study highlighted the presence of three significant factors, which the authors labeled as: 1) "Relationships and Academic Life," which comprised the four items covering perceived stress related to relationships with relatives, relationships with colleagues, relationships with professors, and academic studying; 2) "Isolation," which comprised the two items exploring perceived stress related to social isolation and changes in sexual life due to the containment measures; and 3) "Fear of Contagion," which comprised the item assessing perceived stress related to the risk of infection. Therefore, we decided to analyze any relationships between the increase in left bias and the stress measured through the CSSQ scale.

### Coping Orientation to Problems Experienced—New Italian Version (COPE-NIV; Sica et al., 2008)

The questionnaire consists of 60 items on a 5-point Likert scale ranging from 1 ("I usually don't do this at all") to 4 ("I usually do this a lot") divided into five subscales: Seeking

Social Support (12 items covering strategies centered on seeking support for instrumental or emotional reasons and focusing on and venting of emotions; Cronbach's  $\alpha = 0.88$ ), Avoiding (16 items covering strategies centered on detaching, denial, humor, alcohol and drug disengagement, behavioral disengagement, and mental disengagement; Cronbach's  $\alpha = 0.70$ ), Positive Attitude (12 items covering strategies centered on positive reinterpretation and restraint coping; Cronbach's  $\alpha = 0.76$ ), Problem Solving (12 items covering strategies centered on suppression of competing activities, planning, and active coping; Cronbach's  $\alpha = 0.83$ ), and Turning to Religion (8 items covering strategies centered on seeking comfort in religious and spiritual practices; Cronbach's  $\alpha = 0.85$ ).

## Procedure

### Pre-Lockdown Session (T1)

The first experimental session took place in a quiet room of the University of Naples Federico II. In the room, there was a large table with chairs around it; on the table, there were an 8-inch tablet to be used by participants and a computer in front of the experimenter. Participants sat in front of the experimenter. The total time to complete all tests was around 20 min.

The first session test battery we administered included, among other tests, the Cancellation task, the RAM task, and the Raven's APM task. The Cancellation task and the RAM task were administered by means of specific software running on an 8-inch tablet and performed using a stylus pen to interact with the screen. Participants were comfortably seated with a viewing distance of ~40 cm, and the tablet was placed on the table in front of them in a vertical position.

A digital version of the Raven's APM was first administered, for which the matrices were transposed on Google Modules. Participants used a 14-inch PC and a mouse to perform the APM. Then, the Cancellation task was administered on the tablet. The instructions were as follows: "As soon as you select the green button with the pen you will see little circles, which you will have to select all in the shortest possible time. If you happen to touch the white screen it will turn black for a moment, then you go on." Finally, the digitized RAM task was performed by participants. The instructions were as follows: "The objective of this task is to explore all the arms of the mazes, dragging the ladybug there, and find the ladybugs hidden under the jars within 60 s. Remember that you must always go to the center before moving from one arm to another. The first item is for practice."

### Lockdown Session (T2)

After about 2 months from the start of the lockdown, we contacted the participants of the first experimental session. A subgroup of 47 students agreed to participate in the second experimental session. The procedure consisted in the administration of the questionnaires, then in the online administration of the Cancellation task, and the digitized RAM task to the participants, through Microsoft® Teams, a unified communication and collaboration platform that combines chat, teleconferencing, content sharing, and application integration.

Participants were asked to fill out the questionnaires on Microsoft® Forms, an online survey maker software. A few

days after completing the questionnaires, one experimenter started the cognitive test sessions and carried out the online meetings on Microsoft® Teams platform, with each student separately. The experimenter first explained the test procedure methods, ensuring that both network connections were working properly. The software implementing the spatial tasks ran on the experimenter's computer. After giving the same task instructions as in the pre-lockdown session, the experimenter activated the Microsoft® Teams platform's screen sharing mode, so that the participants had the control of the experimenter's screen and were able to carry out the tasks. Thus, there were minor differences in user interface between T1 (touch stylus used for the Cancellation task and the RAM task) and T2, when the mouse was instead used for all tests.

## Parameters

In both the experimental sessions, the following parameters were analyzed.

For the Cancellation task, we first defined the center of the display as 0, so that the values of the X pixel coordinates assumed a negative sign for the left side of the screen and a positive sign for the right side. Then, we calculated the average position on the x-axis of the first canceled stimulus for each participant (see Gigliotta et al., 2017, for a detailed description of the procedure). In order to assess potential differences in spatial bias before (T1) and during (T2) the lockdown, we calculated the increment of leftward preference, in canceling the first stimuli, from T1 to T2.

For the RAM task, we defined as 0 the center of the display. The values of the X pixel coordinates were negative for the left side of the screen and positive for the right side. We focused on the performance on the 8-arm maze, which offered participants the largest number of potential exploration strategies. We assessed the coordinates of the first explored arm for the 8-arm maze, as well as the spatial sequence of the visited arms.

For Raven's APM, in addition to the test scores, we obtained a measure of position preference (see Costa et al., 1969), by assessing the location in space (left or right) of the error responses chosen below the target figure of each matrix. Therefore, we calculated the average number of items erroneously chosen for each side of space, among the four left-sided and the four right-sided alternatives.

## RESULTS

Data analysis was run on JASP (<https://jasp-stats.org/>), version 0.12.2.

### Cancellation Task

First, we investigated the presence of a lateralization of the first canceled stimulus in the Cancellation task: results showed a left-biased distribution of the first canceled stimulus both for T1 (Wilcoxon–Mann–Whitney two-tailed test,  $Z = -103$ ,  $p < 0.001$ ; mean =  $-60.1$ , SD = 62.33) and for T2 (Wilcoxon–Mann–Whitney two-tailed test,  $Z = -18$ ,  $p < 0.001$ ; mean =  $-83.46$ , SD = 49.97), thus confirming the previously reported tendency to

start the visual search from a left-sided target (pseudoneglect) on this task (Gigliotta et al., 2017).

Then, a repeated measure ANOVA was conducted on the spatial X coordinates of the first canceled stimulus for each trial in T1 and T2, to evaluate potential lockdown-induced changes in patterns of spatial exploration. The independent variable was the time of testing (T1, T2); the dependent variable was the coordinate (in pixels) of the first canceled stimulus. **Figure 1** shows that, on average, the first canceled stimulus at T2 was 23 pixels further to the left (mean =  $-83.46$  pixels, SD = 49.97) as compared with its position at T1 [mean =  $-60.10$ , SD = 62.33,  $F(1,46) = 6.10$ ,  $p = 0.017$ , with a moderate sample size effect,  $\eta^2 = 0.117$ ].

To further assess the potential relationship between stress and magnitude of pseudoneglect, we conducted a two-tailed Pearson's correlation analysis between the results of the CSSQ and the pseudoneglect increment at T2 from T1. The null hypothesis was that the two variables are not related in our sample; conversely, the alternative hypothesis was that the stress and the magnitude of pseudoneglect are related. The results showed a significant correlation between the CSSQ scale and the leftward biased exploration of the space ( $r = 0.407$ ,  $p = 0.004$ ), so we could accept the alternative hypothesis and reject the null one: particularly, as stress levels increase, the exploration bias to the left seems to be also accentuated (**Figure 2**).

A second two-tailed Pearson's correlation analysis investigated the potential relationship between coping (assessed through the five subscales of the COPE-NIV) and pseudoneglect increment at T2. The results showed a significant correlation between 2 out of 5 COPE-NIV subscales (Positive Attitude and Problem Solving) and lower leftward biased exploration of the space

( $r = -0.385$ ,  $p = 0.008$  and  $r = -0.308$ ,  $p = 0.037$ , respectively; see **Figures 3, 4**). This correlation indicates that pseudoneglect decreases with increasing active coping strategies. Instead, no significant correlation resulted between the other COPE-NIV subscales, Seeking Social Support ( $r = 0.100$ ,  $p = 0.507$ ), Avoiding ( $r = -0.072$ ,  $p = 0.633$ ), and Turning to Religion ( $r = -0.116$ ,  $p = 0.445$ ).

### Digitized RAM Task

We investigated the lateralization of the first explored arm of the RAM and verified if there was a significant variability of the lateralization between T1 and T2. A repeated measures ANOVA on the x coordinates of the first arm (of the 8-arm maze) chosen indicated that participants tended to start exploration from a left-sided arm at T2 (mean =  $-23.04$ , SD =  $112.74$ ), whereas they preferred to start from a right-sided arm at T1 [mean =  $21.62$ , SD =  $110.47$ ,  $F(1,46) = 5.31$ ,  $p = 0.03$ ,  $\eta^2 = 0.103$ ] (**Figure 5**).

Then, to assess a potential relationship between stress/coping and the deviation of the maze exploration to the left side at T2, a two-tailed Pearson's correlation analysis between the results of the CSSQ/COPE-NIV and the laterality variation at T2 from T1 was conducted. The results do not show any significant correlation of the variation in lateralization, neither with the global score of the CSSQ scale ( $r = -0.173$ ,  $p = 0.246$ ) nor with the CSSQ subscale scores, nor with the 5 COPE-NIV subscales, such as Positive Attitude and Problem Solving coping strategies ( $r = -0.092$ ,  $p = 0.545$  and  $r = -0.019$ ,  $p = 0.899$ , respectively).

## Raven's APM

Participants obtained scores in the normal range both at T1 (mean = 10.085, SD = 1.851) and at T2 (mean = 9.745, SD = 1.750). There was no significant effect of time of testing on accuracy [repeated measures ANOVA on the correct answers,  $F(1,46) = 2.012, p = 0.163$ ].

To assess changes in position preference for erroneous responses (Costa et al., 1969), we conducted a 2 (period of testing: T1, T2)  $\times$  2 (error side: right, left) repeated measures ANOVA. There was a main effect of error side:  $F(1,46) = 22.41, p < 0.001, \eta^2 = 0.14$ , because participants showed a bias to choose a left-sided item (mean = 1.40, SD = 1.30) over a right-sided one (mean = 0.72, SD = 1.01). Time of testing approached significance ( $p = 0.06$ ), because participants tended to make more errors during quarantine (mean = 1.17) than before it (mean = 0.96). Importantly, the two factors interacted  $F(1,46) = 4.91, p = 0.032, \eta^2 = 0.036$ , because the leftward bias increased during quarantine (Figure 6).

Finally, to assess a potential relationship between stress/coping and the deviation of Raven's errors to the left side at T2, a two-tailed Pearson's correlation analysis between the results of the CSSQ/COPE-NIV and the laterality variation at T2 from T1 was conducted. The results do not show any significant correlation of the variation in lateralization, neither with the global score of the CSSQ scale ( $r = -0.017, p = 0.910$ ) nor with the CSSQ subscale scores, nor with the 5 COPE-NIV subscales, such as Positive Attitude and Problem Solving coping strategies ( $r = -0.148, p = 0.327$  and  $r = -0.079, p = 0.604$ , respectively).

## DISCUSSION AND CONCLUSION

The aim of this research was to assess whether the stressful conditions experienced by students during the harsh quarantine measures taken in Italy (a country strongly hit by COVID-19) had any influence on their spatial cognition abilities. The results indicated several indices of such an influence.

Specifically, we found a significant leftward shift in three tasks tapping on spatial abilities from T1 (pre-lockdown) to T2 (circa after 2 months of harsh quarantine). The tasks were (a) the Cancellation task, (b) the digitized RAM task, and (c) the Raven's APM task. Importantly, there were no changes in the general accuracy on the Raven's APM task, a test of general non-verbal intelligence; the only time-related change was an increase of leftward spatial bias in the choice of an (erroneous) response item. Thus, the time-related changes we observed seem to be relatively specific to the spatial domain. A potential confound could be the mode of response used for the Cancellation task. Participants used a touch pen at T1 and a computer mouse at T2. However, a similar increase in leftward bias with time also occurred on the Raven's matrices, where participants always responded by using the mouse.

Were these changes in spatial bias really related to lockdown-induced stress? Evidence supporting this possibility comes from (1) the positive correlation between stress measured through the CSSQ scale and the increase of pseudoneglect during the lockdown and (2) the negative correlation that we observed between the increment of pseudoneglect and specific active coping strategies, which mirrored the positive correlations between pseudoneglect and time of testing on the Cancellation task (for the other tasks, we should take into account differences on the cognitive functions they rely on and different measures of stress). Individuals who were able to resort to positive attitude and problem-solving coping strategies displayed lesser leftward bias than those who obtained higher scores in perceived stress.

Our findings seem, therefore, in line with research underlining the impact of perceived stress on individuals' performance (Matthews et al., 2000; Matthews and Campbell, 2009). They also provide new evidence supporting the efficacy of the adoption of strategies centered on activity and positive reappraisal (Santarnecchi et al., 2018; Zurlo et al., 2019).

The neurobiological underpinnings of physiological leftward bias (pseudoneglect) are likely to rely on hemispheric asymmetries of attention networks (Corbetta et al., 2008; Bartolomeo and Malkinson, 2019). Shifts in line bisection strictly depend on activity in these fronto-parietal networks (Thiebaut de Schotten et al., 2005). For example, activity in the right ventral attention network seems to correlate with the effect of line length in pseudoneglect (Benwell et al., 2014). In a simulation study, Gigliotta et al. (2017) demonstrated that different patterns of asymmetries in artificial attention networks can lead to different levels of pseudoneglect in neuroagents (robots provided with a simulated brain) performing a Cancellation task similar to the one used here.

On the other hand, abundant evidence suggests a relation of stress-related mechanisms with the right hemisphere (Compton et al., 2000; Ocklenburg et al., 2016; Bartolomeo and Malkinson, 2019). Moreover, early life exposure to stress has been proposed as a determinant of psychiatric and neurodevelopmental diseases characterized by atypical brain asymmetries (Berretz et al., 2020). Finally, a recent study on turning behavior in rats highlighted a leftward shift in turning preferences in a group of animals exposed to stressful conditions during the early stage of their lives compared with a control group (Mundorf et al., 2020).

Acute and chronic stress can thus affect lateralized behavior in humans and animals, as a result of higher right-hemisphere activation (Ocklenburg et al., 2016). In addition, stress in university students was found to increase connectivity in the attention networks, particularly in the right hemisphere (Soares et al., 2013). Over time, this functional modulation might translate into structural plastic changes. For example, Brem et al. (2020) performed white matter tractography on a group of volunteers after 520 days of confinement and found a general reduction in fractional anisotropy in the right temporo-parietal junction. Coping strategies, on the contrary, might be related to greater left hemisphere connectivity. Santarnecchi et al. (2018) found a positive correlation with the connectivity of the left angular gyrus of performance on the problem-solving subscale of the coping scale used in this study, the COPE-NVI.

The specific relation we found between stress and leftward bias is thus likely to depend at least in part on stress-induced increased activity of right-hemisphere attention networks. The right hemisphere may also facilitate stress hormone responses through the hypothalamic–pituitary–adrenal gland axis (Sullivan, 2004), whereas the left hemisphere structures, such as the medial prefrontal cortex, may increase resilience to stress and control its effects on social behavior (Lee et al., 2015).

The present study was conducted on a relatively limited participant sample ( $N = 47$ ). As a consequence of the strict lockdown measures, the test conditions could not be fully controlled at T2. Despite these limitations, our results linking stress and leftward bias were consistent over several tests. More “ecological” tests of spatial cognition, closer to everyday life activities than the tests we employed here (Cerrato et al., 2019, 2020), may be useful to further assess these relationships. Studies in animals, as well as on simulated neurorobots (Broz et al., 2014; Gigliotta et al., 2015a,b, 2017; Pacella et al., 2017), might further

illuminate the intimate mechanisms that link stress to spatial attention.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Local Ethics Committee of the University of Naples Federico II (protocol number: 12/2020). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

OG, LM, MZ, and PB contributed to the conception and design of the study. FS, FV, AA, and AC collected the data and wrote the first draft of the manuscript. OG performed the statistical analysis. All authors contributed to manuscript revision, and read and approved the submitted version.

This research aims to monitor the current situation of confinement in Spanish society motivated by COVID-19 crisis. For this, a study of its socio-family, psychological and educational impact is conducted. The sample ( $N = 165$  families, 89.1% nuclear families with children living in the same household and 20.5% with a relative in a risk group) comes from the Aragonese region (Spain). The instruments used are: Beck-II Depression Inventory (BDI-II); Baron-Cohen and Wheelwright's Empathy Quotient (EQ) with its cognitive empathy subscale, as well as an ad-hoc questionnaire, reviewed by a panel of experts, to learn about socio-personal, family and housing conditions, use of technology, involvement in school tasks and household, and working condition. The multiple regression analysis results show that the anxiety derived from the current situation is explained in 23.1% ( $p < 0.001$ ) by the variables: gender ( $t = -2.31$ ,  $p = 0.022$ ), level of Internet consumption ( $t = 2.139$ ,  $p = 0.034$ ), increase of family conflicts ( $t = 2.980$ ,  $p = 0.003$ ) and help with school tasks ( $t = 2.980$ ,  $p = 0.040$ ). On the other hand, cognitive empathy is explained in 24.6% ( $p < 0.001$ ) by the variables: gender ( $t = -4.690$ ,  $p < 0.001$ ) and mother's hours of teleworking ( $t = 2.101$ ,  $p = 0.037$ ). All this leads us to conclusions related to preventive systems of social, psychological, and educational aspects to better serve families. These conclusions can be also be transferred to the future with an inclusive care to family settings from those three parameters.

**Keywords:** COVID-19, anxiety, cognitive empathy, families, education, social stressors

## INTRODUCTION

The current health emergency due to COVID-19 has led to numerous countries, and, above all, to Spain, to decree very drastic measures of house confinement (Gobierno de España, 2020). Life as it was known until now has been paralyzed. Only the work to produce essential services and products has been allowed and telework has prevailed over on-site work. All these measures have had an impact on people social, family, work, and educational life in the face of an unprecedented situation, which surely will have psychological and sociological consequences on the population, as well as changes in educational methods.

Recently, studies have been published that show how the COVID-19 pandemic is affecting the population health. The biopsychosocial model defends the need to attend not only to physiological symptoms (Guan et al., 2020; Holshue et al., 2020) but also to psychological and social elements such as: anxiety, depression, suicidal intentions, panic disorder, loneliness and psychotic signs (Moghanibashi-Mansourieh, 2020; Wang et al., 2020; World Health Organization, (WHO), 2020) caused both by the situation of isolation and by social consequences such as unemployment, inflation and closure of companies (Moghanibashi-Mansourieh, 2020). In his theoretical review Rajkumar (2020) shows the psychological consequences of this situation, highlighting how the incidence of anxiety and depression is increasing. Likewise, he argues the urgent need to implement specific interventions in vulnerable populations: children, adolescents and people with few resources. Although all age groups present at some extent psychological and social symptoms, age is a determining variable in the appearance and intensity of symptoms of psychological nature, and so is gender. In Iran, Moghanibashi-Mansourieh (2020) exposes how the level of anxiety in women is significantly higher than in men, also being higher in the group between 21 and 40 years old, predictably because this is the most economically affected group. Similarly, he indicates that the low level of education increases the anxiety rate, and, also, the continuous consumption of news related to the coronavirus. On the other hand, people who have relatives or acquaintances with COVID-19 are also severely affected by this type of psychopathology. Similarly, Wang et al. (2020) find that in China, women are the most affected in terms of psychosocial stress, anxiety and depression. It is necessary to contextualize anxiety and stress from the theory of family stress and coping theory (Patterson, 1988; Boss, 2001). In addition, these same authors, contemplate stress as a concept that is not always negative, and that obeys to the response of family adaptation in a communitarian and cultural context including factors or demands of normative and not thermal character, unresolved family tensions and small daily annoyances. Aligned with these studies, Taylor et al. (2008) recall how in the “flu epidemic” (pig flu) those people who lived in areas with a higher rate of cases suffered greater stress, being the youngest and less educated people the group with the highest risk of this disorder.

It is obvious that contextual elements play an essential role in anxiety control in situations of social isolation derived from natural, political or health emergencies, as is the case of COVID-19 crisis (Sugiura et al., 2020). In these situations, in addition to the main stressor, that is the crisis itself, authors such as Lock and Gordon (2012), add a series of secondary stressors derived from the family, social, economic, media or educational contexts that can aggravate these anxiety situations. These would be: economic stressors such as loss of income due to labor issues (Ehrlich et al., 2010; Picou and Hudson, 2010); stressors related to family or friends' health during the emergency (Kun et al., 2010); stress related to exceptional education and schooling in these situations (Kilmer and Gil-Rivas, 2010); stress derived from exposure to catastrophic information provided by the media (Lau et al., 2010); stressors related to the increase in family conflicts (Irmansyah et al., 2010), understood as the disputes

between parents, parents and children or among children that cohabitate (Emery, 1992), or greater burden on the distribution of household chores in some of the family members (McDermott, 2010); anxiety derived from the loss of social contact with friends and colleagues and, consequently, reduction of social capital (Wind et al., 2011); stress derived from loss of leisure and recreation (Irmansyah et al., 2010); and the anxiety related to changes in people's opinions about the world they live in or about themselves (Lock and Gordon, 2012) towards a greater perception of the democratization of risk (Beck, 1998). To these secondary stressors, the publication by Howard et al. (2018) adds in the family context the fact of caring for the elderly, people with disabilities, having children under five years-old, having low incomes and belonging to groups with cultural and linguistically diverse backgrounds.

On the other hand, the empathy is an important construct in humanitarian crisis. This concept is defined as: “empathy allows us to interact effectively in the social world” (Baron-Cohen and Wheelwright, 2004, p.163). In this sense, social support among group members is related to higher levels of empathy in these crisis situations and, therefore, lower levels of anxiety both in who helps and who is helped, regardless of the personality associated factors (Maner and Gailliot, 2007; Siedlecki et al., 2014; Sugiura et al., 2020). This is because, in crisis situations, the human being is eminently social and cooperative (Glassman, 2000), so prosocial behaviors in emergency situations are common and have a positive effect on the psychological well-being of members of the affected community (Afifi et al., 2012; Welton-Mitchell et al., 2016). This aspect is especially important in the present situation of confinement, since families must not only care for their children, but also other family members who are ill (Porzio et al., 2020) or with psychological disorders (Chatterjee et al., 2020), who are more vulnerable to the Covid-19.

Regarding educational elements related to staying at home, it is necessary to refer to research related to home-schooling in which the fundamental difference with the previous situation is the free and responsible option of being at home exercising educational functions with the social and psychological repercussions that this entails. Petrovic and Rolstad (2017) allude to the philosophical part of the idea that from home education autonomy and citizen commitment can be addressed, aspects that Rousseau and Freire highlight (Molina, 2002). Together with these ideas, the bottom line is freedom and knowing how to combine them and create synergies between the individual and the social (Gofen, 2015). Although it is difficult to conduct scientific studies related to this type of teaching due to its own idiosyncrasy, we allude to questions that appear in the reviewed works. The first is that making home schooling compatible, regardless of whether guidelines are followed, ends up having better emotional and academic results (Neuman and Guterman, 2016, 2017). Authors like DeRish et al. (2020) agree on the relevance of external evaluations to students so that monitoring is better for families and for apprentices. At this point it is necessary to remember the value of the evaluation as a way of considering the real situation and improvement guidelines. Although other studies such as Cheng and Donnelly's (2019) do not find significant differences in the emotional development

and socialization of children schooled at home or in educational centers. However, it is decisive to keep in mind that anxiety in mothers who attend school at home can have a negative effect on attachment (Zajac et al., 2020).

Reference has been made to this situation of real isolation (intentional and obligatory), highlighting the repercussion on families at the social, work and educational levels, and this has been linked to anxiety and empathy as outstanding variables. Thus, anxiety is understood as a transitory emotion characterized by subjective feelings of tension and apprehension, which are consciously perceived, accompanied by hyperactivity of the autonomic nervous system that can vary in intensity and over time (Spielberger et al., 1982). On the other hand, empathy is defined as an ability to perceive, understand and share emotions and stands out for its role in maintaining relationships and prosocial behaviors (Haut et al., 2019). Therefore, its importance for family coexistence in the current confinement situation is highlighted.

The objective of the current research is: to study the impact at psychological, educational and socio-familial level derived from the COVID-19 pandemic in families. That is to say, to analyze the different contextual variables and their impact on the states of anxiety and cognitive empathy in confinement. The following hypotheses are expected to be tested: different socioeconomic variables directly affect the states of anxiety and cognitive empathy (Maner and Gailliot, 2007; Siedlecki et al., 2014; Sugiura et al., 2020). In addition, it is expected to find that specific variables such as work situation, distribution of household tasks, care of people at risk and help to children in educational tasks are the variables with greater predictive weight for empathy and anxiety (Ehrlich et al., 2010; Irmansyah et al., 2010; Kilmer and Gil-Rivas, 2010; Kun et al., 2010; Lau et al., 2010; Picou and Hudson, 2010). Finally, it is expected to prove a gender difference in terms of empathy and anxiety produced by the change in the variables previously mentioned (Moghanibashi-Mansourieh, 2020).

## MATERIALS AND METHODS

### Sample

The sample is composed of 145 families from the Autonomous Community of Aragon (Spain), representing a total of 522 people, and with a family composition of 2 parents, or legal guardians with children, who respond the questionnaires. The average age of the adult participants is 42.52 (SD = 6.87) and 8.83 (SD = 6.32) for the children (Table 1). Of these, 32.4% had an only child, 63.9% two, and 4.7% three or more children. The selection was the result of a convenience and non-probabilistic snowball sampling on a national level, with a massive response from a single autonomous community (>90%), since the researchers belong to this region. The percentage of participation of families from other regions was very low (4.2%). Likewise, nuclear-type families exceeded 90% of the sample. It was decided to eliminate this data because it is not representative at a national level. The families excluded for not meeting the selection criteria represented 14.21% with a total of 87 individuals. The

**TABLE 1 |** Significant correlations of sociocultural variables and anxiety and cognitive empathy.

\* $p < 0.05$ , \*\* $p < 0.01$ .

inclusion criteria were: (1) families belonging to the Community of Aragon, (2) families made up of 2 parents with children, (3) that they offer themselves (4) that the survey can be sent from the same address and in one go, and (5) that they send all the questionnaires duly completed. The questionnaires were completed during the first week of April 2020. The Spanish population was strictly confined for two weeks. It was measured at this time because we wanted to study the impact of this health measure, not its follow-up.

### Research Process

The study received the approval of the Ethics Commission of the University of Zaragoza acting under the guidelines of the Ethics Committee of the Autonomous Community of Aragon. To do that, several phases were conducted that began in March 2020. In the first, information explaining the nature and objective of the project was launched massively on trusted social networks related to the educational field: schools, institutes and universities, as well as an invitation to participate to all those families that were interested. In a second phase, those who had expressed their willingness to participate were contacted by signing the informed consent, while ensuring confidentiality and anonymity that respected the ethical procedures of the Declaration of Helsinki (World Medical Association, 2001). The third phase consisted of sending the questionnaires (composed by *ad hoc* socio-educational questionnaire, Beck Anxiety Inventory (BAI) and cognitive empathy subscale of the EQ empathy quotient scale) that they had to fill in online and anonymously. The responses were recorded on a digital data storage base for later exporting.

## Instruments

*Demographic and socio-educational questionnaire ad hoc*, of own elaboration. The questions were related to the type of family structure, number of children, type of home, profession, employment situation during the crisis, family conflicts, household chores, school homework, etc., It consists of 25 items and was evaluated by a panel of experts, reaching an almost perfect level of agreement ( $k > 0.81$ ) following the indications by Cohen (2013). Subsequently, to corroborate the conformity of the results, a post evaluation was established using an advisory council and following the criteria of the communicative methodology. With regard to the panel of experts, the level of agreement or concordance was calculated through the Kappa index, obtaining a value of 0.72 ("good" concordance force). A poor concordance is considered for values less than 0.20, weak of 0.21–0.40, moderate of 0.41–0.60, good of 0.61–0.80 and very good for values higher than 0.81. On the other hand, the internal reliability of the *ad hoc* survey was analyzed through Cronbach's Alpha index reaching values of 0.62, with moderate to high reliability.

*Beck's anxiety inventory (BAI)* in its Spanish adaptation by Sanz et al. (2005). It is designed for a collection of information in a self-report format that allows measuring the degree of anxiety and the aspects or symptoms less related to depression. Specifically, it measures anxiety derived from panic, panic and generalized anxiety disorders following the criteria established in the DSM-III-R. This questionnaire, dedicated to the measurement of cognitive and physiological anxiety consists of 21 items whose responses are evaluated from 0 to 3, being 0 "absolutely not," and 3 "severely." Reliability indices range from 0.41 to 0.58.

*Empaty Quotiente (EQ), Cognitive empathy scale* in its adaptation to the Spanish version (Redondo and Herrero-Fernández, 2018). The empathy quotient informs about the individual's ease and willingness to capture and understand other people feelings and how they are affected by these feelings of others. In this case, the study focused on cognitive empathy, so only this subscale was used. It consisted of 7 items, valued between 0 and 3, being 0 "absolutely not," and 3 "severely." Cronbach's alpha values for all subscales ranged from 0.67 to 0.80.

## Statistical Analysis

Statistical analysis was performed using the IBM SPSS Statistics for Windows software (version 25.0., IBM Cop., Armonk, NY, United States). First, a descriptive analysis of the socio-educational responses reported was performed. Its purpose was to describe the context of the current situation in qualitative terms. Subsequently, a comparison was obtained with the anxiety and cognitive empathy variables through analysis of variance (ANOVA). To establish the relationship between socio-educational factors and psychological factors of anxiety and cognitive empathy, a Pearson correlation analysis was carried out. To finish, a linear regression was performed to establish a predictive model of family and educational habits with the development of states of anxiety and empathy in the current situation of health crisis. All significant correlations were

included in the regression model considering a value of  $p < 0.05$  as statistically significant. On the other hand, linear regressions are carried out with steps forward. In this way, we can determine which element could be the most important.

## RESULTS

### Socio-Educational Comparative Descriptive Analysis

The qualitative analysis of the socio-educational questionnaire yields the following results: Regarding the parents' level of education, it is observed that mothers have university or postgraduate studies in a percentage of 65.7%, 30.8% have secondary studies, and 3.5% primary or basic studies. These data differ with respect to the fathers since 47% of them have university studies, 41.7% have secondary education studies and 11.3% elementary.

Regarding their **job occupation** (Figure 1), the females recognize that 40.2% of them have an indefinite contract, and males the 51.8% of them. Temporary work is performed by 7.7% of women. In the self-employed modality, women are 5.9% and men 12.5%. On the other hand, 8.3% of the females are unemployed compared to the males, which represents a 1.2% and finally 2.4% of them are retired. Regarding the profession, 26% of women are civil servants, compared to 19.6% of men, and 9.5% are engaged in household chores work, that in the case of the males are not reported. These differences between genders are evident when conducting a business activity, where there are no reported data on women, but on the male gender it represents the 4.2%. These observations raise again the debate on the wage gap and equality and equity between genders. Training data is higher for women, but the unemployment rate, unstable employment, and occupation in household chores account for 25.5% of them.

About the **current employment situation** in the confinement situation, the results are similar between the genders with respect to telework (32.5% women; 31.5% men) and those affected by a provisional downsizing plan (12.4% women; 15.5% men). There is a difference in attendance at the workplace, where 17.2% of women do so compared to 28% of men.

On the other hand, the **economic situation** of families in the state of health alarm has undergone some modification. 59.6% of them say that the family economy has been affected during this exceptional situation, with the negative situation being of a serious nature in 27.8% of households.

Arrangement the average scores of the BAI scale, the results derived from the first 15 days of confinement showed a greater presence of cognitive-subjective stress and anxiety in the individual. In this sense, the mean anxiety (Mean:13.9, SD:9.95) during the period of confinement was significantly higher than that which would be expected to be found in the population, according to BAI criteria (Sanz et al., 2005). In other words, anxiety rates skyrocketed. This cognitive determinant is what made the type of empathy focus on the cognitive character and reject the emotional element. The average rate was (Mean: 13.12, SD: 3.87) a superior value in normal conditions (Redondo and Herrero-Fernández, 2018).

Regarding the **size of the house and the existence of a garden or terrace**, 76.3% reported living in a dwelling larger than 76 square meters (21.9% < 105; 34.9% between 76–90 and 19.5% between 91–105) and 14.7% of families occupied smaller houses. In addition, 37.3% of families did not have a large garden or terrace, which increases the possibility of feeling anxiety and seeing empathic development altered. For this reason, an analysis of variance (ANOVA) was performed, showing that there was a difference in the empathy developed at this time in relation to the size of the dwelling ( $F = 3.047$ ;  $p < 0.05$ ). Thus, people living in a space less than 60 square meters are significantly affected by the development of their empathy, obtaining an average score of 9 compared to 13.406 of the overall average score. On the other hand, no significant differences were found regarding the repercussion of this variable on the development of anxiety. Regarding the variable of existence of garden or terrace in the home, the opposite occurs since there are no significant differences with empathy, but they exist in anxiety, when increasing the feeling of confinement ( $F = 4.228$ ;  $p < 0.05$ ), being greater in those families that don't have a terrace or garden ( $M = 15.463$ ).

The results on the **use of leisure time** during the alarm situation caused by the pandemic, indicate that 63.8% of respondents admit to having increased television consumption, with the increase in the Internet consumption becoming even more drastic, as it was reported by the 95.3% of the sample (general family), and 29.6% of them assuring that this increase has occurred severely. Given these response data, a new ANOVA analysis was carried out on these variables and their link with anxiety and empathic-cognitive development, finding a strong impact on the increase in internet consumption with respect to anxiety ( $F = 4.779$ ;  $p < 0.01$ ). Families who claimed not to have increased their Internet use or to have done it very slightly

reported mean anxiety scores of 7.285 compared to scores of 15.297 reported by those families who recognized a moderately high or severe increase of this consumption.

In the **educational field** and with respect to variables related to family hours devoted to children's school tasks, 50.3% of the families affirm dedicating less than 4 h to these tasks. 17.8% of them affirm that they are spending between 4 and 6 h, compared to 7.7% who report a daily dedication of more than 6 h. In contrast, 24.3% of families do not spend any time monitoring their children's homework. Differences in involvement between the maternal and paternal figure are observed. 41.7% of fathers claim not to help their children in the development of academic activities compared to 71% of mothers who do help their children. In addition, as a result of the current situation, family hours devoted to academic development of children has increased, going from 13% before the health crisis to 29.6% in the current situation, as they recognize helping in such tasks "always." This greater involvement and dedication, to the detriment of the enjoyment of free time, can trigger the increase of anxiety states and empathic development. An analysis of variance finds significant differences that point to the possibility of a significant increase in both anxiety and emotional empathy ( $F = 3.565$ ;  $p < 0.05$  and  $F = 3.114$ ;  $p < 0.05$ ) related to this increase in parental involvement.

As for the variables related to **family coexistence** such as the distribution of household chores and the evolution or stagnation of family conflicts in the current situation, in 32.5% of the families the mother is still in charge of carrying out these tasks, compared to 6.5% of the father. However, 61% of families recognize that in the current situation of confinement, the distribution of tasks is more equitable, with 36.7% affirming that the tasks are carried out by both parents or legal guardians and 24.3% that the tasks are carried out by all the members of the family. Regarding the

existence of family conflicts, 22.5% of the respondents report that they have increased and 27.2% of them that they have decreased. By linking these data with respect to the variables of anxiety and cognitive empathy, we found new differences in the ANOVA analysis, mainly with respect to anxiety ( $F = 6,276$ ;  $p < 0.001$ ), which increases in households where conflicts have intensified during the exceptional situation and decreases where tasks are equally distributed.

Finally, regarding the **existence of a person at risk** in the face of the health alarm caused by COVID-19 within the family nucleus, 20.7% of the respondents answered affirmatively, adding in 7.8% of the cases that these people also needed help. Another 27.8% of the sample had to attend someone at risk outside home. In this sense, an analysis of variance (ANOVA) determined the difference in terms of cognitive empathy with respect to this factor ( $F = 5.000$ ;  $p < 0.005$ ), turning out to be significant and establishing the increase in empathy in those who must assist people in risk at the present time. In contrast, no significant differences were found that affected the development of anxiety states.

## Correlational Statistical Analysis

To establish the relationship between socio-educational and psychological variables such as anxiety and cognitive empathy, a Pearson correlation analysis was performed (Table 1). A low positive significant correlation is found between these last two variables ( $0.183$ ;  $p < 0.05$ ). The results establish a significant negative correlation of anxiety and empathy with **age** ( $-0.257$ ,  $p < 0.01$ ;  $-0.182$ ,  $p < 0.05$ ), that is, the older the parents are, the lower the level of anxiety and empathy will be. **Gender** correlated significantly with anxiety ( $0.257$ ;  $p < 0.01$ ) and with empathy ( $0.399$ ;  $p < 0.01$ ), females have greater empathic capacity and greater anxiety. The **number of children** only correlates with empathy ( $0.166$ ;  $p < 0.05$ ), a higher number of children correlates with more empathy. In contrast, the **age of the children** correlates significantly and negatively with anxiety ( $-0.167$ ;  $p < 0.05$ ) and with empathy ( $-0.186$ ;  $p < 0.05$ ), the younger the children, the greater it is the parents' level of anxiety and empathy. The **father's occupation** only correlates significantly, low, and negative, with empathy. The higher father's employment status is, the lower level of empathy towards the members of his family. On contrary, **mother's hours of telework** presents a significant positive correlation with empathy ( $0.236$ ;  $p < 0.01$ ), indicating that the greater the number of hours teleworking, the greater her ability to empathize.

On the other hand, the time dedicated to **school tasks** by the children correlates significantly with anxiety ( $0.229$ ;  $p < 0.01$ ) and with empathy ( $0.216$ ;  $p < 0.01$ ). The same happens in the **assistance** provided by parents, at present time, to carry out these school tasks ( $0.276$ ;  $p < 0.01$ ;  $0.251$ ;  $p < 0.01$ ) and the help provided before the crisis ( $0.163$ ;  $p < 0.05$ ;  $0.212$ ;  $p < 0.05$ ). The difference is that the **mother's help** correlates significantly positively with anxiety ( $0.335$ ;  $p < 0.01$ ) and with empathy ( $0.238$ ;  $p < 0.01$ ), and **father's help** correlates only with anxiety ( $0.164$ ;  $p < 0.05$ ). Parental involvement an increase in parents' anxiety and, at the same time, empathy towards their children's feelings. In turn, the time spent helping their children increases

anxiety in the father and mother, but empathic development towards their children only occurs in the case of the mother. The variables of the existence of a **garden or terrace** in the home ( $0.169$ ;  $p < 0.05$ ), longer time watching **television** ( $0.166$ ;  $p < 0.05$ ) and increase in **internet** use ( $0.302$ ;  $p < 0.01$ ) only correlate with anxiety in a significantly positive way, being low for the first two, and moderate for the last one. On the other hand, **family conflicts** show a significant positive correlation with anxiety ( $0.297$ ;  $p < 0.01$ ). These variables pose a risk that negatively affects anxiety, altering family life. In contrast, the **children's use of technological resources** correlates significantly with empathy and in a low positive way ( $0.171$ ;  $p < 0.05$ ), which implies an increase in empathy between them. Another variable that affects family life is the performance of **household chores**. This variable correlates significantly and negatively with anxiety ( $-0.193$ ;  $p < 0.05$ ), that is, with less collaboration from others, anxiety increases in the person in charge of them. Finally, **assistance to other at-risk persons outside family home** correlates significantly and in a low way with empathy ( $0.184$ ;  $p < 0.05$ ). Therefore, assisting people at risk outside home increases empathic capacity.

## Statistical Regression Analysis

Two regression analysis were conducted using the method of successive steps forward. The first was based on a predictive model of anxiety due to socio-educational causes in the context of current confinement (Table 2). The second elaborates a predictive model for the development of cognitive empathy in the same circumstances (Table 3).

In the anxiety prediction model,  $R^2$  values of 0.211 were obtained, which means an explanatory capacity on the variance of 21.1%. The variables that were significant for anxiety caused by the current situation were gender ( $\beta = 0.186$ ;  $p < 0.05$ ), children's average age ( $\beta = 0.151$ ;  $p < 0.05$ ), mother's help with homework ( $\beta = 0.249$ ;  $p < 0.001$ ) and the increase of the Internet use ( $\beta = 0.252$ ;  $p < 0.001$ ) (Table 2).

## Regression Model for Predicting Anxiety

For the predictive model of cognitive empathy,  $R^2$  values of 0.274 were obtained, explaining the 27.4% of the variance. The significant variables for this model were gender ( $\beta = 0.377$ ;  $p < 0.001$ ), children's average age ( $\beta = 0.181$ ;  $p < 0.05$ ), help in the current situation with homework ( $\beta = 0.159$ ;  $p < 0.05$ ), mother's teleworking hours ( $\beta = 0.178$ ;  $p < 0.05$ ) and the fact of assisting other at-risk persons out of home ( $\beta = -0.185$  y  $p < 0.05$ ) (Table 3).

## DISCUSSION

The main findings of this research are that: anxiety derived from the pandemic situation is explained by gender, the level of Internet consumption, the increase in family conflicts and help with homework. Cognitive empathy is explained by gender and mother's teleworking hours.

The state of confinement has meant a new home structuring for families, becoming a place of work, upbringing, and care for

both children (Zhang et al., 2020) and sick relatives (Chatterjee et al., 2020; Porzio et al., 2020). This study describes the current family situation where parents, in a 50%, have had to opt for teleworking or they are affected by a provisional downsizing plan and all children continue their studies at home through the use of ICT. It is also evident that, regarding the level of studies and type or modality of parents' job, despite the fact that women have a higher level of education, they are also those who present the highest percentage in temporary jobs or unemployment. On the contrary, men are those who have indefinite jobs and conduct business activities. Regarding performing household chores and caring for people at risk, women still mainly do these tasks. These results are the consequence of a socio-cultural tradition that attributes stereotype and static roles based on gender (Blossfeld and Kiernan, 2019; McDermott et al., 2019). Regarding the variables that affect family life, the economic situation has been affected in more than the 50% of households, and television and internet consumption has increased as an alternative to outdoor

leisure. On the other hand, it is shown that most of the respondents lived in houses of less than 76 square meters, but only a third of them did not have a garden or terrace. Regarding family conflicts, there is no unanimity, since, in the same proportion, they indicate that they have increased as well as decreased (between 20 and 25%), therefore it is inconsistent with studies that indicate that this type of situation generates stress that causes an increase in family conflicts (Irmansyah et al., 2010).

**Anxiety** is one of the main consequences of the COVID-19 pandemic, with the **females** and **young adults** being especially vulnerable (Moghanibashi-Mansourieh, 2020; Rajkumar, 2020; Wang et al., 2020). In this sense, older age means better crisis management (Kang, 2014), being data that are aligned with our results. To the above we must add that the lack of a garden or terrace that supposes a greater feeling of confinement, the increase in hours watching the television as an alternative to outdoor activities, dedicating more hours to carrying out school tasks and helping children with them (to a lesser extent by

fathers), and an increase in family conflicts, lead to intensification of anxiety levels in confined persons. These data are in line with those provided by Lock and Gordon (2012) since the crisis situation is aggravated by effects derived from the family context and with those by Irmansyah et al. (2010) related to the loss of hours of leisure and outdoor recreation. On the other hand, the **predictive model** exposes that not only **gender** is an explanatory element, since there are other contextual and socio-family elements that can significantly affect stress and anxiety in this type of situation, as suggested by Sugiura et al. (2020). For example, the **children's average age** (the younger they are, the higher parents' anxiety levels), **mother's help in school tasks** and increase in the **use of Internet** are factors that also influence the development of states of anxiety in the current situation. These elements are aligned with previous research, in which pointed out as stressors we find: having children under 5 years-old (Howard et al., 2018), exceptional education and schooling in these situations (Kilmer and Gil-Rivas, 2010), or the unequal distribution of household chores (McDermott, 2010). Regarding the role of the Internet in this process, it is necessary to reference how its remarkable growth has been paired with alarming figures of addiction worldwide, and its consequences in the increase of depression and anxiety (Cheng and Li, 2014; Al Mamun and Griffiths, 2019; Lozano-Blasco and Cortés-Pascual, 2020). The Internet is the key to a new environment where a multitude of activities are carried out, from shopping to establishing affective relationships (Király et al., 2015) and in a confined environment, networks offer the maintenance of lost daily life: work, consumer goods and services, or attending to the education of children. Although, it should be borne in mind that norm-typical human behavior can be altered by its continuous interaction in the cloud (King et al., 2013; He et al., 2017).

On the other hand, the highest levels of **empathy**, in crisis situations, are related to the greater support among the members of the family unit, which is generated especially in those who carry out a greater proportion of help, work or assistance (Siedlecki et al., 2014). In these types of situations, a positive effect arises in those with the highest cooperative commitment (Glassman, 2000). In this sense, the results obtained in this research coincide with these previous studies since, as indicated above, being mother, having younger children, as well as their number, mother's teleworking hours, time helping with school tasks (especially for the mothers), having technological resources and assistance to people at risk outside home, are positively associated with empathy. The **predictive model** indicates that cognitive empathy is modulated by gender (greater empathy in women), the average age of the children (the younger the children, the greater the empathy), current help with school tasks, assistance to people at risk outside home and mothers' hours of teleworking, variables that increase these levels of empathy. Empathy within parental relationships is explained by the strength of the relationship between them and by the generation of response to affective states, being in full agreement with research such as the one by Eisenberg and Miller (1987) and Verhofstadt et al. (2008). On the other hand, it has sometimes been found that the level of education predicts the level of empathy (Haut et al., 2019) and in the present study it has already

been pointed out that the sample formed by females had higher academic levels than males.

In relation to the first two variables, gender and age of the children, there would be a correspondence with the levels of anxiety, since, as specified, the fact of being a woman and having younger children increases anxiety (Howard et al., 2018; Moghanibashi-Mansourieh, 2020; Rajkumar, 2020; Wang et al., 2020), but empathy also increases with these variables, explaining the correlation established between both variables of anxiety and empathy. Regarding the variables related to help or collaboration with others, assistance to other people-at-risk outside home and the help to children with school tasks are key factors in modulating cognitive empathy, so that it is increased in these situations, but almost exclusively in females. In this sense, although authors such as Maner and Gailliot (2007), Porzio et al. (2020), Siedlecki et al. (2014), and Sugiura et al. (2020) point out that assisting family members can be a major stressor in emergency situations (also in the case of our study, where the mother's school help was also an anxiety factor), in general, publications on this matter have been focused on how the social support network (family, friends, community members) is an element of great relevance when managing stress situations derived from different types of crises. These two examples of prosocial behaviors, common in emergency situations (Afifi et al., 2012; Welton-Mitchell et al., 2016), are a factor promoting empathy and cooperative spirit in the face of adversity (Zakour and Gillespie, 2012; Kim and Zakour, 2017). In other words, the human being has the ability to increase his cognitive empathy in the moments of greatest need in crisis situations (Glassman, 2000), seeking the psychological well-being of the group (Afifi et al., 2012; Welton-Mitchell et al., 2016) having a positive effect on both the person helping and the person being helped (Maner and Gailliot, 2007; Siedlecki et al., 2014, Sugiura et al., 2020). This last element is verified in our study in the increase of empathy when helping children in school tasks. Lastly, the mother's hours of teleworking seem to be an element that promotes empathy, and can be related to the fact of not having lost a job and having a greater ease of reconciling work and personal life in an emergency situation, being aligned with studies such as those by Ehrlich et al. (2010), Howard et al. (2018), and Picou and Hudson (2010).

Regarding the limitations of the study, the urgency of the situation, the sampling method, and the reception of a majority response from only one region in Spain can cause the sample to be slightly biased. However, the results present optimal indicators and seem to be aligned with the literature (Glassman, 2000; Maner and Gailliot, 2007; Afifi et al., 2012; Siedlecki et al., 2014; Welton-Mitchell et al., 2016; Sugiura et al., 2020). Regarding prospective, a repetition of the study once the period of confinement has ended and the population will adapt to the new normality, would serve to verify whether this crisis has changed the socio-family dynamics and the levels of empathy and anxiety of the population.

We consider what response we give from education, science, and society to attend these moments of emergency and that are linked to normative or cultural elements. It would have to be transversal, regardless of the moment in which one lives, empathy

towards the complex situations of other people, the search for emotional balance, compassion and actions linked to justice and social well-being. In and after this crisis, we can take many positive aspects to implement in families and in society, such as knowing how to work as a family team, respecting emotional singularities and looking for the contagion effect to the rest of social areas. An example of this is the [librosqueunen.org](http://librosqueunen.org) project in which a bond is created with the family in a situation of educational disconnection due to the digital divide. It has been proven that we are able to increase our empathy and regulate our anxiety, although we need more formal and non-formal education in this line, taking into account all the factors that are included in a family, and that are not only the family members or the "school inside the house" elements, but also the technological, media and social networking sites.

## CONCLUSION

With this research we approach the current situation of confinement in Spanish society motivated by COVID-19 crisis. For this, a study of the social, psychological, and educational impact on families is conducted. Undoubtedly, the results highlight the inequalities that still exist within the family sphere. Derived from our data, we could hypothesize that the mother figure continues to bear the burden of work at home and she is the sustenance that maintains family relationships and harmonious coexistence. The father figure continues to establish his work relationships as a priority, occupying a secondary place in the relationship with children and adults. Anxiety increases in strange situations in this context and empathy, especially by females, dampens the stress caused. Although authors such as Howard et al. (2018) and Sugiura et al. (2020) list a greater variety of stressors related to the personal, family, social and work environment than those identified in this study, the uniqueness of the global emergency situation caused by the COVID-19 crisis, justifies that the assimilation of this situation to other previous emergencies is not possible. Although many

of the studies collected in this research analyze exceptional situations (health emergencies, natural disasters, socio-political conflicts), the characteristics and global nature of this crisis places us in a new scenario, in which the truths assumed up to now are questioned. As Beck (1998) stated in the current Risk Society these new threats, derived from human action, shake the central components of society, motivating a series of debates and reformulations that science and society must jointly explore.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by CEICA (Comité Ético de Investigación Clínica en Aragón) del Gobierno de Aragón and Universidad de Zaragoza (ACUERDO de 2 de abril de 2020, del Gerente de la Universidad de Zaragoza, por la que se aprueba el Tratamiento de datos personales "Monitorización del Covid-19: Impacto social, psicológico y educativo"). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

AQ-R coordinated the design and research process. AQ-R and RL-B designed the psychological research. TÍ-B designed the sociological questionnaire. AC-P the educational one. AQ-R and RL-B carried out the statistical analysis. RL-B, AC-P, and TÍ-B carried out the theoretical framework, discussion and conclusion. All authors contributed to the article and approved the submitted version.

Coronavirus disease 2019 (COVID-19) is likely to have long-term mental health effects on individuals who have recovered from COVID-19. Rightly, there is a global response for recognition and planning on how to deal with mental health problems for everyone impacted by the global pandemic. This does not just include COVID-19 patients but the general public and health care workers as well. There is also a need to understand the role of the virus itself in the pathophysiology of mental health disorders and longer-term mental health sequelae. Emerging evidence suggests that COVID-19 patients develop neurological symptoms such as headache, altered consciousness, and paraesthesia. Brain tissue oedema and partial neurodegeneration have also been observed in an autopsy. In addition, there are reports that the virus has the potential to cause nervous system damage. Together, these findings point to a possible role of the virus in the development of acute psychiatric symptoms and long-term neuropsychiatric sequelae of COVID-19. The brain pathologies associated with COVID-19 infection is likely to have a long-term impact on cognitive processes. Evidence from other viral respiratory infections, such as severe acute respiratory syndrome (SARS), suggests a potential development of psychiatric disorders, long-term neuropsychiatric disorders, and cognitive problems. In this paper, we will review and evaluate the available evidence of acute and possible long-term neuropsychiatric manifestations of COVID-19. We will discuss possible pathophysiological mechanisms and the implications this will have on preparing a long-term strategy to monitor and manage such patients.

**Keywords:** coronavirus disease 2019, neuropsychiatric disease, cognition, depression, mental health

## INTRODUCTION

Coronaviruses are single-stranded RNA viruses, which caused two well-known outbreaks: (1) severe acute respiratory syndrome (SARS) in 2002 and (2) Middle East respiratory syndromes (MERS) in 2012. Since December 2019, several cases of atypical pneumonia have been reported from Wuhan, China. A novel coronavirus was identified to be the cause and was subsequently named by the WHO as: “severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).” It is well known that coronaviruses affect the respiratory tract, with most patients experiencing only mild symptoms akin to the common cold (e.g., blocked/runny nose, headaches, sneezing, a raised temperature, loss of taste and smell, etc.) and the illness is self-limiting. However, if the virus reaches lower respiratory tract, in

vulnerable individuals such as new-born, elderly, and immunocompromised, it can cause severe illness such as pneumonia, bronchitis, exacerbation of asthma, chronic obstructive pulmonary disease (COPD), and acute respiratory syndrome (ARS), as seen in SARS, MERS, and now COVID-19 (Desforges et al., 2014; Raj et al., 2014). Unfortunately, coronavirus is an opportunistic virus and can allude immune response, potentially spreading to cells other than the respiratory tract's epithelial cells. Several coronaviruses have shown to be neuro-invasive, including SARS and MERS (Gu et al., 2005; Xu et al., 2005; Arabi et al., 2015).

As of the 28th of June 2020, SARS-CoV-2 has now infected over 10 million people worldwide (Dong et al., 2020) and the pandemic continues to grow. The disease caused by SARS-CoV-2 is known as corona virus disease 2019 (COVID-19), which manifests not just as a respiratory illness but also impacts the cardiovascular, renal, and the nervous system functions (Yuki et al., 2020). It is known from previous pandemics, such as Spanish influenza and SARS, that there are not just acute effects of the viral infection but also long-term sequelae due to disease itself as well as social effects due to governmental measures of containment such as quarantine, social distancing, and lockdown.

In this paper, we aim to present an understanding of pathophysiology, possible effects of SARS-CoV-2 infection to the brain and its long-term neuropsychiatric and cognitive consequences. Understanding neuropsychiatric and cognitive consequences are important, as millions of individuals have been affected; many more are undetected, and the number of infections is still rising. If even a fraction of such individuals experience neuropsychiatric complications, the public health implications could be considerable. Therefore, it is important to understand the neuropsychiatric and cognitive consequences of COVID-19. In this paper, we will briefly outline how COVID-19 can affect the central nervous system (CNS), review emerging evidence of effects on CNS and explore the possible neuropsychiatric sequelae of the COVID-19 infection. We will discuss diverse neuropsychiatric and cognitive complications following COVID-19 infection, possibly affecting a large proportion of individuals previously suffering from COVID-19. This, in turn, could lead to a potential increase in patients with psychiatric and cognitive problems. Understanding and assessing cognitive consequences following COVID-19 is important as it could be used to estimate an individual's capacity to work effectively, drive, manage finances, participate in daily family activities, or make informed decisions. Appropriate neuropsychological rehabilitation could be planned to remediate or compensate for cognitive deficits in COVID-19 survivors.

Neuropsychiatric consequences are neurological, psychiatric, and cognitive problems due to direct brain damage, disease, or indirect effects on the CNS *via* an immune response or medical therapy (Rogers et al., 2020). The acute psychiatric manifestations of COVID-19 reported in surveys are increased stress, anxiety, and depression (Asmundson and Taylor, 2020). In the long-term, psychiatric presentations could also be affected by the outcome of their illness, stigma or memories,

and amnesia associated with the critical care they receive (Jones et al., 1998). Acute neurological symptoms such as headache, altered sensorium, acute cerebrovascular incidents, convulsions, and ataxia have been reported in more than a third of hospitalized patients (Mao et al., 2020). Reports of acute cognitive complications such as attention and dysexecutive symptoms are also emerging (Rogers et al., 2020; Varatharaj et al., 2020). However, we can just speculate about the long-term neuropsychiatric and cognitive consequences of COVID-19.

## **PATHOPHYSIOLOGY OF NEUROPSYCHIATRIC AND COGNITIVE CONSEQUENCES OF COVID-19**

SARS-CoV-2 is a novel virus and its pathophysiological mechanism on various physiological systems is yet to be fully understood. However, a lot can be learnt from other subtypes of coronaviruses. Coronaviruses primarily affect upper respiratory tracts, but they have been detected both in the brain and cerebrospinal fluids of the infected individuals (Bohmwald et al., 2018). There are several mechanisms through which coronaviruses can damage the nervous system. These may include direct infection injury, virus entering through blood circulation pathway, neuronal pathway, hypoxic injury, immune injury, and *via* binding to the angiotensin-converting enzyme 2 (ACE2). The neurotropic capacities of coronaviruses allow them to evade the immune response of the host and achieve latency. This makes them a potent factor to cause acute and late neurological effects. Although early indication shows that the expression of SARS-CoV-2 in the brain deviates slightly compared to SARS-CoV-1 and MERS expression, it is still a potential source for causing short and long-term neuropsychiatric and cognitive complications. For a detailed discussion of these mechanisms, please see Wu et al. (2020). The neuronal pathway *via* the olfactory nerve and role of ACE2 has been observed to be the primary pathophysiological mechanisms contributing to neuropsychiatric and cognitive complications in COVID-19 (Mirfazeli et al., 2020; Pantelis et al., 2020). This is mainly because coronaviruses affect the respiratory tract and can reach the ACE2-enzymes in the respiratory epithelial cells, and the olfactory nerve, providing a pathway for the coronavirus to enter the CNS.

### **Neuronal Pathway**

Neurotropic viruses, such as coronaviruses, use sensory and motor neuronal pathways to enter the CNS. One example of a neuronal pathway is the olfactory nerve (Desforges et al., 2019). This is mediated by the unique organization of olfactory nerves and the olfactory bulb in the nasal cavity and forebrain. The virus thus can reach the brain and CSF, which can cause inflammation and a demyelinating reaction. If the infection is set, then the viruses can reach the whole brain and CSF in less than 7 days (Bohmwald et al., 2018). Altered olfaction and gustatory problems (anosmia, hyposmia, and ageusia) have

been reported in 49% of COVID-19 patients (Hornuss et al., 2020; Vaira et al., 2020) implicating the possibility of CNS infection through the olfactory neuronal pathway.

## ACE2 and Its Role in Neuropsychiatric Complications

ACE2 enzyme is widely present in various organs including oro-nasal, respiratory, cardiovascular, cerebrovascular, and immune systems. The high density of ACE2 in oro-nasal mucosa and their binding with SARS-CoV-2 may account for olfactory symptoms of anosmia in COVID-19 (Lechien et al., 2020). Coronaviruses directly bind to ACE-2 receptors in respiratory epithelial cells cause cytokine storm, which causes widespread inflammation in patients with COVID-19, leading to multiple organ damage and immune-mediated encephalopathy manifesting as delirium and convulsions. Neuroinflammation is a well-recognized mechanism for the development of psychiatric disorders (Yuan et al., 2019). It can also cause hypercoagulable states causing ischaemic stroke besides other vascular events (Fotuhi et al., 2020). ACE2 plays an important role in controlling blood pressure but binding to SARS-CoV-2 can cause an increase in blood pressure, which can increase the propensity to cerebral hemorrhage. This may also explain the increase in mortality in patients with COVID-19 with comorbid metabolic conditions such as hypertension, high body mass index and diabetes (Fang et al., 2020). It has also been proposed that the spike protein of SARS-CoV-2 can bind to ACE2 receptors in capillaries, breaking the blood-brain barrier and allowing the virus to enter the brain directly (Wu et al., 2020). Neurons have a high density of ACE-2 and high binding to coronaviruses if they cross the blood-brain barrier. SARS-CoV-2 can lie latent in the neurons of patients who recover from acute effects of COVID-19, increasing the risk of long-term consequences by causing demyelination and neurodegeneration (Lippi et al., 2020).

## NEUROPSYCHIATRIC AND COGNITIVE EFFECTS OF CORONAVIRUS INFECTION

### Acute Effects

In the short-term, 20–40% of COVID-19 cases may present with neuropsychiatric complications, such as cerebrovascular events, headache, dizziness, encephalopathies, anosmia, ageusia, and mood problems (Bo et al., 2020; Crunfli et al., 2020; Lu et al., 2020; Mao et al., 2020; Mirfazeli et al., 2020; Troyer et al., 2020; Varatharaj et al., 2020; Wu et al., 2020; Zhang et al., 2020), see **Table 1**. The acute effect of CoV infections on the CNS is manifested in viral encephalitis, infectious toxic encephalopathy, and acute cerebrovascular disease. In a recent meta-analytic review, Rogers et al. (2020) reported the neuropsychiatric short- and long-term consequences of SARS and MERS infection. They reported that during the acute illness, 27–41% of cases had neuropsychiatric symptoms such as confusion, depressed mood, anxiety, impaired memory, and insomnia. Steroid-induced mania and psychoses were also reported. The meta-analysis also looked at the available data related to COVID-19 infection and neuropsychiatric consequences and found that confusion and agitation were present in 65–69% of the intensive care unit patients. Importantly, at discharge, 33% of the patients with COVID-19 had dysexecutive syndromes. Similarly, in a United Kingdom wide surveillance study, 153 patients were reported to have neurological and neuropsychiatric complications following COVID-19 infection (Varatharaj et al., 2020). Twenty-one of these cases developed a new diagnosable psychiatric disorder. The other noteworthy observation was the effect of age on altered mental status and cerebrovascular incident. Thirty-seven patients had altered mental status and 49% of these patients were younger than 60 years. However, of 74 patients who presented with cerebrovascular incidents, 81% of the patients were aged over 60. In another report, Mao et al. (2020) reported

**TABLE 1** | Percentage of COVID-19 patients showing neuropsychiatric and cognitive effects.

Reference	COVID-19 patients showing neuropsychiatric and cognitive effects							
	CNS <sup>1</sup>	PNS <sup>2</sup>	Affective disorders	Anxiety	Fatigue	PTSD	Impaired attention	Impaired memory
Short-term								
Bo et al., 2020						96%		
Crunfli et al., 2020			20%	28%			45%	28%
Lu et al., 2020	25%	35% <sup>a</sup>	42%		27%			13%

Woo et al., 2020			11%		17%		44%	50%

<sup>1</sup>Central nervous system (CNS) includes dizziness, headaches, mental state, ataxia, seizure, and acute cerebrovascular disease.

<sup>2</sup>Peripheral nervous system (PNS) includes an impaired sense of smell, taste, vision, and nerve pain.

<sup>a</sup>A count of PNS symptoms occurring, it is possible a single patient had multiple symptoms.

<sup>b</sup>Average of reported PNS symptoms.

<sup>c</sup>Significant SD away from the healthy control group, indicating cognitive impairments for groups with different levels of medical assistance, the value here is the SD for patients requiring hospitalization with a ventilator.

neurologic manifestations of COVID-19. The study had 214 patients with mild to severe COVID-19 infection. Around 36.4% of the patients showed neurologic manifestations involving the CNS, peripheral nervous system (PNS) and skeletal muscles. These neurologic manifestations were more prevalent in patients with a severe infection and included signs of impaired consciousness and acute cerebrovascular diseases. Autopsy results have indicated degenerated neurons and an increased blood flow to some regions together with edematous brain tissue (Mao et al., 2020).

Structural brain abnormalities have also been reported with SARS-CoV-1 and MERS infections. In an MRI study looking into the post-infectious neurological consequences of MERS in three patients with severe neurologic syndrome found hyperintensities in the white matter of the parietal lobes, temporal lobes, frontal lobes, basal ganglia, and corpus callosum (Arabi et al., 2015). The neurological manifestations shown by these patients included: altered mental status (ranging from confusion to coma) ataxia, and focal motor deficits. Similarly, a study investigating autopsies of six SARS patients found evidence of edema and scattered red degeneration of the neurons (likely the result of neuronal hypoxia or ischemia), after finding evidence of SARS genome sequences in the hypothalamus and cortex (Gu et al., 2005). Structural brain abnormalities have been reported in COVID-19 patients too. Montalvan et al. (2020) have reported cases with brain abnormalities present in the bilateral thalamic, medial temporal lobes, hippocampus, and insular regions.

As reported by Helms et al. (2020), there are some findings of encephalopathy and reduced blood flow in the frontotemporal brain region following a COVID-19 infection. The extent to which COVID-19 infection leads to neurological damages and neuronal symptoms is currently still unknown. However, several studies have found patients with neurological diseases ranging from encephalitis to strokes (Mao et al., 2020; Moriguchi et al., 2020). Encephalitis alone is linked to an increased risk of a range of long-term sequelae such as epilepsy, bipolar disorders, psychotic disorders, anxiety disorders, cognitive problems, and dementia (Granerod et al., 2017).

## Long-Term and Chronic Neuropsychiatric Sequelae

It is known that the neural and immune cells can host latent CoV which could contribute to delayed neurologic and neuropsychiatric complications (Desforges et al., 2019). However, long-term neuropsychiatric sequelae of COVID-19 are currently unknown. We can speculate long-term effects from our understanding of the mechanisms of the COVID-19 on the CNS and evidence from long-term neuropsychiatric effects of SARS-CoV-1 and MERS. Lam et al. (2009) reported that 55% of survivors of SARS-CoV-1 had post-traumatic stress disorder (PTSD). Furthermore, depression was in 39%, pain disorder in 36.4%, panic disorder in 32.5%, and obsessive-compulsive disorder in 15.6% of SARS-CoV-1 survivors. In their meta-analytic review, Rogers et al. (2020) also reported long-term neuropsychiatric consequences of SARS and MERS infections in 10–20% of the cases, such as depressed mood,

insomnia, anxiety, irritability, memory impairment, and fatigue. However, it is important to understand that the neuropsychiatric manifestations, such as PTSD, depression, or anxiety, following COVID-19 infection could also be a psychological reaction to being infected, being in intensive care unit or experiencing stigma of contracting the infection.

If similar proportions of long-term neuropsychiatric complications emerge following COVID-19, then we can expect a crashing wave of neuropsychiatric sequelae (Troyer et al., 2020), which will have huge implication for management of the stretched healthcare resources in every country. Besides the neuropsychiatric sequelae, long-term implications will be observed with many neurological problems. For example, loss of smell is considered one of the hallmark symptoms of COVID-19 infection implying CNS involvement. This might have long-term implications for neuro infections and neurodegenerative diseases. Indeed, loss of olfaction is considered an early manifestation in Parkinson's disease (Doty, 2012; Chase and Markopoulou, 2020). Therefore, the emergence of cognitive symptoms following COVID-19 may indicate an underlying neurodegenerative process. Furthermore, individuals with certain immunocompromised neurological conditions such as multiple sclerosis (MS) may show alterations in their non-motor symptoms following COVID-19, which may indicate an underlying neurodegenerative process. Higher risk of developing Parkinson's disease and MS has been previously linked to SARS-CoV-1 infection (Fazzini et al., 1992; Murray et al., 1994). Indeed, long-term assessment of cognition will become a critical part of the care pathway for such individuals.

## Long-Term Cognitive Sequelae

From the emerging evidence and our understanding of the mechanism of CoV in the CNS, one can expect to have a range of cognitive consequences of COVID-19 infection. Attention and dysexecutive symptoms have commonly been reported with COVID-19 (Rogers et al., 2020; Varatharaj et al., 2020). Hypoperfusion in the frontotemporal region of the brain has also been reported (Helms et al., 2020) as well as structural brain abnormalities thalamic and temporal regions (Montalvan et al., 2020). Considering the demyelinating nature of the viral infection in the CNS, we can expect common cognitive problems that characterize demyelinating illnesses (such as MS). The Symbol Digit Modalities Test (SDMT), a test to assess the speed of information processing, is an exceptionally reliable and sensitive cognitive test for MS patients (Benedict et al., 2017). Similarly, a link between loss of smell in COVID-19 patients and the prodromal phase of Parkinson's disease should be kept in mind while examining long-term cognitive consequences. A large amount of research has shown that executive functions are primarily affected in the prodromal phase of Parkinson's disease along with prominent memory problems (Fengler et al., 2017). Taken together, the long-term cognitive examination of COVID-19 survivors should at least include tests assessing attention, executive functions, learning, and memory as well as the speed of information processing.

## Implications for Monitoring Long-Term Neuropsychiatric and Cognitive Sequelae

It is clear from the past outbreaks of SARS-CoV-1 and MERS and current reports of neurological and neuropsychiatric complications following COVID-19 that a large number of survivors will experience a range of neuropsychiatric and cognitive sequelae. These are likely to affect their mental, physical, and cognitive well-being. Which, in turn, will affect their emotional, occupational, and financial situations. Some of these patients may develop a full-blown neurological or psychiatric illness, or some might experience mild cognitive problems and that will increase their risk of developing dementia. Early indications show that the cognitive domains of executive functions, attention, and memory appear to be affected by COVID-19. Furthermore, there are potential increases in affective disorders, anxiety, fatigue, and PTSD (Hampshire et al., 2020; Lu et al., 2020; Woo et al., 2020), see **Table 1**. These symptoms can be due to pathoplastic change in brain physiology where the COVID-19 infection may modify brain functions after infection, which can lead to the development of brain vulnerabilities that may increase the probability to develop psychological distress. It is also possible that these neuropsychiatric symptoms and disorders are the psychological reactions of having contracted COVID-19 and undergoing associated medical interventions. This complex nature of neuropsychiatric presentations can be understood through a careful study of case history, accompanied by standardized neuropsychological assessments. This will help clarify if the neuropsychiatric and cognitive problems are a direct consequence of structural brain abnormalities or are a psychological reaction of the potential physical and the mental stress associated with recovering from COVID-19. Therefore, early detection and

prevention of neuropsychiatric and cognitive problems should be the long-term aim of health services and governments across the world as this could present as a “**third wave**” of the pandemic.

## CONCLUSION

The short-term neuropsychiatric and cognitive complications following COVID-19 are varied and affect a large proportion of COVID-19 survivors. In the medium- and long-term period, there is going to be an influx of patients with psychiatric and cognitive problems who were otherwise healthy prior to COVID-19 infection. Increased neuropsychiatric manifestations could be observed in the form of an increase in cases of depression, anxiety, PTSD, and in certain cases severe mental illnesses. Cognitive sequelae are also likely to be varied and a detailed cognitive evaluation should be considered for such individuals to monitor the emergence of new neurological cases. Robust neuropsychiatric and cognitive monitoring will enable health care providers to plan adequate health care delivery and allocate resources adequately. Early intervention for emerging cognitive problems will be critical for independent functioning and improved quality of life for many COVID-19 survivors.

In February 2020, the coronavirus disease 2019 (COVID-19) appeared and spread rapidly in Italy. With the health emergency and social isolation, parents started spending more time with their children, and they might have experienced greater distress. Attachment style is considered as an effective emotion regulation strategy in the parent-child relationship. However, few empirical studies have addressed this issue. Based on attachment theory, this study aimed to find parental attachment style as a candidate to moderate the relation between parents' negative emotions and their perceptions of their children's negative emotions related to COVID-19. Parents ( $M_{age} = 42.55 \pm 6.56$ , 88.2% female) of 838 Italian children and adolescents aged 3 to 18 years participated in an online survey. Results showed that parents with a fearful attachment style had significantly higher negative emotions when facing COVID-19 than those with other attachment styles. Moreover, parents with a dismissing attachment style perceived fewer negative emotions in their children than parents with fearful and preoccupied styles. At last, higher parents' negative emotions were associated with greater perception of children's negative emotions only in parents classified as secure and fearful. These findings suggest that parents with dismissing and fearful attachment styles and their children may be at higher risk during the COVID-19 pandemic and they should be given long-term attention.

**Keywords:** attachment style, negative emotion, emotion regulation, COVID-19, children, parent

## INTRODUCTION

In February 2020, the coronavirus disease 2019 (COVID-19) spread rapidly in Italy and then forced a comprehensive lockdown on March 10, 2020. The whole country entered a large-scale isolation stage for the first time to control the pandemic (Liang et al., 2020). Together the health emergency and social isolation has caused great psychological pressure and several daily life changes for individuals.

In a recent survey of Chinese adults, it was found that individuals' perceived severity of COVID-19 increased their negative emotions (Li Y. et al., 2020), with higher levels of stress, anxiety, depression, and other symptoms (Wang H. et al., 2020). A survey with adults aged 16–75 years in the United Kingdom also showed that social isolation and loneliness brought on by COVID-19 increased the risk of anxiety, depression, and other negative consequences (Holmes et al., 2020). Similar results were also found in other countries (Moccia et al., 2020; Odriozola-González et al., 2020; Orgilés et al., 2020). In addition to adults, studies have shown that even young children can be aware of changes in their surroundings (Dalton et al., 2019, 2020). In a survey of Italian and Spanish parents, they realized that some of their children's emotions (such as boredom and irritability) and behaviors (such as sleep time) had changed compared with those before isolation (Orgilés et al., 2020).

During the isolation period, most people had to stay with their families, parents and children spent more time with each other, and they might have experienced greater distress. Adults' attention, reactions, and emotions toward COVID-19 affect their ability to sensitively recognize their children's troubles (Dalton et al., 2020). Research suggests that regardless of the child's age and gender, children and adolescents adjust their own emotions and behaviors according to adults' emotions and reactions (Stein et al., 2009; Xu et al., 2020). They are more likely to experience the pain, fear, and anxiety of those around them than adults (Bartlett et al., 2020). They would display more negative emotions and problem behaviors than usual (Liang et al., 2020). Previous studies on the impact of major disasters or sudden public health events on children's mental health have emphasized that children's negative emotions in different degrees may be due to the negative emotions of their parents (Sprang and Silman, 2013; Juth et al., 2015; Cobham et al., 2016). Unexplained and unpredictable situations such as the COVID-19 pandemic and the time of quarantine might be perceived as threatening and stressful by adults leading to negative emotions such as anxiety. Thus, when parents showed more negative emotions than those before isolation, children and adolescents were likely to be affected and might be at higher risk for psychological maladjustment (Dalton et al., 2020).

Parents are an important part of a child's personal resources, which can provide resilience-related factors to alleviate children's mental health problems in particularly stressful situations (Holmes et al., 2020). Parents, as a result of spending more time with their children and adolescents during lockdown, are their main and most available support. Previous findings suggest that parental stress is a powerful predictor of children's post-disaster adjustment (Pfefferbaum et al., 2015). Parents under a lot of pressure can be detrimental to a child's recovery from a disaster. The outbreak of the COVID-19 pandemic and the subsequent implementation of social isolation measures are not only inconvenient to life and daily routines, but also cause most parents to undertake a conversion in their family (parent) and work (employee) roles, in which, the boundary between family and work becomes challenging (Restubog et al., 2020). In the face of such changes, parents bear high levels of stress, anxiety, and other negative emotions (Sang et al., 2019;

Li S. et al., 2020; Pfefferbaum and North, 2020). Therefore, paying attention to parents' reactions and emotions can help find children and adolescents who are at a higher risk for psychological maladjustment during COVID-19, and plan specific interventions in the long term.

Parents' attachment style is one of the crucial factors connecting parents and their children (Li et al., 2015; Schimmenti and Bifulco, 2015). In times of stress, such as in the face of the pressure of COVID-19, attachment style may be seen as one of the key factors contributing to the emotion regulation of parents and children (Shaver and Mikulincer, 2007; Mikulincer and Shaver, 2019). Individuals with different attachment styles have different emotional reactions and ways of dealing with negative and positive events in life. Bartholomew and Horowitz (1991) proposed a four-category attachment model: secure, dismissing, fearful, and preoccupied. Secure attachment can be used as a flexible resource when needed, and it is the foundation of an individual's mental health and social adaptation (Mikulincer and Shaver, 2019). People with secure attachment style are more likely to effectively regulate their negative emotions and have hope for solving problems when they experience fear and threats (Nielsen et al., 2017). On the other hand, insecure adults have difficulties in emotion regulation (Jones et al., 2014). Dismissing, preoccupied, and fearful attachment styles are all seen as insecure, and they exhibit a higher level of anxiety and avoidance than secure attachment (Bartholomew and Horowitz, 1991; Welch and Houser, 2010). In detail, those with preoccupied and fearful attachment styles show stronger negative emotional reactions when facing negative events (Gentzler et al., 2010). Insecure attachment strategies will repeatedly activate and suppress negative emotions, and continue to rely on the distorted self and others, leading to poor physical and mental health (Mikulincer and Shaver, 2019; Pace et al., 2019).

Parents differ in their ability to communicate, feel, and respond to their children's emotions based on their attachment style (Sloman et al., 2002). Parents with a secure attachment style can provide emotional feedback to their children and respond to children's various emotions in a consistent and sensitive manner, so that children can adjust their emotional experience and promote the development of emotion regulation ability, whereas parents with insecure attachment styles provide less supportive and constructive behavior (Feeney and Collins, 2001; Jones et al., 2015). For example, parents with dismissing attachment style show limited ability to express emotions, and they show withdrawal if there is negative influence in the interaction with their children. Children of such parents adopt unsafe and avoidant emotion regulation strategies to minimize the expression of their own emotions, in order to get as close to the caregiver as possible (Sloman et al., 2002). Fearful parents have low trust in others and have a certain reaction to their children's emotional needs, but they keep a distance from them and avoid intimate contact with children to protect themselves from the expected rejection of others (Kilmann et al., 2009). Parents with a preoccupied attachment style have no goals to express themselves; they respond differently to their children and provide few emotional anchors to assist in regulating their emotional state. Children of such parents

cannot predict their parents' reactions and will develop greater insecurity and anxiety (Sloman et al., 2002). Mothers who reported greater attachment-related avoidance and anxiety had greater difficulties in regulating their emotions, resulting in more painful and less supportive responses to their children's negative emotions (Jones et al., 2014). Surprisingly, children with dismissing parents would report that their parents are warm and caring (Borelli et al., 2013). Researchers suggest that individuals with dismissing attachment style will not only evaluate stressful events as threatening but also evaluate themselves as able to cope with stressors (Mikulincer and Shaver, 2007). They have higher resilience and have a positive effect on well-being (Karreman and Vingerhoets, 2012). It may be because they have a higher degree of avoidant behaviors (Bartholomew and Horowitz, 1991; Wei et al., 2011); when encountering stressful events, they preferably use distancing coping strategies (such as stress denial) to maintain distance to others (Karreman and Vingerhoets, 2012). They may develop a survival tool of compulsively relying on themselves because of their caregivers' rejection and unresponsiveness (Wei et al., 2011). They often avoid or do not express their distress and idealize their parent-child relationship or tend to evaluate it positively (Borelli et al., 2013). However, such individuals may lack the correct understanding of themselves (Wei et al., 2011). Children whose parents were unresponsive to their needs would tend to, as adults, deactivate their attachment system in order to repress their emotions and withdraw from intimate relationships (Mikulincer et al., 2003). Thus, children with dismissing parents seem to be worthy of attention, because they would have resilience when dealing with short-term stress events, but if they were under long-term stress, they may be in trouble in later development (Bowlby, 1969).

Recent research suggests that COVID-19 and its consequences represented a risk factors for several kids (Holmes et al., 2020; Jiao et al., 2020; Lee, 2020; Liang et al., 2020; Orgilés et al., 2020; Wang G. et al., 2020). The long duration of isolation, fear of infection, frustration and boredom, lack of face-to-face contact with classmates, friends, and teachers, and the lack of personal space at home and other stress factors have caused children and adolescents to display varying degrees of negative emotions (Brooks et al., 2020; Wang G. et al., 2020). According to a survey of children and adolescents aged 3–18 years in China, which was completed by the parents, stress, distraction, and restlessness were the most common psychological and behavioral problems during isolation (Jiao et al., 2020). Similar results have been found in survey of parents with children aged 3 to 18 years old from Italy and Spain (Orgilés et al., 2020).

A recent survey on the psychological impact of COVID-19 showed that adults' attachment style modulated stress responsivity, and contrary to secure individuals, insecure individuals had a weaker ability to regulate emotion (Moccia et al., 2020). Furthermore, empirical studies showed that, in the face of disaster, supportive parenting behaviors can reduce children's anxiety (Pfefferbaum et al., 2015). Parents with secure attachment style have fewer conflicts with their children (La Valley and Guerrero, 2010), and it is negatively

related to adolescents' emotional problems, such as depressive symptoms (Zhang et al., 2010; Li et al., 2015). Therefore, it can be inferred that, under the influence of the COVID-19 pandemic, parents would experience different degrees of negative emotions due to their different attachment, among which, parents with secure attachment would have the lowest negative emotions compared to others, while parents with fearful attachment would display the most serious negative emotions. Moreover, parents reporting higher negative emotions were expected to depict children and adolescents with more negative emotions. Furthermore, it was hypothesized that parents' attachment style moderated the relation between parents' negative emotions and children's negative emotions as perceived by their parents. In detail, parents with a secure attachment style would report a lower level of negative emotions in their children than parents with insecure attachment. Dismissing parents would perceive a lower level of negative emotions in their children due to the habit of covering up their negative emotions, while parents with fearful and preoccupied attachment styles would describe children as having a higher level of negative emotions due to their less effective parenting behaviors linked to their own negative emotional reaction.

## MATERIALS AND METHODS

### Participants and Procedures

Between March 26 and April 5, 2020, parents of 838 Italian children and adolescents participated in our online survey. The children's ages ranged from 3 to 18 years old ( $Mage = 9.65$ ,  $SD = 4.36$ , 49.4% female). **Table 1** lists the sample characteristics. Parents had a mean age of 42.65 years ( $SD = 6.49$ , 88.3% female). In total, 69.9% had more than one child. Almost all participants (97.1%) had an Italian nationality, most of them had a monthly family income of more than 2,000 Euros (60.8%), and 57.8% of them held a bachelor degree or above, suggesting that a majority of the families came from a middle class context (i.e., SES level 3; Hollingshead, 1975).

This study was approved by the Ethical Committee for psychological research by the authors' university. Due to quarantine constraints, school principals and/or social networks (e.g., WhatsApp groups) were used to send out emails, using a snowball sampling strategy, to invite parents to join in the study. Informed consent was obtained before participants filled in all the questions voluntarily and anonymously, and it took about 10 min to complete the survey. Only one parent per household was required to participate in the study. Parents with more than one child were asked to fill in the questionnaire for each child.

### Measures

#### Parental Attachment Style

The Italian version of the Relationship Questionnaire (RQ) was used to measure adult attachment style (Fossati et al., 2007; Ravitz et al., 2010). This questionnaire includes two sections in which participants are required to evaluate: (a) four short essays

**TABLE 1** | Sample characteristics in sociodemographic variables ( $N = 838$ ).

Variables	<i>N</i>	%
<b>Parents</b>		
Mother	740	88.3
Age, <i>M</i> ( <i>SD</i> )	42.65	6.49
<b>Monthly family income (Euros)</b>		
Up to 999	43	5.1
Between 1000 and 1999	186	22.2
Between 2000 and 3999	240	28.6
Between 3000 and 4999	206	24.6
5000 or more	64	7.6
<b>Education level</b>		
Primary school	39	4.7
Secondary school	315	37.6
Undergraduate	357	42.6
Doctoral or master	127	15.2
<b>Mother's current employment situation</b>		
Self-employed	129	15.4
Part-time	153	18.3
Full-time	216	25.8
Unemployed	53	6.3
Lost job due to COVID-19	41	4.9
Smart-working	178	21.2
Other	55	6.6
<b>Father's current employment situation</b>		
Self-employed	225	26.8
Part-time	19	2.3
Full-time	399	47.6
Unemployed	16	1.9

<b>Children</b>		
Female	411	49.4
Age, <i>M</i> ( <i>SD</i> )	9.65	4.36

describing the prototypes of the four attachment styles in the attachment process, which are secure, fearful, preoccupied, and dismissing; (b) their degree of conformity to each essay with a 7-point scale. For the present work, it was administered only for the first section. RQ showed adequate psychometrics characteristics (Ruvolo et al., 2001; Cozzarelli et al., 2003).

### Parents' Negative Emotions

Parents' negative emotions during the COVID-19 pandemic were measured with the Impact Scale of COVID-19 and home confinement (Orgilés et al., 2020). This scale includes three items rated on a 5-point Likert scale (from 1 = *nothing serious* to 5 = *very serious*). A higher score indicates that participants' negative emotions when facing COVID-19 are more severe. Sample items include: "How afraid are you of losing your job?" The Cronbach's  $\alpha$  was 0.539 in this study.

### Children's Negative Emotions

Children's negative emotions were measured by the Impact Scale of COVID-19 and home confinement on children and

adolescents (Orgilés et al., 2020). This scale includes 31 items of children's psychological responses to quarantine with a 5-point scale (from 1 = *Much less* to 5 = *Much more*). For the present work, parents reported on 18 items related to children's negative emotions based on their observations. A higher score indicates that participants' perception of children's negative emotions when facing the COVID-19 are more severe. Sample items include "Is afraid about COVID-19 infection" and "Is worried". The Cronbach's  $\alpha$  was 0.931 in this study.

### Data Analysis

Statistical Package for Social Science (IBM SPSS Version 21) and R Studio (Version 3.6.2) were used for data analysis. First, we carried out descriptive statistics to describe the data of the present sample. Second, correlation analysis and a series of analyses of variance (ANOVAs) were carried out to examine the association among the variables. Effect size was measured using partial eta-squared, in which small, medium, and large effects were 0.0099, 0.0588, and 0.1379, respectively (Cohen, 1988, p. 283). The Bonferroni *post hoc* test was used to compare means. Finally, hierarchical regression models were used to examine the moderation effect of attachment style in the association between parents' negative emotions and children's negative emotions. In the case of significant interaction effects, simple slope analysis was completed to examine the effects of parents' negative emotions separately by attachment styles. Given that attachment styles were multi-categorical variables representing four groups, three dummy variables (R1, R2, and R3) were created, with dismissing attachment serving as the reference group (dismissing: R1 = 0, R2 = 0, R3 = 0; fearful: R1 = 1, R2 = 0, R3 = 0; preoccupied: R1 = 0, R2 = 1, R3 = 0; secure: R1 = 0, R2 = 0, R3 = 1).

## RESULTS

### Descriptive Statistics, Correlations, and ANOVAs

Parents perceived more negative emotions ( $M = 3.04 \pm 0.781$ ) when they faced COVID-19, and they noticed an increase in children's negative emotions compared to before quarantine ( $M = 2.90 \pm 0.726$ ).

Correlation analysis showed that parents' negative emotions were significantly positively related to perceived children's negative emotions ( $r = 0.135, p < 0.01$ ).

The results of the ANOVAs showed that a main effect was found on parents' negative emotions depending on different attachment styles ( $F_{(3,834)} = 6.71, p < 0.001, \eta_p^2 = 0.024$ ). *Post hoc* analyses revealed that parents with a fearful attachment style had significantly higher negative emotions when facing COVID-19 than those with other attachment styles. Children's negative emotions perceived by their parents also showed a significant effect depending on different attachment styles ( $F_{(3,834)} = 4.22, p < 0.01, \eta_p^2 = 0.015$ ). Children with dismissing parents were perceived to display significantly lower negative emotions than those with parents with a fearful and preoccupied attachment style (see **Table 2**).

**TABLE 2** | Parents' negative emotions and children's negative emotions according to attachment styles and *post hoc* comparisons.

	Secure (1) (n = 385)		Fearful (2) (n = 172)		Preoccupied (3) (n = 109)		Dismissing (4) (n = 172)		F	Effect size ( $f^2$ )	Post hoc

\*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

## The Moderation of Attachment Styles in the Association Between Parents' Negative Emotions and Children's Negative Emotions

We conducted hierarchical regression models to examine the association between parents' negative emotions and children's negative emotions as well as the moderation of attachment styles. The results of the full model are summarized in **Table 3**. The results showed that the main effect of parents' negative emotions on children's negative emotions was significant, suggesting that parents who perceived COVID-19 to be more severe observed more negative emotions in their children (see Model 1). The main effect of different attachment styles on children's negative emotions were also significant (see **Table 3**, Model 2). Parents with fearful, preoccupied, and secure attachment styles depicted their children with higher negative emotions than parents classified as dismissing. Furthermore, looking at Model 3, results showed that the interaction effects between parents' negative emotions and attachment styles were also significant.

Simple slope analysis revealed that the association between parents' negative emotions and perceived children's negative emotions had a significant positive slope in both the fearful and secure group (see **Figure 1**). In other words, higher parents' negative emotions were associated with greater perception of children's negative emotions only in parents with secure and fearful attachment styles. No significant effects were found referring to dismissing and preoccupied ones.

## DISCUSSION

COVID-19 has spread rapidly around the world, and the scope and extent of its impact was unexpected (Brooks et al., 2020; Holmes et al., 2020; Liang et al., 2020; Pfefferbaum and North, 2020). The current study aimed to explore how negative emotions observed in parent-child dyads in normative situations could assume a central role during not-normative situations such as the COVID-19 pandemic. In particular, parental attachment style appeared as a possible risk or resilience factor for emotional regulation of negative feelings showed by parents and perceived in their children during the pandemic.

This study found that compared with the emotions before isolation, both parents and children showed higher negative emotions during the isolation period. Parents' negative emotions affected children's negative emotions, when parents showed more

negative emotions, their children were perceived as showing more negative emotions. It was consistent with our hypothesis, and previous studies which have shown the same results, indicating that the performance of parents' emotion regulation affects their children's emotion regulation in particularly stressful situations (Sprang and Silman, 2013; Juth et al., 2015; Pfefferbaum et al., 2015; Cobham et al., 2016; Holmes et al., 2020; Liang et al., 2020; Orgilés et al., 2020).

In addition, more importantly, it was found that the attachment style moderated the association between parents' negative emotions and children's negative emotions. When parents showed greater negative emotions, they could observe that children with parents with a dismissing attachment style reduced their negative emotions. According to the four-category attachment model (Bartholomew and Horowitz, 1991), parents with a dismissing attachment style find it difficult to trust or rely on others, so they often adopt negative parenting strategies when facing their children. Previous studies have also shown that dismissing individuals have less close and less satisfying relationships (Bartholomew and Horowitz, 1991; Wei et al., 2011; Tan et al., 2012). If parents and children are not used to expressing their emotions to each other, then children are more likely to control or cover up, deliberately underestimate, or even defensively deny the presence of their negative feelings without showing their true emotions in front of their parents (Sloman et al., 2002). Such children might be at higher risk because their parents cannot recognize their true feelings and have a weak sense of their emotional state (Brenning et al., 2012).

In contrast, parents with a fearful attachment style showed more negative emotions, and in turn, their children were reported as displaying more negative emotions as well. Parents classified as fearful harbor a negative view of the self, showing a strong sense of dependence on others and high anxiety. In the interaction activities between parents and children, parents may question their own value and worry about losing the child, so they will pay too much attention to the child and constantly monitor the child's emotions, but sometimes they are more focused on their own relational needs and worries of being rejected than on their children's emotional state. It may exacerbate the child's negative experience (Sloman et al., 2002). Under the pressure of COVID-19, these children may not only bear the worry and pressure of the pandemic but also bear the parents' maladjusted emotions and reactions, thus exacerbating the children's negative emotional burden. Unexpectedly, the perception of children's negative emotions by

**TABLE 3** | Hierarchical regression model of the association between parents' negative emotions and children's negative emotions and the moderation effect of attachment styles.

		<i>B</i>	<i>SE</i>	<i>R</i> <sup>2</sup>	Adjusted <i>R</i> <sup>2</sup>	<i>F</i>

*R*1, *R*2, *R*3 were dummy variables for coding attachment styles. Dismissing: *R*1 = 0, *R*2 = 0, *R*3 = 0; fearful: *R*1 = 1, *R*2 = 0, *R*3 = 0; preoccupied: *R*1 = 0, *R*2 = 1, *R*3 = 0; secure: *R*1 = 0, *R*2 = 0, *R*3 = 1. \**p* < 0.05; \*\**p* < 0.01; \*\*\**p* < 0.001.

**FIGURE 1** | The association between parents' negative emotions and children's negative emotions by attachment styles.

secure parents was also more severe with the increase of their own negative emotion. This may be because secure parents have close relationships with their children, and their children often calm themselves and increase feelings of safety by seeking proximity to parents (Esbjorn et al., 2012). This might allow parents to have a more comprehensive and accurate perception of their child's emotions. In the face of the pandemic situation, when parents' emotional performance was more negative, children would feel the same strong severity, so they would be more negative. However, compared with the fearful attachment style, secure parents and their children displayed lower levels of negative emotions, it might be because in the daily activities between parents and children, the supportive parenting behaviors promote the development of the children's emotional regulation ability (Jabeen et al., 2013; Jones et al., 2015; Shlafer et al., 2015). Under the influence of the pandemic, they could regulate their emotions better.

The results of this study indicate that, in the face of major disasters or sudden public health events, attachment style plays a key role in moderating the relationship between parents

and children. These findings offer important implications in understanding and improving the mental health of children and adolescents under the influence of COVID-19. Parents with secure attachment can regulate their emotion under stressful situations, and their children will also be affected by them. Parents should provide more supportive parenting behaviors to promote children's emotional regulation ability. Parents with insecure attachment have a higher degree of adverse adaptation reactions under stressful and threatening events, and at the same time, their children may also experience negative emotions. These children may need more attention in the long term. In particular, the dismissing attachment style can buffer the association between parents' and children's emotions, but these kind of children may suppress their own emotions or their emotions have been ignored by their parents. Therefore, parents and children dyads characterized by dismissing and fearful parents might need long-term attention in order to monitor and support their negative emotions and their intrapersonal and interpersonal psychological adjustment.

It should be pointed out that there are still some limitations in this study. First, due to the limitation of pandemic isolation and considering the children's cognitive levels and comprehension, the information was only reported by parents, which increases common method bias. Moreover, the cross-sectional nature prevents us from inferring causality. Future research should collect self-reports from children and further reveal a causal relation through longitudinal design. In addition, some populations were over-represented, such as mothers. Future studies should collect a wider variety of representative samples in order to achieve more robust findings. Third, only three items were used to measure the parents' negative emotions, which may have made the internal consistency reliability of the scale not as high as desired. In addition, future research can explore other variables possibly affecting parents' emotions, and the perceptions of their children's feelings such as emotion regulation (Pace et al., 2018), alexithymia (Pace et al., 2015), and reflective functioning (Schultheis et al., 2019). Furthermore, future studies should also take into account children's attachment and they should explore in-depth the direction of the relation between parental negative emotions and children's negative emotions. Despite these limitations, this study could be the first applying the knowledge of the normative processes of parent-child emotion regulation, mediated by parental attachment style, in a non-normative situation like COVID-19. Moreover, the findings can be useful to support how certain processes, highlighted in non-risk situations, are applicable and take on particular relevance in planning family support and interventions in critical situations such as the current pandemic.

**Aim:** The coronavirus disease 2019 (COVID-19) pandemic has abruptly changed the life of millions as travel and social contacts have been severely restricted. We assessed the psychological impact of COVID-19 on adults and children, with special attention to health care workers (HCWs).

**Methods:** A self-rated online survey, including the Impact of Event Scale-Revised (IES-R) for adults and the Children Revised Impact of Event Scale-Revised-13 items (CRIES-13) for their 8–18-year-old offspring, was conducted in Italy on March 20–26, 2020. Linear mixed-effects models were applied to the data, accounting for age, sex, education, and other demographic characteristics.

**Results:** Data were available from 2,419 adults (78.4% females, mean age 38.1 ± SD 13.1 years; 15.7% HCW) and 786 children (50.1% male, mean age 12.3 ± 3.2 years). Median (IQR) IES-R score was 30.0 (21.0–40.0), corresponding to mild psychological impact, with 33.2% reporting severe psychological impact. IES-R was lower in HCWs (29.0) than non-HCWs (31.0), but HCWs directly involved in COVID-19 care had higher scores [33.0 (26.0–43.2)] than uninvolved HCWs [28.0 (19.0–36.0)]. Median CRIES-13 score was [21.0 (11.0–32.0)], with 30.9% of the children at high risk for post-traumatic stress disorder. Parent and child scores were correlated.

**Conclusions:** Up to 30% of adult and children in the pandemic area are at high risk for post-traumatic stress disturbances. The risk is greater for HCWs directly involved in COVID-19 care and for their children.

**Keywords:** children, COVID-19, health care workers, pandemic, psychological impact

## INTRODUCTION

On the 11th of March 2020, the WHO reported that the coronavirus disease 2019 (COVID-19) had become a pandemic, involving 114 countries and more than 118,000 cases. Italy, with 42,220 cases and 3,200 deaths as of March 20, 2020 (1) had the second highest number of COVID-19 cases worldwide, after China (2). On March 10th, in an attempt to contain the spreading of the infection, the Italian government closed all non-essential businesses and services,

including also schools, universities, parks, theaters, and museums, and imposed severe limitations on the freedom to move and interact socially. In the following days, these public health dispositions were further tightened so that the entire Italian population was put on a lockdown.

Despite all efforts to contain the infection, the Italian National Health Care System was severely tested and health care workers (HCWs) overwhelmed by the demand (3). As previously happened in Wuhan, during the peak of the COVID-19 outbreak, HCWs faced a particularly stressful situation, with high risk of infection, inadequate access to protective devices, and social isolation, with consequent emergence of anxiety and depressive symptoms (4–7). These mental health problems can not only affect HCWs' attention, understanding, and decision-making ability, but also have lasting consequences for their well-being. During the 2003 outbreak of severe acute respiratory syndrome (SARS), a similar but much more limited epidemic, high levels of psychological distress and post-traumatic stress symptomatology (PTSS) were reported among HCWs (8, 9). A study conducted by Wang and colleagues 2 weeks into the China's outbreak of COVID-19 found that about half of the surveyed HCWs reported moderate to severe psychological impact, with about one-third reporting moderate to severe anxiety symptoms (10).

While data are available on the impact of the pandemic on HCWs (6, 7), little is known about possible effect on children, and in particular the children of HCW directly involved in COVID-19 care. In fact, since the beginning of the pandemic, more than 15,000 HCWs had been infected and 109 had died as of April 10, 2020 (11). Another relevant and yet unexplored issue is the worry that parents, and particularly HCWs, may have of infecting their children and of possible long-term consequences of COVID-19 (12, 13).

In this study, we evaluated the psychological impact of the COVID-19 pandemic on a sample of adults and their children, with special attention to HCWs, during the first 2 weeks of the COVID-19 outbreak in Italy, at time when the entire country was on general lockdown. We hypothesized that HCWs involved in COVID-19 care and their children would have greater indexes of psychological distress.

## MATERIALS AND METHODS

### Design and Participants

We conducted a cross-sectional survey among the general public in Italy during the peak of the COVID-19 pandemic to assess adult and child psychological response through an anonymous online questionnaire. A snowball strategy was adopted. The online survey was first spread through WhatsApp among HCW colleagues and acquaintances in the North-West of Italy, encouraging them to pass it on to others, health professionals or not. Participants gave informed consent and completed the survey via an online platform (Google Forms, Google LLC, 1600 Amphitheater Parkway, Mountain View, CA 94043, USA). Participants who had children between 8 and 18 years of age were instructed to have them complete the child survey (CRIES-13). Expedited approval was obtained from the institutional ethics

committee. Data were collected between 3 P.M. of the 20th March 2020 and 6 P.M. of the 26th.

### Assessments

Participants provided information about their age, gender, birthplace, residence area, education level, marital status, and any offspring between 8 and 18 years of age. Participants also were asked about place of work and whether they or their family partner were HCWs (physician or nurse) and directly involved in providing COVID-19-related care. Participants were also queried about having tested positive to the virus, or if any relative or friend had contracted COVID-19. Work exposure to COVID-19 was coded yes/no, and extent of daily exposure to COVID-19 patients was rated on Likert scale from never to always. As we were in a very early stage of the pandemic, we only inquired whether participants' close relatives had tested positive to the COVID-19 virus, as death from the disease was still a relatively rare event.

The psychological impact of COVID-19 among adults was measured on the Impact of Event Scale-Revised (IES-R) (14). The IES-R is a self-administered questionnaire that has been validated in the Italian population (15) to measure post-traumatic stress symptomatology in the past seven days. It is a 22-item questionnaire on a five-point Likert scale (0–4, with labels of “Not at all” to “Extremely”) with three subscales measuring avoidance, intrusion, and hyperarousal, and generating a total score. Total IES-R score can be considered normal (0–23) or indicative of mild (24–32), moderate (33–36), or severe ( $\geq 37$ ) psychological impact. In our sample, the IES-R Cronbach's alpha was excellent ( $\alpha = 0.91$ ).

Children completed the Children's Revised Impact of Event Scale (CRIES-13), which is a 13-item scale adapted from the Impact of Event Scale (IES) (16, 17). It is widely used to screen children at high risk for post-traumatic stress disorder (PTSD). Items are rated on a four-point Likert scale (None = 0, Rarely = 1, Sometimes = 3, and A lot = 5), according to the frequency of recurrence of post-traumatic stress reactions during the past week, as well as in relation to a specific traumatic event noted at the top of the scale. The total score can range from 0 to 65, and is obtained from the scores of the three subscales (intrusion, avoidance, and arousal). A cut-off of 30 identifies children at risk for PTSD (16). In the study sample, CRIES-13 had a high level of internal consistency, as shown by a Cronbach's alpha of 0.86.

### Statistical Analyses

Statistical analyses were performed using the statistical programming language “R” (version 3.5.1) (18). Descriptive statistics were calculated for sociodemographic characteristics, current job activity, and risk exposure to COVID-19 (Tables 1, 2). Continuous variables were described by median and interquartile range (IQR). Categorical data were expressed as percentage. Linear mixed models (lme4 package) were used to identify variables associated with IES-R and CRIES-13 scores (19). Separate models were run for adults and children. The specified model for adults had fixed effects for HCW (yes/no) and CoV-SARS2 exposure (high/low). As HCWs were expected to have higher exposure than non-HCWs, the interaction between

these two factors was taken into account by including a further fixed effect. The difference between HCWs currently employed in COVID-19 wards and those uninvolved in direct COVID-19 care was modeled with the use of a second model with fixed effect for COVID-19 ward employment (yes/no). Both models were adjusted for workplace, gender, educational attainment and age (categorized).

As parental stress could influence children, offspring stress expression models included IES-R as a fixed effect (20). Child age and having or not a HCW parent were the other fixed effect factors. To verify whether there was an association between siblings' psychological impact, we added sibling's CRIES-13 for fixed effect in the analysis of data from families with more than one child aged 8–18 years. To this end, we alternatively used the CRIES-13 score of one sibling (sibling 1) as the outcome measure and the score of other (sibling 2) as a predictor. The difference between children of HCWs currently employed in COVID-19 wards and children of other HCWs was modeled with the use of a third model with fixed effect for parents' COVID-19 ward employment (yes/no). Random effects in all the offspring models were: parent education, parent's workplace, gender, number of siblings, and parent's COVID-19 exposure intensity. Group differences were assessed with Mann Whitney *U*-test. Statistical significance was set at  $p < 0.05$ . To verify whether violation of the normality of residuals assumption and outliers affected the linear mixed model analyses, robustified versions of the same linear mixed models were also conducted (data not shown) (21).

## RESULTS

### Socio-Demographics Characteristics

We received responses from 2,438 adults, of whom 19 did not give consent to the use of the data (participation rate: 99.2%). Participants were 2,419 adults (mean age  $38.1 \pm 13.1$  year;

78.4% females) from all parts of Italy (North:  $n = 2,086$ , 86.2%; Central:  $n = 220$ , 9.1%; South:  $n = 113$ , 4.7%). Most participants were married or cohabitant (1,337, 55.3%), 937 (38.7%) were single, 123 (5.1%) divorced or separated, and 22 (0.9%) widowed (Table 1). Almost half of the sample (49%) had children. Of the adult participants, 380 (15.7%) were HCWs, of whom 294 (77.4%) physicians and 86 (22.6%) nurses. Of the HCWs, 122 (32.1%) were currently employed in COVID-19 wards. Only 27 subjects (1.1%) had tested positive to Covid-19. Data were collected on 786 children (394 or 50.1% males), with mean age  $12.3 \pm 3.2$  years. Demographics are reported in Table 2.

### Psychological Impact of COVID-19

In adults, the IES-R total score median (IQR) was 30.0 (21.0–40.0), corresponding to mild psychological impact (Table 1; Figure 1). For 30.4%, the IES-R score was in the normal range (0–23). One third (33.2%) had a score consistent with severe psychological impact (i.e., IES-R  $\geq 37$ ), with no significant difference between HCW (29.7%) and non-HCW participants (33.8%). However, HCWs involved in direct COVID-19 care had higher median IES-R scores [33.0 (26.0–43.2)] than uninvolved HCWs [28.0 (19.0–36.0)]. Having a relative who had tested positive to SARS-CoV-2 was not associated with a higher IES-R score.

In children, the CRIES-13 total score median (IQR) was [21.0 (11.0–32.0)], i.e., below the cut-off of 30 for being at risk for PTSD. For 30.9% the CRIES-13 score was 30 or greater (Table 2). No significant differences were found between children of HCW parents [21.0 (9.0–31.7)] and those of non-HCWs [21.5 (12.0–32.2)] on the total CRIES-13 score. Furthermore, there was no significant difference between children of HCW parents who were directly involved in COVID-19 care and those of HCW parents who did not have such an involvement (Table 5).

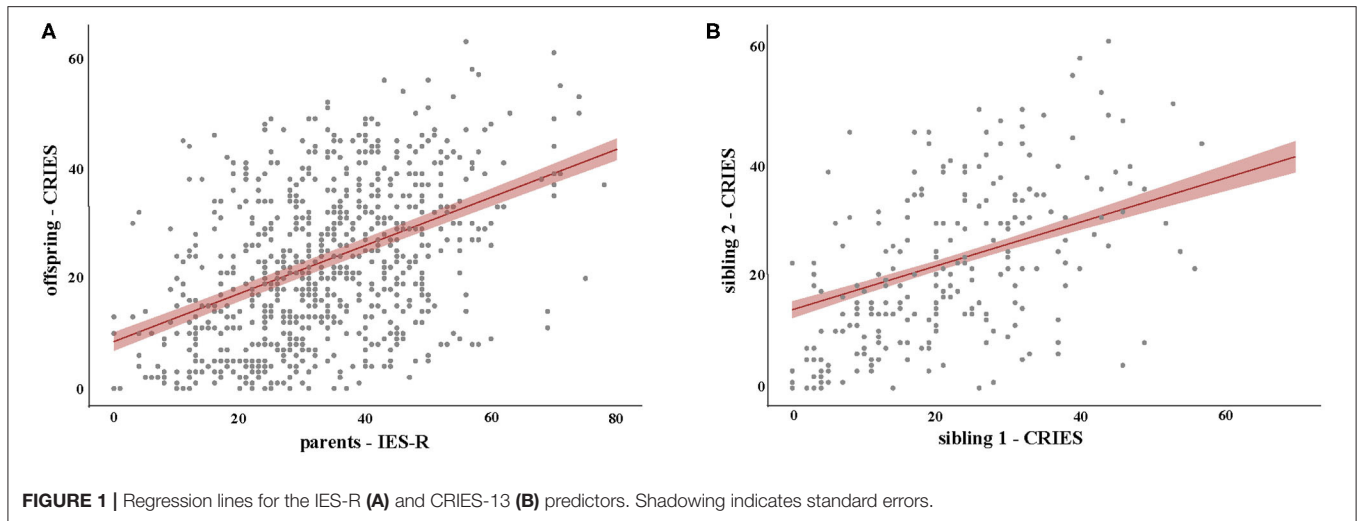

### Factors Associated With Psychological Distress

In adults, being female was strongly associated with higher IES-R scores ( $p < 0.001$ , Mann-Whitney *U*-test) (Table 3). Thus, data were also analyzed by sex. Overall, being a HCW was associated with lower IES-R total scores [estimated mean difference  $-2.48$  ( $-4.39$  to  $-0.57$ )], as shown in Table 3 (Model 1). However, HCW employed in COVID-19 wards reported more distress than other HCWs [estimated mean difference 5.71 ( $-2.92$  to 8.50), Model 2, Table 3].

In males, age or being a HCW was not associated with the reported level of distress (Table 3). But male HCWs who were employed in COVID-19 wards reported significantly higher distress than other male HCWs (Model 2, Table 3).

In females, all previously identified factors (i.e., HCW, COVID-19 exposure, and employed in COVID-19 wards) were associated with IES-R scores (Table 3).

In children, CRIES-13 scores were related to their parents' IES-R scores (see Table 4 and Supplementary Figure 1). Importantly this finding held true for both single children and for siblings (Table 4 and Supplementary Material). Additionally, siblings' CRIES-13 are correlated, suggesting a possible "family effect" for distress. In agreement with previous

findings (22) and similarly to adult results, girls expressed higher distress level ( $p < 0.001$ , Mann-Whitney  $U$ -test). No other factors were significantly associated with CRIES-13 scores in our model (Tables 4, 5 and Supplementary Material).

## DISCUSSION

This study investigated the psychological impact of the COVID-19 epidemics on adults and children at the time of the highest daily increase in infections in Italy (11). By using a large, nationwide, self-selected sample and validated measures of psychological impact from traumatic situations, we found that about one third of the participants reported moderate-to-severe psychological distress. HCWs were not, as a group, at higher risk for psychological distress

**TABLE 4** | Factors associated with psychological impact in children.

\*\*\* $p < 0.001$ .

than non-HCWs, but those HCWs directly involved in providing COVID-19 care had significantly higher indexes of distress.

Children's ratings were correlated to those of their parents, and about 30% of them had indexes indicative of higher risk for post-traumatic distress. A correlation between parent and child ratings is expected, reflecting a commonality of contextual factors related to COVID-19 and a similarity in temperamental traits and emotional communication capacity that are likely to be both genetically and environmentally influenced (23). Consistent with the psychiatric literature on mood and anxiety disorders and other reports on post-traumatic stress, females reported greater psychological distress than males, in both the whole sample and the HCW subgroup (4).

The IES-R scores in our sample are consistent with those recently reported in studies of the general population (IES-R mean 32.98) and HCWs (IES-R median 21.0) in the Wuhan area in China (4, 10). Our study expands on previous reports by examining HCWs within a sample of the general population and by assessing the impact of COVID-19 on children in relation to their parents.

The results suggest that HCWs experienced, in general, less psychological distress than non-HCWs, but HCWs currently working on COVID-19 wards reported more distress, with IES-R scores indicating high risk for experiencing psychological breakdown and developing PTSD. Being directly involved in COVID-19-related healthcare was in fact the only predictor of higher distress in both males and females. Several reasons could explain these findings. On one hand, greater familiarity with health issues in general and a deeper understanding of the infection mechanisms could have helped HCWs control anxiety and reduce distress. Even during the pandemic social lockdown, HCWs were allowed to leave home and continue working, and were less restricted in social contacts than the general population, thus limiting possible feelings of boredom, frustration, and uselessness brought by the lockdown. Additionally, while many people suffered from job insecurity and faced economic uncertainty, HCWs had greater job security during the pandemic.

On the other hand, HCWs who were directly involved in COVID-19 care were more exposed to the risk of contagion and might have faced emotional pain and stress at work. During the SARS outbreak in 2003, 17.3% of the HCWs reported mental symptoms, which persisted in 15.4% at 1-year follow-up (24). In another study during the SARS outbreak in Singapore, the rate of HCWs reporting psychiatric symptoms was 17.7%, using a cut off of 26 on the IES (9). These rates are lower than in our study, possibly reflecting the extraordinary morbidity and global reach of the COVID-19 pandemic in Italy, as well as the influence of cultural factors on the perception and reporting of emotional distress.

Relatively little has been known about the psychological distress of children exposed to the pandemic. Concern has been raised that children might be particularly sensitive to the psychological effects of COVID-19 (10, 25–27). Fear of infection and home confinement could be particularly stressful for young people. Children and adolescents may be more vulnerable also because of home confinement, school closure, lack of in-person contact with classmates, friends, romantic partners, and teachers, and limitation in personal space at home (28). In this context, the role of parents becomes especially important for attenuating the

psychological detrimental effects of confinement. From the child development literature, we know that children rely on trusted adults for protection and as a reference for assessing danger and attributing meaning to events (20, 29–31). Thus, it can be especially frightening for a child to perceive that the parent is distressed and unable to prevent a traumatizing event from happening. The correlation between parent (IES-R) and child (CRIES-13) psychological distress underscores the strong link existing between parent-child mental health and brings attention to the critical role of the parent in buffering the distressing effects of the pandemic and its consequences upon their children. Unlike other reports of young age being a risk factor for post-traumatic reactions (32–34), we did not find age to be a significant moderator of psychological distress in children, possibly because the sample did not include very young children.

## Limitations

This study has several limitations that must be considered in interpreting the data. First, even though the survey was widely disseminated nationwide, the sample was self-selected and not representative of the Italian population. This is evident, for example, by the 3:1 female/male ratio. This higher proportion of females is, however, comparable to previous studies on the pandemic (4, 10), thus indicating that females are more prone to complete this type of surveys. Second, the data rely on just one self-rating instrument, the IES-R for adults or the CRIES-13 for children, without other measures of current or past psychopathology. Indeed, this is a cross-sectional study and future time points will be needed to understand the psychological impact of the pandemics. Another limitation of the present study is that the IES-R had not been structured for ongoing stressful events, such as pandemics, and is not a diagnostic tool for PTSD. However, to the best of our knowledge, no more specific assessment tools have been so far validated for such events. Finally, the online survey could not control for possible heterogeneity in the way parents had their children complete the questionnaire.

## Conclusion

This study informs on the psychological impact of the COVID-19 pandemic on adults and children in Italy, with special attention to the greater risk for psychological distress among those HCWs directly involved in COVID-19 clinical care and their children. About one-third of the surveyed children reported significant distress. The close link between parent- and child-reported distress suggests that interventions aimed at preventing and managing COVID-19 related anxiety in children should take into account parental distress. Successful management of distress in parents may positively reflect on their children's mental health.

doi: 10.3389/fpsyg.2021.565845

The coronavirus COVID-19 pandemic is an unprecedented health crisis. Many governments around the world have responded by implementing lockdown measures of various degrees of intensity. To be effective, these measures must rely on citizens' cooperation. In the present study, we drew samples from the United States ( $N = 597$ ), Italy ( $N = 606$ ), and South Korea ( $N = 693$ ) and examined predictors of compliance with social distancing and intentions to report the infection to both authorities and acquaintances. Data were collected between April 6th and 8th 2020. We investigated the role of cultural orientations of horizontal and vertical individualism and collectivism, self-conscious emotions of shame and guilt related to the infection and trust in the government's action. Across all countries, vertical collectivism (VC) predicted stronger shame, whereas horizontal collectivism predicted stronger trust in the government. Only in the United States, VC was associated with stronger trust. Stronger feelings of shame predicted lower compliance and intentions to report the infection to both authorities and acquaintances. In contrast, guilt was associated with stronger intentions to report the infection to the authorities. Finally, trust was associated with stronger compliance and intentions to report the infection to the authorities. Unlike Italy and South Korea, the association between trust on compliance was not statistically significant in the United States, implications of the findings, and directions for future research are discussed.

**Keywords:** horizontal and vertical individualism and collectivism, shame, guilt, trust, COVID-19, pandemic, self-reporting, social-distancing

## INTRODUCTION

The coronavirus COVID-19 pandemic is an unprecedented health crisis that has forced nearly a third of the world population into lockdown (Kaplan et al., 2020). Lockdowns are "behavioral" (non-pharmaceutical) measures involving forced isolation, movement restrictions, and active government surveillance. These measures effectively slow the virus's diffusion because they reduce contagion rates (Cowling et al., 2020; Ferguson et al., 2020; Flaxman et al., 2020). Reducing

contagion is an important objective, especially in the absence of effective antiviral drugs, vaccines, or widespread population immunity, all still unavailable in the context of the new pandemic.

To be sustained in time, and be more effective, non-pharmaceutical interventions must rely, at least in part, on citizens' active cooperation with authorities, especially in those countries characterized by democratic political systems. In the present research, we examined critical predictors of cooperation across three different contexts: the United States, Italy, and South Korea. Specifically, we focused on trust toward the government (e.g., Morse et al., 2016), and self-conscious emotions related to the infection (guilt and shame; Finerman and Bennett, 1995). We contribute to the growing psychological literature on COVID-19 (Capraro and Barcelo, 2020, 2021; Lalot et al., 2020a,b; Van Bavel et al., 2020a,b; Yamada et al., 2021) by investigating the associations between these variables and individuals' compliance with social distancing rules, as well as their intentions to report the infection to both health authorities and acquaintances/friends. Because cultural values may be associated with these variables differently across contexts, we also examined the role of individual-level cultural orientations of vertical and horizontal individualism and collectivism.

## HORIZONTAL AND VERTICAL INDIVIDUALISM AND COLLECTIVISM

Culture may be defined as shared meaning, shaping individuals' basic psychological processes and informing their understanding of the world (Triandis, 2001). Two of the most fundamental dimensions of cultural variations are individualism and collectivism (Triandis, 1995; Hofstede, 2001). These values frame individuals' interpretation of reality, emphasizing the importance of "the individual" or "the collective," respectively. Because responses to the novel pandemic are likely to involve tradeoffs and adjustments between these two value frameworks, individualism and collectivism are likely to play an essential role in how people behave.

Individualism and collectivism reflect the extent to which cultural groups value independence vs interdependence (Markus and Kitayama, 1991; Kitayama et al., 2009; Park et al., 2016). In individualistic cultures, individuals are socialized toward independence, autonomy of the self and self-reliance. Conversely, in cultures where collectivism is a principal value, individuals are socialized toward interdependence, an interconnected self and the importance of relationships. Individualism and collectivism have attracted a substantial share of research attention across various countries and settings (Gudykunst and Ting-Toomey, 1988; Hofstede, 2001; House et al., 2004).

These dimensions have recently been extended to consider cultures' different emphasis on equality vs hierarchy (Triandis and Gelfand, 1998; Oyserman et al., 2002; Shavitt et al., 2011a,b). "Horizontal" cultures place importance on equality in status, either in the context of an independent (horizontal individualism, HI) or interdependent (horizontal collectivism, HC) self. Conversely, "vertical" cultures place importance on

hierarchical relationships and differences in status, either in the context of competing individuals (vertical individualism, VI) or ranked groups (vertical collectivism, VC). This fourfold typology is an important predictor of a range of behaviors and attitudes (Triandis and Gelfand, 1998; Shavitt et al., 2006, 2011a,b; Moon et al., 2018; Travaglino and Moon, 2020).

In the present research, we sampled participants from three different contexts characterized by different prevalent cultural themes. The United States' dominant themes are individualism and verticality (e.g., Shavitt et al., 2006; Torelli and Shavitt, 2010), with a strong emphasis on the uniqueness and independence of the self as well as status and competition. In Korea, the prevalent cultural themes are group harmony, obedience to authority and an emphasis on status hierarchies, a configuration of values congruent with VC (Triandis and Gelfand, 1998; Shavitt et al., 2006). Relatively less research has examined the Italian context concerning the horizontal and vertical individualism and collectivism (HVIC) typology. However, there seems to be some evidence that the prevalent cultural theme in Italy falls between the United States and Korea in terms of the individualism-collectivism dimension, with a stronger emphasis on horizontality compared to the other two countries (Hofstede et al., 2010; Burton et al., 2019; Germani et al., 2020).

Beyond country-level differences, there is heterogeneity in the values that individuals within countries endorse (cf. Oyserman et al., 2002; Green et al., 2005; Cho et al., 2010; Taras et al., 2016; Burton et al., 2019). It is thus essential to examine endorsement of cultural values at the individual level, as well as variations across contexts. In the subsequent text, "*cultural values*" or "*themes*" refer to the country level of analysis, and "*cultural orientations*" refer to the individual level of analysis.

In the present study, we investigated how cultural orientations within countries characterized by different cultural themes may predict a range of responses to the virus-related emergency, namely trust in the government's action, and self-conscious emotions of shame and guilt. We then investigated how such factors predict individuals' intentions to comply with social distancing and report the infection to authorities and acquaintances.

## Trust in Government

Trust in government refers to beliefs and attitudes about the government's competence and good faith (cf. Levi and Stoker, 2000; Nannestad, 2008). It is a critical feature of the relationship between individuals and institutions. Trust is linked with the government's performance and reflects the levels of social and civic engagement within society (i.e., social capital; Putnam, 2000). Societies in which the government is efficient and citizens have higher social capital also tend to report stronger trust in government (Tyler, 2001, 2006; Job, 2005; Blind, 2007; Keele, 2007).

The degree of trust in authorities has especially significant implications in emergency and risk situations, where norms about appropriate behavior are unclear, and events may unfold in unpredictable ways. For instance, individuals' lack of confidence in the governments' ability to handle terrorist attacks may seriously harm officials' efforts to shape public responses to such

attacks (Wray et al., 2006). Conversely, reliable communication that inspires confidence can help the government reduce anxiety and prevent harm among citizens (Covello, 2003; Wray et al., 2004).

In the health context, trust in authorities was associated with individuals' compliance with authorities' recommendations during the H1N1 2009 pandemic in both the United Kingdom (Rubin et al., 2009) and Italy (Prati et al., 2011). Similarly, research from Tang and Wong (2003) showed an association between a composite measure of trust in institutions (including the government's ability to control the spread of the infection) and the likelihood of wearing a face mask during the outbreak of the Severe Acute Respiratory Syndrome (SARS) in Hong Kong. More recently, Morse et al. (2016) demonstrated that distrust in authorities was associated with reduced usage of health services in Liberia during the Ebola outbreak (2014–2016). In the present study, we tested the role of trust in the governments' ability to handle the current COVID-19 pandemic by comparing three different countries. We also investigated the cultural values that predicted trust in each of the three settings.

## Self-Conscious Emotions: Guilt and Shame in Response to Infection

Research has yet to examine the role of emotions in individuals' compliance with authorities' recommendations in the course of an epidemic outbreak (cf. Prati et al., 2011). Especially relevant in the context of diseases and infections are self-conscious emotions of guilt and shame. Individuals experience guilt or shame when they perceive they have done something wrong, or in response to stigma and blame (Giner-Sorolla, 2012). Although similar, guilt and shame refer to two different appraisals of the self (Lewis, 1971). Individuals feel guilt when they feel responsible for the consequences of a specific action, such as acting in ways that may increase the likelihood of contracting the coronavirus. Instead, shame involves an appraisal of the self as immoral and unworthy (Giner-Sorolla, 2012). Whereas guilt is generally defined as a private emotion, shame is theorized as externally driven (see Benedict, 1946; Wolf et al., 2010). This is because guilt implies a negative evaluation of the self by *oneself*, whereas shame implies a negative assessment of the self by *others*.

Guilt and shame play an essential role in shaping individuals' health-related decisions in various settings (Donahue and McGuire, 1995; Finerman and Bennett, 1995). These emotions have been examined in the context of multiple conditions, such as sexually transmitted diseases (Goldenberg et al., 2008), cancer (Chapple et al., 2004), type 2 diabetes (Browne et al., 2013), and obesity (Conrad et al., 2008). For instance, concerning sexually transmitted diseases, these emotions are associated with lower disclosure to partners, and lower intentions to seek treatment or testing (Cunningham et al., 2002; Balfe et al., 2010). Moreover, lung cancer patients may perceive guilt and shame about the disease, with significant impact on their intentions to disclose the disease or seek support (e.g., Chapple et al., 2004).

In this research, we investigated the role of guilt and shame in the context of individuals' responses to the COVID-19 pandemic.

Groups may tighten their norms when confronting ecological threats such as outbreaks of diseases (Gelfand et al., 2011; Gelfand et al., 2017). Tighter norms are beneficial because they foster group coordination, sustaining collective efforts (Gelfand et al., 2021). However, tighter norms may also encourage the stigmatization of those perceived as undermining them. For example, across many countries, several social media campaigns stigmatize individuals who were perceived as defying social distancing norms. Moreover, there is anecdotal evidence that contracting the infection leads to the stigmatization of the survivors (Maslin Nir, 2020), and blame toward them (Reicher and Drury, 2021).

## The Present Research

To summarize, this research investigated the role of trust and self-conscious emotions in predicting individuals' intentions to comply with social distancing norms and to report the infection to either health authorities or acquaintances. We examined these factors in three contexts (the United States, Italy, and South Korea) characterized by different prevalent cultural themes of HI and VI, and HC and VC. Moreover, we examined the role of individuals' cultural orientations within each country.

Concerning shame and guilt, research differentiating between the two emotions suggest that shame has mostly negative implications and is associated with avoidance and withdrawal, whereas guilt is associated with more positive coping and engagement (Tangney and Fischer, 1995; Tangney, 1998; Conrad et al., 2008). These findings suggest that shame should be associated with lower compliance and intentions to report the infection to authorities and others. In contrast, guilt may have fewer negative implications and even be associated with more substantial compliance and reporting.

We investigated differences in the role of shame and guilt across countries. Research suggests that self-conscious emotions are more prevalent, socially constructive, and have fewer negative implications for individuals' well-being and behavior in contexts characterized by higher collectivistic values and influenced by Confucianism (Menon and Shweder, 1994; Kitayama et al., 1997; Fischer et al., 1999; Li and Wang, 2004; Wong and Tsai, 2007). This is because these emotions are broadly consistent with the culturally sanctioned goals of self-improvement and adherence to collective standards and norms. In contrast, in individualistic contexts, shame and guilt are seen as negative emotions that should be avoided, and they are thus less socially constructive. This evidence suggests that VC, which emphasizes duties and obligations toward group goals, should predict stronger self-conscious emotions concerning the infection. Conversely, HC, which emphasizes equality and interdependence should predict lower levels of self-conscious emotions. Moreover, such emotions (and particularly shame) should have more substantial negative implications in more individualistic countries where VC is not the dominant value.

Concerning trust, we predicted a positive association between trust toward the government's efforts to tackle the pandemic and individuals' intentions to comply with social distancing norms and report the infection to health authorities (e.g., Tang and Wong, 2003; Rubin et al., 2009;

Prati et al., 2011; Morse et al., 2016). This is because higher trust in the government means that individuals are more likely to believe in the competence and good faith of the governments' recommendations, and abide by its regulations (Tyler, 2001).

However, the meaning and implications of trust may be shaped by culture (Shin and Park, 2004; Yuki et al., 2005). Cross-cultural research indicates that the association between trust and individualism and collectivism is complex and multifaceted, owing to the very different operationalizations of these constructs adopted within the literature (see Realo and Allik, 2009). Definitions of individualism that emphasize competition and narrow self-interest (similar to VI) suggest that individualism may have negative implications for trust (Putnam, 2000; Gelfand et al., 2004). However, evidence from cross-country comparisons indicates that individualism (conceptualized as autonomy and self-sufficiency, closer to HI) is associated with stronger (rather than weaker) interpersonal trust (Allik and Realo, 2004; Realo and Allik, 2009). There is also some evidence pointing at the relevance of horizontality and collectivism in fostering the emergence of trust. For instance, Realo et al. (2008) found that countries that scored higher on institutional collectivism – the extent to which institutional arrangements favor collective action (Gelfand et al., 2004) – displayed higher levels of social capital, an essential component of trust in government (Job, 2005).

At the individual level, research by Beilmann and Realo (2012) indicates that social capital is positively associated with two components of collectivism (i.e., relationships with peers, and dedication to the nation), as well as one of individualism (i.e., mature self-responsibility; Job, 2005). Similarly, research shows that the HC orientation – which encompasses values such as benevolence toward others and interdependence – is a predictor of generalized trust (Shin and Park, 2004). In the narrower context of trust toward the authorities, there is also some evidence of an association between VC and authority endorsement in crisis communication (Jakubanecs et al., 2018). This evidence can be explained by the fact that the VC orientation emphasizes respect for authority (see Devos et al., 2002). These findings suggest that both HC and VC may be relevant in predicting trust.

In the analyses, we tested our hypotheses controlling for gender and age due to the samples' heterogeneity included in the analyses. Moreover, we added political orientation (left-right) as a covariate to control for individuals' stance toward the current government. Finally, because countries experienced different infection rates, we controlled for individuals' perceived danger related to the spread of the virus within the country.

## MATERIALS AND METHODS

### Participants and Procedure

Five-hundred-and-ninety-seven participants were recruited from the United States (296 men, 291 women, 7 other, 3 preferred not to answer;  $M_{\text{age}} = 39.35$ ,  $SD_{\text{age}} = 11.62$ ). Of the American participants, 43.6% indicated they lived in a city/large town, 42.4% in a smaller/average town, 14.1% in a village/rural area. Participants were from different states, including Florida (9.7%),

New York (8.4%), California (7.7%), Texas (6.5%), Pennsylvania (5.4%), and Ohio (5.4%). The other states represented in the sample each accounted for <5% of the total number of participants.

Six-hundred-and-six participants were recruited from Italy (301 men, 294 women, 8 other, 3 preferred not to answer;  $M_{\text{age}} = 26.94$ ,  $SD_{\text{age}} = 7.72$ ). Of the Italian participants, 41.1% indicated they lived in a city/large town, 40.4% smaller/average town, 18.5% village/rural. Participants were from different regions, including Piemonte (21.8%), Lazio (14.7%), Lombardia (10.7%), Veneto (8.9%), Campania (8.7%), Sicilia (6.6%), and Emilia Romagna (5.9%). The other regions represented in the sample each accounted for <5% of the Italian sample.

Six-hundred-and-ninety-three participants were recruited from South Korea (342 men, 346 women, 5 preferred not to answer;  $M_{\text{age}} = 44.46$ ,  $SD_{\text{age}} = 13.15$ ). Of the Korean participants 81.8% indicated they lived in city/large town, 16.2% in a smaller/average city, and only 2% in a village/rural area. Participants were from different metropolitan cities and provinces, including Seoul (28.6%), Busan (16.0%), Incheon (14.9%), Daegu (12.4%), Gyungi (8.7%), Gwangju (7.1%), and Daejeon (6.3%). The other regions represented in the sample each accounted for <5% of the Korean sample.

Data from the United States and Italy were collected using Qualtrics via Prolific Academic© (see Peer et al., 2017). Data from Korea were collected using Qualtrics via a local research panel. The studies involving human participants were reviewed and approved by the Psychology Ethics Committee of Leeds Beckett University. Participants were paid 2 GBP in Italy and the United States, and 2.25 GBP in Korea.<sup>1</sup> All scales included for the present study were initially developed in English and subsequently translated into Italian and Korean. Back-translation was used to achieve equivalent meanings in the two languages following guidelines by Brislin (1986).

Participants were invited to participate in a larger research study on “political and current issues” which also included a module on the “the current COVID-19 situation.” Items were presented to participants in random order. After completing the measures, all participants were debriefed in writing, thanked, and compensated for their time. Data in all countries were collected between April 6th and 8th 2020 (the COVID-19 outbreak was declared a Public Health Emergency of International Concern on January 30, 2020). At that time, the United States had reported 12,895 deaths due to COVID19, Italy 17,129 and Korea 200. According to the University of Oxford's Stringency index, the three countries had 72.69/100, 91.67/100, and 82.41/100 stringency levels between April 6th and 8th. The Stringency Index is a measure of the severity of the government's responses to the pandemic. The index is a composite measure of seven indicators rescaled to vary from 0 to 100 (Hale et al., 2020). A higher number means that more restrictions are in place in a given country (see Hale et al., 2020 for details).

<sup>1</sup>Participants were paid in USD, EUR, and WON, respectively. Here we report prices converted in GBP.

## Measures

### Horizontal and Vertical Individualism and Collectivism

Twelve items drawn from Sivadas et al.'s (2008) 14 item-scale were used to measure HI (3 items; e.g., *I enjoy being unique and different from others in many ways*), VI (3 items; e.g., *I enjoy working in situations involving competition with others*), HC (3 items; e.g., *The well-being of my co-workers is important to me*), and VC (3 items; e.g., *I would do what would please my family, even if I detested that activity*).<sup>2</sup> Participants answered items using a 7-point Likert scale (1 = *strongly disagree* to 7 = *strongly agree*). The structure of the short scale of horizontal and VI and collectivism has been validated in four contexts (Sivadas et al., 2008) and further confirmed by a recent cross-cultural study (Moon et al., 2018).

### Shame and Guilt

Feelings of shame and guilt were measured using one item for each emotion. Participants were asked to indicate the extent to which they would feel ashamed and guilty if they became infected with the new coronavirus COVID-19 (1 = *not at all*, 7 = *very much*).

### Trust in Governments

Participants indicated the extent to which they agreed or disagreed with a statement "I trust how the government of my country is handling the spread of the coronavirus" using a 7-point scale (1 = *strongly disagree*, 7 = *strongly agree*).

### Compliance With Social Distancing

Using six items, we measured the extent to which people complied with standard guidelines indicating how to behave during the COVID-19 emergency. The items were "I avoid leaving my home unnecessarily," "I wash my hands often," "I follow instructions from health authorities," "I stay away from crowded places," "I advise others about how to act in response to the virus," and "I stand away from others in public places" (1 = *not at all*, 7 = *very much*).

### Self-Reporting of the Infection to Authorities and Acquaintances/Friends

Participants reported their intentions to report the infection to health authorities and acquaintances/friends. Participants first read "if I suspected I were infected with the new coronavirus. . ." and answered two items "I would notify the health authorities immediately" "I would hide it from my acquaintances and friends" (1 = *not at all*, 7 = *certainly*).

### Concerns About the Virus

Using a 7 point scale, participants indicated how concerned they were by the spread of the new coronavirus (COVID-19) in their country (1 = *not at all concerned*, 7 = *extremely concerned*).

<sup>2</sup>In the present study, we did not include the two items "My happiness depends very much on the happiness of those around me" and "Children should feel honored if their parents receive a distinguished award" from Sivadas et al.'s (2008) scale because these items had inconsistent loadings in previous cross-cultural research involving samples from the United States and Korea (Moon et al., 2018).

## Political Orientation

Participants indicated how they would describe themselves considering their country's current political context using a 100-point scale slider (0 = *I am a left-winger*, 100 = *I am a right-winger*). Political orientation was added as a covariate to the model.

## Analytical Strategy and Statistical Power

Data were analyzed using structural equation models with latent and observed variables. Analyses were performed using R with the lavaan (Rosseel, 2012), semTools (Jorgensen et al., 2019), and cpsych (Fischer and Karl, 2019) packages. The recommended sample size to be able to detect a minimum small-to-medium effect size ( $\delta = 0.2$ ) at 80% power and  $\alpha = 0.05$  in a model with 5 latent and 27 observed variables is  $N = 376$  (Soper, 2019).

We first sought to establish measurement invariance across countries for the latent measures included in the final model (He and van de Vijver, 2012; Fischer and Karl, 2019). Measurement invariance indicates that a construct is interpreted similarly by respondents in different groups (i.e., cultures, nations, etc.) and can thus be meaningfully compared. Specifically, using a confirmatory factor analysis and robust standard errors, we tested measurement invariance of the 12-item horizontal and vertical individualism and collectivism (HVIC) scale, and the 6-item compliance scale. For each scale separately, we first tested the configural invariance models to examine whether all items loaded on the respective latent factors across countries. These models were then compared to models where factor loadings were constrained to be equal across countries (i.e., metric invariance). Finally, we fixed intercepts to test for scalar invariance. We sought to establish partial invariance for models that did not achieve full invariance. Partial invariance involves individuating what loading(s) or intercept(s) are causing misfit, thus allowing them to vary freely across the groups compared. Partial invariance (with at least two invariant indicators) is often considered a more realistic and sufficient goal in cross-cultural research (cf. Steinmetz, 2018).

Overall model fit was evaluated using four indices, comparative fit indices (CFI: acceptable  $\geq 0.95$ , excellent  $\geq 0.97$ ), adjusted goodness of fit index (AGFI: acceptable  $\geq 0.90$ , excellent  $\geq 0.95$ ), Root Mean Square Error of Approximation (RMSEA; acceptable  $\leq 0.10$ , excellent  $\leq 0.05$ ) and Standardized Root Mean Square Residual (SRMR; acceptable  $\leq 0.10$ , excellent  $\leq 0.05$ ; Hu and Bentler, 1998; Schermelleh-Engel et al., 2003). We also report  $\chi^2$ , although it should be noted that this index is less reliable due to its dependency on multivariate normality and sample size (Schermelleh-Engel et al., 2003). Invariance was determined by examining whether the CFI difference between the constrained nested models was higher than the recommended threshold of  $\Delta CFI = 0.01$  (Cheung and Rensvold, 2002).

Subsequently, to test the hypotheses, we estimated a multi-group structural equation model in which self-conscious emotions of shame and guilt, and trust were predicted by the four cultural dimensions of HI, VI, HC, and VC across countries. Self-conscious emotions and trust, in turn, predicted compliance, intentions to report the infection to health

authorities and acquaintances/friends. Gender, age, concern about the spread of the virus and political orientation were added as covariates to the model.

First, we estimated the latent means using the marker method (Little et al., 2006). We fixed the intercept of each factor's marking item to zero in order to estimate the latent means and interpret them using the same scale as the marker items. Next, we compared means across countries. Finally, we proceeded to examine differences across countries in the model structural paths using the scaled difference Chi-square tests (Satorra and Bentler, 2001).

## RESULTS

### Measurement Invariance

The configural model of the HVIC scale had good fit,  $\chi^2$  (144,  $N = 1896$ ) = 394.34,  $p < 0.001$ , CFI = 0.95, AGFI = 0.99, RMSEA = 0.05, SRMR = 0.05. Constraining the loadings to be equal across groups did not cause the model to deteriorate significantly, indicating that metric invariance was achieved across countries,  $\Delta$ CFI = 0.005 (Cheung and Rensvold, 2002). However, fixing intercepts across countries caused the model fit to deteriorate more than the recommended threshold ( $\Delta$ CFI = 0.04), suggesting that the model did not achieve scalar invariance. Thus, we sought to establish partial scalar invariance by examining what intercepts were the source of the misfit in the model. Releasing the intercepts of two items ("I enjoy working in situations involving competition with others" and "I usually sacrifice my self-interest for the benefit of my group") to vary freely across countries resulted in a model with partial scalar invariance ( $\Delta$ CFI = 0.009).

Analogously, we tested for invariance across countries for the compliance measure. The six-item scale demonstrated acceptable fit across groups,  $\chi^2$  (24,  $N = 1896$ ) = 59.557,  $p < 0.001$ , CFI = 0.98, AGFI = 0.99, RMSEA = 0.07, SRMR = 0.03. The model's fit did not deteriorate significantly when we constrained intercepts to be equal across countries ( $\Delta$ CFI = 0.009). However, the model did not achieve full scalar invariance ( $\Delta$ CFI = 0.029). Therefore, we established partial scalar invariance by releasing the intercepts of the items, "I wash my hands often" and "I stand away from others in public places."

### Primary Analyses: Comparisons Across Countries

Zero-order correlations, means, standard deviations, and alpha coefficients for measures across countries are summarized in **Table 1**. The indices of AGFI = 0.99, RMSEA = 0.05, SRMR = 0.06 indicated good fit. CFI was below the recommended threshold of acceptability (=0.91) and  $\chi^2$  (806,  $N = 1896$ ) = 1794.92,  $p < 0.001$  was significant. Overall, we judged the model fit adequate and retained this model for cross-country comparisons.

### Latent Means

The measurement models of the latent variables were constrained to be partially invariant across countries to enable comparisons of latent means across groups. Results of latent means comparisons

using the market method are summarized in **Table 2**. Participants in the United States endorsed HI and VI significantly more strongly than participants in Korea. Italian participants did not differ significantly from those in the United States and Korea in their endorsement of HI and VI but endorsed HC significantly more strongly than participants in either country. Participants in Korea endorsed VC more strongly than Italian or United States participants. Moreover, participants reported stronger compliance with social distancing norms in Italy, followed by the United States and then Korea.

### Structural Paths

Fixing all the structural paths (except the covariates) to be the same across countries produced a significantly worse fit,  $\Delta\chi^2(42) = 67.954$ ,  $p = 0.006$ . This result suggested the presence of differences between some of the paths. To examine these differences, we proceeded by systematically constraining one path at the time to be equal across countries. Fixing the effects of the HI, HC, VI and VC paths on shame [ $\Delta\chi^2(2) < 5.57$ ,  $p > 0.06$ ] or guilt [ $\Delta\chi^2(2) < 4.91$ ,  $p > 0.08$ ] across countries did not produce a significantly worse fit. Similarly, fixing the effects of HI and VC on trust did not worsen the fit significantly [ $\Delta\chi^2(2) < 4.04$ ,  $p > 0.13$ ], but fixing either paths between HC [ $\Delta\chi^2(2) < 7.64$ ,  $p = 0.02$ ] or VC [ $\Delta\chi^2(2) < 12.14$ ,  $p = 0.002$ ] and trust produced a significantly worse fit. Thus, these paths were allowed to vary freely.

Next, fixing the paths between shame [ $\Delta\chi^2(2) < 2.96$ ,  $p > 0.22$ ] or guilt [ $\Delta\chi^2(2) < 0.56$ ,  $p > 0.75$ ] and compliance, intentions to report the infection to authorities, or acquaintances/friends did not produce a significantly worse fit. Only the path between trust and compliance [ $\Delta\chi^2(2) < 16.17$ ,  $p < 0.001$ ] was allowed to vary freely across countries, whereas the path between trust and intentions to report the infection to authorities or acquaintances/friends [ $\Delta\chi^2(2) < 2.43$ ,  $p > 0.29$ ] were fixed. The resulting model with the freed paths specified above had no significantly worse fit than the model where all paths were free to covary [ $\Delta\chi^2(36) < 36.43$ ,  $p = 0.454$ ;  $\chi^2$  (842,  $N = 1896$ ) = 1834.27,  $p < 0.001$ , AGFI = 0.99, RMSEA = 0.05, SRMR = 0.06]. The model unstandardized solution is comparable across groups (Kline, 2015) and is summarized in **Figure 1**. Within groups completely standardized solutions for each country are reported in **Table 3**.

Guilt and shame were negatively predicted by HC and positively predicted by VC across countries. Interestingly, HC significantly and positively predicted trust only in Italy ( $b = 0.22$ ,  $p = 0.02$ ) and Korea ( $b = 0.33$ ,  $p < 0.001$ ). In the United States, trust was predicted by VC ( $b = 0.29$ ,  $p < 0.001$ ). There were some smaller but significant associations between VI and shame ( $b = 0.09$ ,  $p = 0.01$ ), and VI and trust ( $b = 0.12$ ,  $p = 0.04$ ). There was no significant association between HI and other constructs, but only a marginally significant association ( $p = 0.054$ ) with trust.

Shame negatively predicted compliance and individuals' intentions to report the infection to authorities and positively predicted individuals' intentions to hide the disease from acquaintances/friends. Conversely, stronger guilt was positively associated with individuals' intentions to report the disease

Correlations between variables for the entire sample ( $N = 1896$ ), American ( $N = 597$ ), Italian ( $N = 606$ ), and Korean ( $N = 693$ ) participants are presented in order. Correlations for American and Korean participant are presented in parenthesis. For all scales, higher scores are indicative of more extreme responding in the direction of the construct assessed. HI, horizontal individualism; VI, vertical individualism; HC, horizontal collectivism; VC, vertical collectivism; PD, perceived danger; PO, political orientation; self-reporting, intentions to report contracting the disease to health authorities; hiding, intentions to hide contracting the infection from acquaintances and friends. \*\*\* $p < 0.001$ , \*\* $p < 0.01$ , \* $p < 0.05$ .

to authorities. Finally, stronger trust positively predicted individuals' intentions to report the infection to authorities. However, trust was significantly associated with compliance only in Italy ( $b = 0.06, p < 0.001$ ) and Korea ( $b = 0.13, p < 0.001$ ).

We inspected the indirect effects from the cultural orientations of HI, VI, HC, and VC to the criterion variables via self-conscious emotions and trust. The indirect effects of HC via shame on compliance,  $b = 0.02, SE = 0.01, CI_{95\%} (0.004 \text{ to } 0.03)$ , self-reporting to health authorities,  $b = 0.03, SE = 0.01, CI_{95\%} (0.01 \text{ to } 0.06)$ , and hiding from acquaintances/friends,  $b = -0.07, SE = 0.02, CI_{95\%} (-0.10 \text{ to } -0.03)$  were significant. HC was also indirectly (and negatively) associated with self-reporting via guilt  $b = -0.01, SE = 0.01, CI_{95\%} (-0.02 \text{ to } -0.001)$ . The indirect effects of VC via shame on compliance,  $b = -0.01, SE = 0.003, CI_{95\%} (-0.014 \text{ to } -0.002)$ , self-reporting,  $b = -0.02, SE = 0.01, CI_{95\%} (-0.03 \text{ to } -0.01)$ , and hiding,  $b = 0.04, SE = 0.01, CI_{95\%} (0.02 \text{ to } 0.06)$ , were also significant (and in the opposite directions, compared to HC). There was a positive indirect effect of VC via guilt on self-reporting,  $b = 0.01, SE = 0.01, CI_{95\%} (0.003 \text{ to } 0.03)$ . None of the indirect effects of VI were significant.

Finally, with regard to trust, the indirect effects of HC via trust on compliance was significant in the Italian  $b = 0.02, SE = 0.01, CI_{95\%} (0.01 \text{ to } 0.03)$  and Korean samples,  $b = 0.04, SE = 0.01, CI_{95\%} (0.01 \text{ to } 0.07)$ . The indirect effect of HC on self-reporting via trust was significant only in the Korean sample  $b = 0.04, SE = 0.01, CI_{95\%} (0.01 \text{ to } 0.06)$ . In the United States, the indirect effect of VC on self-reporting via trust was significant,  $b = 0.03, SE = 0.01, CI_{95\%} (0.01 \text{ to } 0.05)$ . Other indirect effects were not statistically significant.

## DISCUSSION

In this research, we investigated how trust in government and self-conscious emotions of shame and guilt explained individuals' compliance with social distancing, and their intentions to report the infection to health authorities or acquaintances/friends. These associations were investigated in three countries characterized by different cultural themes (the United States, Italy, and Korea). In each country, we also measured individuals' cultural orientations. Results indicated the existence of cultural similarities across contexts. Differences mostly emerged with regard to trust.

In all three countries, feelings of shame at the idea of contracting the virus were negatively associated with compliance and individuals' self-reporting intentions. These associations emerged regardless of the overall cultural theme of the country, suggesting that they are stable across cultures. The findings suggest that stigmatizing or blaming individuals for contracting the infection could potentially backfire.

Several recent episodes reported in the news or on social media imply the existence of stigmatizing attitudes toward people who are perceived as flaunting lockdown rules and social distancing norms. For instance, hashtags such as "covidiot" (a portmanteau combining the words "covid-19" and "idiots") are used on Twitter to mock or blame individuals who do not abide by the norms (Reicher and Drury, 2021). Moreover, there are

**TABLE 2** | Latent means and standard errors in the structural equation model.

	United States (SE)	Italy (SE)	South Korea (SE)
Horizontal individualism	5.41 <sup>a</sup> (0.26)	5.09 <sup>a,b</sup> (0.26)	4.62 <sup>b</sup> (0.31)
Horizontal collectivism	4.77 <sup>a</sup> (0.26)	5.87 <sup>b</sup> (0.19)	4.28 <sup>a</sup> (0.25)
Vertical individualism	4.36 <sup>a</sup> (0.28)	3.85 <sup>a,b</sup> (0.24)	3.38 <sup>b</sup> (0.20)
Vertical collectivism	2.11 <sup>a</sup> (0.34)	1.70 <sup>a</sup> (0.29)	3.57 <sup>b</sup> (0.26)
Compliance	4.76 <sup>a</sup> (0.28)	5.82 <sup>b</sup> (0.17)	2.94 <sup>c</sup> (0.29)

Means that do not share a superscript within each row are significantly different at  $p \leq 0.05$ . Means were estimated using the marker method and are therefore interpretable on a 1 to 7 scale.

anecdotal reports of people being attacked, insulted or publicly shamed because they were found walking in the streets during the lockdown. The president of an Italian region even asked for lists of violators to be made public, intending to shame transgressors (Pellegrino, 2020). Such discourses and actions are unlikely to have positive implications for individuals' willingness to abide by the new norms. Instead, feelings of shame could even limit the authorities' ability to trace and test new cases, or acquaintances' and friends' ability to know about potential contacts with infected individuals.

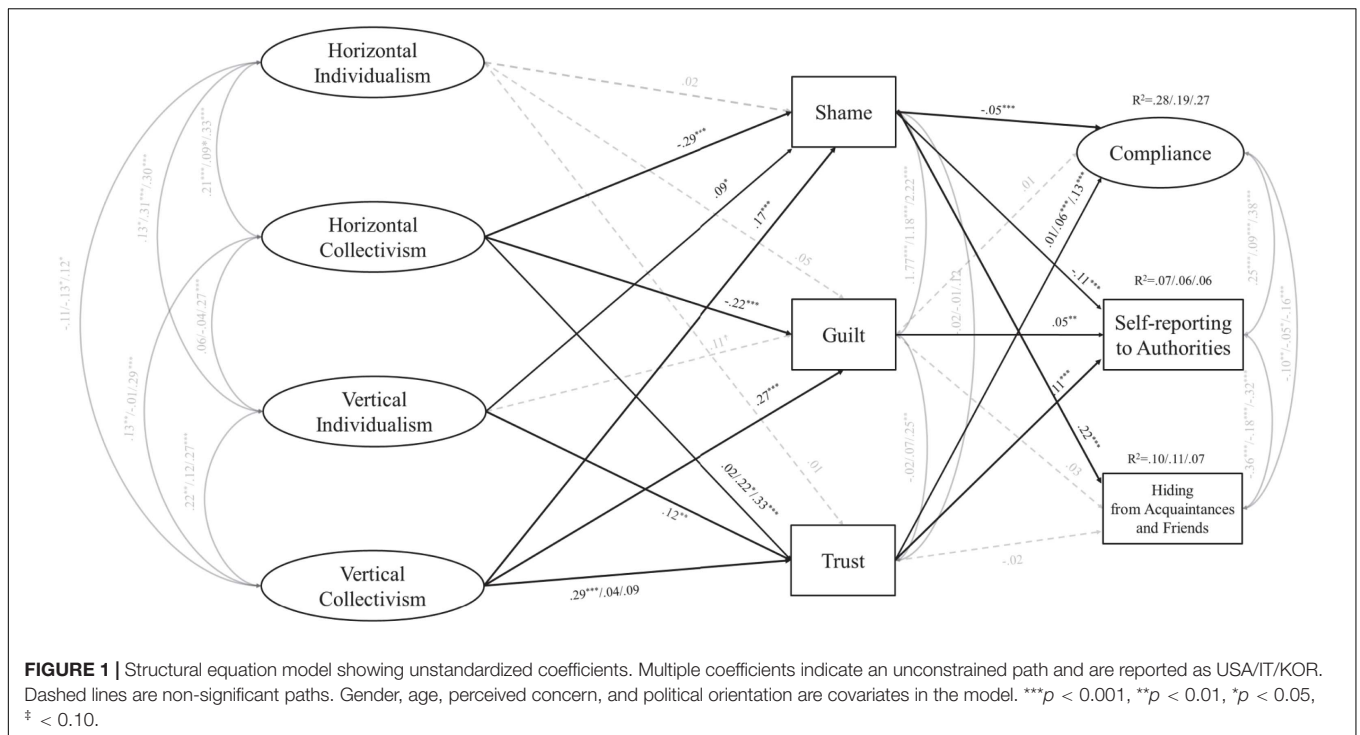

Results about shame were obtained controlling for the effects of guilt. Conversely, the only effect of guilt independent of shame was a positive association between guilt and individuals' intentions to report the infection to authorities. This finding is congruent with previous research suggesting that guilt may foster more constructive responses to transgressions (Tangney and Fischer, 1995). Notably, however, guilt explained less overall variance compared to shame.

Finally, the hypothesized association between trust in government and compliance was statistically significant only in Italy and South Korea. In contrast, the association in the United States was closer to zero and non-statistically significant. Although we controlled for participants' political orientation, this pattern of associations could reflect the political situation in the United States at the time of the study, where the Republican-led central government had been notably slow in its responses to the pandemic, sending out contradictory signals to the public and undermining the experts' recommendations (cf. Mirvis, 2020). Nonetheless, the association between trust and self-reporting did not differ significantly across countries, indicating that individuals who trust the government's handling of the pandemic are more likely to report the infection to authorities.

## Cultural Orientations and Cross-Cultural Comparisons

The pattern of means of the cultural orientations of HI, HC, VI, and VC suggested that overall levels of individualism were higher in the United States than Korea and that the Italian sample fell between these two countries. Whereas Korean participants reported higher levels of VC than other groups, Italian participants reported higher HC levels. Within countries, however, there were strong similarities concerning the role of cultural orientations.

HI, horizontal individualism; HC, horizontal collectivism; VI, vertical individualism; VC, vertical collectivism; self-reporting, intentions to disclose contracting the disease to health authorities; hiding, intentions to hide contracting the disease from acquaintances and friends; =, indicates structural paths constrained to be invariant across groups; \*\*\* $p < 0.001$ , \*\* $p < 0.01$ , \* $p < 0.05$ .

Vertical collectivism (and to a lesser extent VI) was positively associated with individuals' feelings of shame at the thought of contracting the disease. This resulted in a negative indirect effect of VC on compliance and intentions to report the infection to authorities and acquaintances/friends. Conversely, HC was negatively associated with shame. HC may be less conducive to stigma concerning the infection, thus creating a positive indirect effect on compliance and self-reporting intentions. There were also significant associations between VC, HC and guilt. Individuals who endorsed VC were also more likely to report stronger guilt concerning the infection.

Conversely, those who endorsed HC reported lower feelings of guilt. This pattern of associations created contrasting indirect effects of VC and HC on individuals' intentions to report the disease to authorities. Specifically, the indirect effect of HC on self-reporting intentions via guilt was negative, whereas that of VC was positive.

The findings highlight the relevance of individuals' cultural orientations in their responses to the pandemic. Across countries, participants who valued vertical relationships were more likely to perceive stronger self-conscious emotions. Instead, valuing horizontal relationships was associated with weaker

self-conscious emotions. These emotions, in turn, predicted different responses to the disease. Shame was associated with less constructive (from the perspective of the group) responses, whereas guilt was linked to a higher likelihood of reporting the infection to authorities. The values of individualism (whether horizontal or vertical) were overall less relevant, and HI and VI's indirect effects were non-statistically different from zero.

The larger difference across countries concerned the articulation between cultural orientations, trust and individuals' responses to the virus. Research on the association between cultural orientations and trust indicates the existence of a complex and multifaceted relationship among these constructs (e.g., Shin and Park, 2004; Realo and Allik, 2009). Our results indicated that in Italy and South Korea, individuals who endorsed the HC orientations were also more likely to trust the governments. This finding is in line with previous research emphasizing the importance of values of interdependence in predicting generalized trust (Shin and Park, 2004). This finding also highlights the fact that trust in government does not depend only on government performance (Keele, 2007), which likely varied across countries. Rather, our findings highlight the relevance of valuing cohesive relationships for individuals' trust toward the government (Job, 2005). Consistent with this idea, there was an indirect effect of HC on compliance via trust in both Italy and Korea. HC's indirect effect on self-reporting intentions was instead significant only in Korea, a result likely due to the stronger association between HC and trust in this country.

Differently from Italy and South Korea, VC predicted stronger trust in the government in the United States. Trust in government's action was not significantly associated with greater compliance with social distancing norms in that country. At the time of the study, the federal administration had emphasized the importance of loyalty, deference to authority and an "America first" policy. It has also repeatedly signaled its contempt for scientific advice or social distancing norms. For instance, President Trump stated (via social networks) his support for protesters who openly defied lockdown orders in Michigan or elsewhere. This political response might explain why VC values predicted individuals' trust for the government in the United States. Notably, however, the association between VC and trust was significant independently from individuals' political orientation or concern for the spread of the coronavirus within the country, underlining cultural orientations' relevance *vis-à-vis* trust.

## LIMITATIONS, FUTURE DIRECTIONS, AND CONCLUSION

This research is the first to report evidence for the roles of self-conscious emotions and trust in individuals' compliance and self-reporting intentions. We complemented current work on the pandemic by examining the relationships

between cultural orientations and these constructs across three countries (the United States, Italy and South Korea). Nonetheless, the research was affected by some limitations.

First, some constructs in the study, such as trust in the government and self-conscious emotions, were measured with single-item measures. The use of single-item measures offers practical advantages, such as reducing the survey's completion time and minimizing participants' drop-outs. Notably, single-item measures tend to have similar predictive validity to multiple-item measures when they tap constructs that are "singular" and can be "concretely imagined" by participants (Rossiter, 2002; Bergkvist and Rossiter, 2007). However, future research may consider the use of multiple-item measures, which enable researchers to examine the role of different facets of a construct (Churchill, 1979).

Another limitation of this study concerns the fact that some emotions relevant in the context of individuals' reactions to the pandemic were not measured. For example, it is likely that individuals' feelings of fear could play a role in their intentions to comply with social distancing, or report the disease to the authorities (e.g., Harper et al., 2020). Moreover, feelings of disgust may augment the sense of stigma or the stigmatization of those who have contracted the infection (e.g., Herek et al., 2002). A priority for future work is to consider the role of these, and other emotional reactions, in the context of the current pandemic, as well as cross-cultural similarities and differences in people's appraisals of the infection.

Finally, it should be noted that individualism and collectivism are complex "syndromes," encompassing a cluster of different beliefs, norms and practices as well as emphasizing different levels of self-construal (see Brewer and Chen, 2007). Whereas individualism has generally been associated with an independent self-construal, collectivism has been linked to an interdependent self-construal (Markus and Kitayama, 1991). Nonetheless, more recent work highlights that the relationship between individualism-collectivism and self-construal is multifaceted (Vignoles et al., 2006). A given cultural context may foster independence in a particular domain of the self, but interdependence in another domain. Thus, there are multiple different ways of being independent and interdependent. Future research should examine how different configurations of independence and interdependence are associated with trust in government and, indirectly, compliance with social distancing and self-reporting intentions.

To conclude, our findings indicate that attempting to deter people from defying social distancing by blaming or stigmatizing them may negatively impact public health. Results about guilt had slightly more positive implications. However, it is hard to separate feelings of guilt from those of shame, especially in some cultures (Wong and Tsai, 2007). Thus, governments and decision-makers may obtain better results by focusing on the importance of social cohesion and trustworthiness in their attempts to tackle the pandemic and manage public responses.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Psychology Ethics Committee of Leeds Beckett University. The participants provided their informed consent online prior to taking part in this study.

The COVID-19 emergency has hit the whole world, finding all countries unprepared to face it. The first studies focused on the medical aspects, neglecting the psychological dimension of the populations that were forced to face changes in everyday life and in some cases to stay forcedly at home in order to reduce contagion. The present research was carried out in Italy, one of the countries hardest hit by the pandemic. The aim was to analyze the perception of happiness, mental health, and the sense of loneliness experienced by adults during the lockdown due to the COVID pandemic. Specifically, the variables will be examined in relation to gender difference, living alone, with partner, or with partner and children. The research followed a quantitative approach using an online questionnaire. The project involved 1100 subjects from whom 721 participants (75.5% women) were extrapolated. Of them, 17.3% claimed to live alone, 39.5% with their partner, and 43.1% with their partner and children. The results show that people in general experienced a lower level of happiness and mental health and higher levels of loneliness compared to normative sample. The lockdown and pandemic condition due to COVID-19 seems to have canceled the gender differences in the perception of happiness and mental health, while it seems to have increased the perception of loneliness experienced by males compared to the pre-pandemic condition. In addition, those who lived alone perceived a greater level of loneliness than those who lived with their partner or partner and children. Unexpectedly, no significant differences emerged regarding the level of happiness and mental health between those who had direct contact with the virus and those who did not. These data should make political decision-makers reflect on the need to pay more attention to the implications that such drastic measures as a lockdown can have on people's psychological well-being.

**Keywords:** COVID-19, happiness, psychological well-being, loneliness, mental health, gender differences, Italy

## INTRODUCTION

On January 30, 2020, the World Health Organization declared the COVID-19 epidemic a public health emergency of international interest (World Health Organization, 2020a), although this information was not disclosed by the media in the various countries but only after the situation manifested itself in Europe with countless deaths. Many people stayed at home and socially isolated

themselves to prevent being infected, both in China and in other countries or because it was imposed by governments or because individuals considered it the only way to protect themselves. The first signs of the COVID-19 in Italy dated to January 31, 2020, but the first outbreak of infections was detected on February 21, 2020, followed by the first deaths. As a result of the first outbreaks, some municipalities were immediately quarantined and subsequently restrictive measures, progressively more stringent, were extended to the entire country, not allowing the population to leave their homes if not strictly necessary and blocking all activities not related to food production. Despite these measures, Italy appears to be the third country in the world for number of positive cases and the second in the world for number of deaths (European Centre for Disease Prevention and Control, 2020). In this scenario, the management of the coronavirus epidemic (COVID-19) by the Italian government, with highly restrictive measures compared to other countries, has made it impossible for the population to continue leading a normal life. Alongside the very strong media attention linked to physical and behavioral restrictions, the government failed to consider the psychological and social aspects that such decisions could have on the population. The government task force also focused on the medical and health aspects as did the international and national scientific literature in the first articles published in the early months of 2020 on the COVID-19 pandemic (COVID Contents n. 1 of 9 April 2020; Istituto Superiore di Sanità [ISS], 2020a, COVID Contents n. 2 of 16 April, 2020, Istituto Superiore di Sanità [ISS], 2020b Study Group COVID-19, Contents n. 1 of 9 April, 2020).

## Mental Health and COVID-19

Mental well-being has been conceptualized in various ways highlighting the multidimensionality of the concept. Diener et al. (1999) depicted subjective well-being as consisting of cognitive (judgment about one's life satisfaction) and affective (balance between positive and negative emotions) aspects. Seligman (2011), on the other hand, introduced a model where psychological well-being encompassed the following domains: positive emotions, engagement, relationships, meaning, and accomplishment. Furthermore, several definitions of mental health have been given over the years: Galderisi et al. (2015) underline how first it was described only as the absence of mental illness and later as a state of well-being that allows the individual to cope with stressful life events, to carry out work in a productive way, and to make a contribution to their own community (World Health Organization, 2004). However, the authors, underlining the possible misunderstandings that could have arisen from this definition, proposed a further one: "Mental health is a dynamic state of internal equilibrium which enables individuals to use their abilities in harmony with universal values of society. Basic cognitive and social skills; ability to recognize, express, and modulate one's own emotions, as well as empathize with others; flexibility and ability to cope with adverse life events and function in social roles; and harmonious relationship between body and mind represent important components of mental health which contribute, to varying degrees, to the state of internal equilibrium" (Galderisi et al., 2015, pp. 231–232). Other

authors argue that mental health is an ambiguous concept (Van Droogenbroeck et al., 2018), one of the basic components in the broader dimension of an individual's general health and therefore difficult to define (Kvrgic et al., 2013). Mental health, in fact, is part integral to health and well-being and can be influenced by several interacting psycho-social, biological, and demographic factors (such as sex, age, and family environment; World Health Organization, 2001; Kvrgic et al., 2013).

Focusing on mental health is of fundamental importance when entire nations are facing catastrophic events, such as the recent one caused by COVID-19, which can compromise the mental health of citizens. However, it is not the first time that entire nations have faced a catastrophic situation due to an uncontrollable medical condition, with repercussions on the economic, political, social, and individual systems. In fact, think of the 2003 epidemic caused by Severe Acute Respiratory Syndrome (SARS) or even the most recent swine flu of 2009. In these cases, the literature had mainly focused on the psychological implications suffered by the patients directly involved and by the medical and healthcare personnel working on the front line: the emotional reactions experienced by those who during the SARS epidemic worked closely with the disease were extremely intense and included fear of contagion, feelings of stigma, loneliness, boredom, anger, anxiety, stress, and a sense of uncertainty (Maunder et al., 2003; Al-Rabiaah et al., 2020). Chua et al. (2004) also found that during the 2003 outbreak, stress levels were high in both patients and healthy participants, indicating that the whole community had been affected regardless of the educational level. Patients also reported feelings of loneliness and boredom caused by prolonged quarantine (Chua et al., 2004) and a high prevalence of psychological distress (Hawryluck et al., 2004).

In relation to the COVID-19 pandemic, most of the research initially focused mainly on the medical aspects, in particular on identifying the epidemiology and clinical characteristics of infected patients (Chen, 2020), on the genomic characterization of the virus (Lu, 2020), on comorbidity with other diseases such as cardiovascular and diabetes mellitus (Kuno et al., 2020), and on the global health challenges (Rubin and Wessely, 2020). Other areas of investigation have focused on the pathology's symptoms associated with acute respiratory distress syndrome (Xu et al., 2020) or the symptoms of posttraumatic stress disorder in patients with stable COVID-19, highlighting how many of these patients suffer from significant PTSD symptoms at the time of discharge with possible negative consequences on their quality of life and work performance.

These data highlight the need for appropriate psychological interventions especially for stabilized COVID-19 patients (Duan and Zhu, 2020). In this regard, online mental health services have been organized in the Chinese context to intercept the psychological needs of the population, who had COVID-19 but also in general, in order to improve the quality and effectiveness of the emergency interventions (Liu S. et al., 2020).

Furthermore, particular attention should be paid to the psychological problems of those who work not only in the front line in the COVID-19 emergency, for example, medical personnel and nurses but also to the population in general, given that vicar traumatization scores of the general population were found to

be significantly higher than those of nurses on the front line (Li et al., 2020).

During the COVID-19 pandemic, the attention was also focused on the psychological repercussions that this situation could cause in healthcare workers especially in stress management (Greenberg et al., 2020; Joob and Wiwanitkit, 2020) caused by the work overload, frustration, and being faced with very difficult choices on a daily basis. It is therefore essential to take into consideration the psychological health of healthcare professionals to prevent the onset of possible issues not only during the critical stages of the epidemic but also in the following ones, to prevent long-term consequences. The mental health of health workers is indeed essential to better controlling infectious diseases and better responding to future unexpected infectious diseases (Chen et al., 2020). As highlighted by Zowalaty and Järhult (2020), the success in containing the COVID-19 pandemic will depend on the ability of the various countries to adopt public health measures capable of identifying clinical cases, to implement a rigorous control of infections in healthcare facilities, to isolate patients, and to be able to contain the spread of the virus in the community and in public education contexts.

Still few research studies have examined the psychological impact of COVID-19 on the general population within the first weeks of the COVID-19 outbreak and related lockdown. The first data have shown symptoms of anxiety, sleep disorders, depression, lower mental well-being, and psychological distress in the general population and the importance of monitoring these dimensions (Ahmed et al., 2020; Brooks et al., 2020; Casagrande et al., 2020; Ko et al., 2020; Moccia et al., 2020; Tian et al., 2020; Wang C. et al., 2020; Wang Y. et al., 2020; Yang and Ma, 2020). Ahmed et al. (2020) also highlighted how the confinement in their homes, due to the COVID-19 epidemic, led to higher levels of anxiety, depression, and a lower level of mental well-being. In Italy, attention has been focused in particular on specific groups such as university students (Capone et al., 2020) and families (Centro di Ateneo Studi e Ricerche sulla Famiglia, Università Cattolica del Sacro Cuore, 2020; Ferrario and Profeta, 2020; Lagomarsino et al., 2020; Libellula Foundation, 2020), and in a few cases on the general population (Ferrucci et al., 2020; Pakenham et al., 2020).

## Emotions and Mental Health

Emotions are fundamental components of the life of human beings from which people draw the stimuli that activate their daily activities. However, even if every emotion is important, the search for positive sensations such as happiness affords an emotional state of well-being and a general realization. The research on happiness conducted in recent years (Luhmann et al., 2012) follows two approaches: studies on eudaimonic well-being, which focuses on psychological well-being, and those on hedonic well-being, which focus on subjective well-being (Ryff and Keyes, 1995). According to Diener et al. (1999), happiness can be considered a dimension of the complex and multidimensional concept of psychological well-being. Among the different notions of happiness presented in the literature, Lyubomirsky et al. (2005) define it as the shortest way to refer to the experiences of frequent

positive emotions. Their review also shows how happiness is positively correlated with health indicators, both mental and physical; this could be due to the fact that it has effects on social relationships, on coping skills (Lyubomirsky et al., 2005; Piqueras et al., 2011), and on stress (Lyubomirsky et al., 2005; Heizomi et al., 2015). Furthermore, happiness and depression are considered two dimensions of the complex and multidimensional concept of well-being (Diener et al., 1999).

Considering emotional well-being during quarantine can be important for understanding the impact that this situation has on the general well-being of people. The ongoing COVID-19 epidemic is generating negative emotions like fear as already argued by Khalid et al. (2016), above all with regard to the emotions of healthcare workers during a Middle East Respiratory Syndrome-Coronavirus outbreak, but also recently underlined by Horton (2020), who proposed “A desperate plea from an ordinary citizen in China.” Furthermore, both studies on previous and current pandemics have highlighted how the epidemic situation has a negative impact on the dimension of happiness (Yip et al., 2010; Yang and Ma, 2020). As pointed out by Wang C. et al. (2020), previous research has revealed multiple psychosocial impacts both on an individual level such as fear of getting sick or dying (Hall and Chapman, 2008) or the negative emotions experienced by individuals following the closure of schools and businesses (Van Bortel, 2016), but also the psychological impacts on the uninfected population, revealing significant psychiatric morbidity (Sim et al., 2010). Furthermore, Cipolletta and Ortu (2020) underline how COVID-19 emergency suspended time, causing uncertainty and anxiety, both for the future and for the coronavirus (“coronaphobia”; Asmundson and Taylor, 2020), which can be reduced making meaning to the events. Moreover, Yang and Ma (2020) found how the outbreak of the epidemic influenced people’s emotional well-being, identifying some factors that can further affect it, such as the probability of contracting a disease and developing relationship problems, while the perception of greater knowledge of the epidemic increases the sense of control, thus becoming a protective factor for emotional well-being.

## Loneliness and Mental Health

Among the relevant risk factors of depression, there is the dimension of loneliness; therefore, happiness and loneliness can be considered two components of individual subjective well-being capable of defining depressive risk conditions (Cacioppo et al., 2006) as well as mental health. In the literature, several authors have been interested in the concept of loneliness, and Henriksen et al. (2019) considered loneliness a very common condition in Western communities. In the past, it has been defined as a complex set of feelings that include reactions to the absence of intimate and social needs (Ernst and Cacioppo, 1999), a problem for society (Cacioppo and Cacioppo, 2018) as well as for the individual, which may have serious health consequences (Luanaigh and Lawlor, 2008; Henriksen et al., 2019). Hyland et al. (2019) argue that loneliness has traditionally been presented as a one-dimensional concept, when in reality it is a multidimensional construct (Cacioppo et al., 2015; Hyland et al., 2019). In particular, some authors (Hawkey et al., 2005, 2012;

Cacioppo et al., 2015) present loneliness as a construct that includes three connected dimensions: intimate loneliness, relational loneliness, and collective loneliness. Hyland et al. (2019), instead, present loneliness as a construct defined by four quantitatively and qualitatively differentiated classes: low, social, emotional, and “social and emotional.” Their study also revealed that the perceived quality, rather than quantity, of interpersonal connections was associated with poor mental health. In fact, as pointed out by Cacioppo and Patrick (2008) and Cacioppo et al. (2015), the construct of loneliness clearly highlights how the human species needs significant others, people to trust, and with whom to plan life. Finally, some authors have found that loneliness is a risk factor for the development of depressive symptoms and is negatively associated with life satisfaction and positive affect (Cacioppo et al., 2010; Chang et al., 2020). It follows that exploring these constructs, still little investigated in the literature on pandemics, is very important. Some authors have found (Porcelli, 2020; Tull et al., 2020) that compulsion at home during the COVID-19 lockdown was associated with greater stress, social isolation, loneliness, and anxiety about their health and the economic aspects.

## Gender Differences During the COVID-19 Pandemic

In relation to mental health, the literature confirms sharp differences between the genders. It is a constant in the literature that women reported worse mental health outcomes (Kvrgic et al., 2013; Giorgi et al., 2014; Van Droogenbroeck et al., 2018). Even during the period of the COVID-19 pandemic, the first data collected by the researchers highlight this trend (Casagrande et al., 2020; Wang C. et al., 2020; Wang Y. et al., 2020).

Furthermore, from the first studies on the psychological effects due to COVID-19, it was found that women were more affected by this situation, manifesting more negative alterations in cognition or mood and hyperarousal than males (Liu N. et al., 2020).

Moreover, also with regard to loneliness, there are gender differences in the literature. Some studies show a higher prevalence of loneliness among women (Pinquart and Sorensen, 2003; Henriksen et al., 2019). Hyland et al. (2019) emphasize that males, mirroring women, show higher social loneliness and less emotional loneliness. In fact, women tended to fall more into the emotional loneliness class, while no differences emerged in relation to “social loneliness.”

Research has shown that, in particular, during the COVID-19 epidemic, women were most exposed to stress and depressive symptoms (Casagrande et al., 2020; Wang C. et al., 2020; Wang Y. et al., 2020), while, in some cases, being men has been associated with to be a protective factor against the risk of mild psychological distress in response to stressful events (Moccia et al., 2020). Even a month after the first cases, it was found that women showed symptoms of posttraumatic stress disorder, to a greater extent than men, in terms of the negative alternation of mood and cognition and hyperarousal (Liu N. et al., 2020). Unlike other studies, Ahmed et al. (2020), despite having identified higher

levels of anxiety and depression and a lower level of mental well-being in the population, did not, however, find gender-related differences.

Therefore, in the light of this situation, a timely understanding of mental health status, an aspect surprisingly overlooked, is urgently needed for society. As can be seen from the analysis of the current literature, little is known about the psychological impact, mental health and well-being of the general population, and the related gender differences at the peak of the COVID-19 epidemic worldwide, while this is one of the first Italian studies to have focused on the population in general to understand the effects of the lockdown.

## AIMS OF THE CURRENT STUDY

Considering this theoretical and contextual framework, the present study aims to investigate psychological well-being in relation to some social dimensions during the initial quarantine period that the Italian population had to cope with. In particular, the research objective is to analyze the perception of happiness, mental health, and the sense of loneliness experienced by the adult Italian population during this period. Specifically, the variables will be examined in relation to gender differences, living alone, living with partner, living with partner and children, or having family members or friends who had COVID-19. Furthermore, we want to investigate the relationships between the variables considered and the dimensions that affect well-being and loneliness.

## MATERIALS AND METHODS

This study is part of a larger multidisciplinary, anonymous online survey; only some specific variables concerning the psychological field and related to the proposed objectives will be presented here. The research design is longitudinal, and in this paper, present data relating to first lockdown in Italy started on March 11th, 2020, with Dpcm #IoRestoaCasa (#IStayatHome). The survey was carried out over a 10-day period, after the first 2 weeks of lockdown, from March 25th to April 4th, 2020. This situation forced most of the population not to work or to engage in smart working and students not to attend face-to-face lessons and to follow lessons via distance learning. The methodology used is quantitative, and the protocol is based on previous studies on the psychological impacts of SARS and influenza outbreaks (Rubin et al., 2010; Park et al., 2018; Al-Rabiaah et al., 2020), as well as on the few studies that had already been published in the psychological field relating to the COVID-19 pandemic in early March 2020 (Liu S. et al., 2020; Rajkumar, 2020; Wang C. et al., 2020). Furthermore, general health, as seen from the analysis of the literature, is a composite construct and, as several authors point out happiness and loneliness are two components of individual subjective well-being. Therefore, taking into account these considerations, in order to measure psychological well-being, a protocol was prepared that included the following scales widely used in the literature and specific questions related to the COVID-19 outbreak.

## Measures

- **Subjective Happiness Scale (SHS)** measures the subjective global happiness, developed by Lyubomirsky and Lepper (1999), and in this study, we used the Italian version by Iani et al. (2013). The scale is made up of four items (e.g., “Some people are generally not happy. They enjoy life regardless of what happens and take the best of everything. How much does this phrase describe it?”) with a Likert response scale, from 1 = *not at all* to 7 = *very much*. The total score ranges from 4 to 28 points; higher scores indicate higher levels of happiness. The scale showed a good internal consistency ( $\alpha = 0.58$ ).
- **General Health Questionnaire (GHQ-12;** Goldberg and Williams, 1988; Italian version Piccinelli and Politi, 1993) consists of 12 items that assess the severity of a mental problem over the past few weeks. Participants have to report whether they have experienced a particular symptom of mental distress on a four-point Likert-type scale from 0 = *less than usual* to 3 = *much more than usual*. The six positive items were corrected from 0 (much more than usual) to 3 (less than usual) and the six negative ones from 3 (much more than usual) to 0 (less than usual). The total score ranges from 0 to 36 points; higher scores indicate worse health. The scale showed a good internal consistency ( $\alpha = 0.83$ ). GHQ-12 is widely used for mental health trend analysis for its ease of use, breadth of distribution, and capacity to reproduce “remarkably robust” results contrasted with longer initial versions (Griffith and Jones, 2019).
- **Loneliness Scale:** we used the Three-Item Loneliness Scale developed by Hughes et al. (2004) from the revised UCLA Loneliness Scale (Russell et al., 1980), Italian version of the revised UCLA Loneliness Scale (Solano and Coda, 1994). It is a short scale for measuring loneliness in large surveys, and it assesses feelings of isolation, disconnectedness, and not belonging. Respondents are placed on a three-point Likert scale from 1 = *hardly ever* to 3 = *often*, with a total score ranging from 3 to 9 points; higher scores indicate greater loneliness. The three-item scale showed a good internal consistency ( $\alpha = 0.60$ ).
- Compilation of a socio-demographic datasheet which included age, gender, education, type of work during the COVID-19 health emergency, size of the home, income, with whom the subject lives during the COVID-19 health emergency, and having family members or friends who had COVID-19.

## Procedure

The online study was promoted through email, WhatsApp, discussion forums, and social networks such as Facebook. The call to the study, with indications of the purpose of the study, the tools proposed, and the type of restitution, included a link to access the questionnaire. Before filling out the questionnaire, subjects had to read the informed consent, declare to agree, to be of age, to have understood that participation was voluntary, and that they could withdraw at any time by closing the browser

window. The convenience sample was recruited through random cascade sampling, starting from some subjects known by the research team. The research, therefore, is characterized by its exploratory nature which does not aim to return a representative image of the Italian population but propose a picture of the perceptions of the population during the lockdown in relation to their psychological well-being. It took an average about of 22 min for each participant to fill out the survey.

The data were collected in compliance with the privacy and research ethics code of the Italian Association of Psychology, after the protocol was approved by the Ethics Committee of the Department of Education Sciences of the University of Genoa.

## Data Analysis

Descriptive statistics were calculated for sociodemographic characteristics and information about variables, and the SHS, GHQ, and UCLA scores were expressed as mean and standard deviation. To investigate the gender differences in relation to SHS, GHQ-12, and UCLA, *t*-tests were used for independent samples. Also, to investigate differences between those who had or did not have family members or friends with COVID-19 in relation to SHS, GHQ-12, and UCLA, *t*-tests were used for independent samples. To compare the differences between our participants and the Italian normative sample for SHS (Iani et al., 2013), GHQ (Giorgi et al., 2014), and UCLA (Caputo, 2017), *t*-tests were conducted for single samples. The Italian samples to which reference was made to perform *t*-tests were chosen on the basis of the socio-demographic characteristics of the participants (gender, age, and non-clinical sample), who took part in the research carried out prior to the COVID-19 [Iani et al. (2013) for SHS, Giorgi et al. (2014) for GHQ-12, and Caputo (2017) for UCLA]. The characteristics were similar to those possessed by the participants in our research. While ANOVA was used to investigate the differences between groups (I live alone, I live with my partner, and I live with my partner and children or people), with *post hoc* Tukey (for homogeneous variances) between group comparisons in case of a significant overall *F*-value. Appropriate effect size statistics that adjust for differences in group sizes were obtained of Cohen's *d* for *t*-tests and  $\eta^2_p$  for ANOVAs.

To explore the relationship between the SHS, GHQ, and UCLA scales, correlation analyses were performed. We used multiple linear regressions to calculate the univariate associations between sociodemographic characteristics, and SHS, GHQ, and UCLA scales. Statistical analysis was performed using SPSS Statistic 18.0.

## Participants

Overall, the sample comprised 1100 participants, distributed throughout the national territory, from whom 721 subjects who claimed to live alone (17.3%), with partner (39.5%), or with partner and children (43.1%) were extrapolated. The majority of respondents were women (75.5%), with an average age of 49.48 years (SD = 12.71, range 22–81), while men had an average age of 52.32 years (SD = 12.85, range 26–83). In **Table 1**, socio-demographic variables of our sample are reported.

**TABLE 1** | Sociodemographic characteristics of the participants ( $N = 721$ ).

Category variables	%
<i>Gender</i>	
Male	24,5
Female	75,5
<i>Marital status</i>	
Unmarried	15,1
Married/cohabiting	74,3
Separate/divorced	8,2
Widower	2,4
<i>People with the subject lives</i>	
Alone	17,3
With partner	39,5
With partner and children	43,1
<i>Educational qualification</i>	
Junior high school	3,4
Secondary school	34,1
Graduation	42,6
Postgraduate specialization	20,0
<i>Work arrangements during COVID-19</i>	
Unchanged	24,5
Smart-working	57,0
Loss of job/work permit/leave	18,5
<i>Household income</i>	
Up to 15,000 euros	11,9
Between 15,001 and 28,000 euros	30,1
Between 28,001 and 55,000 euros	37,3
Between 55,001 and 75,000 euros	11,6
Over 75,000 euros	9,1
<i>Contact with COVID-19</i>	
Subjects that have had some contact with COVID-19	62,8
Subjects that have had COVID-19	6,7
Subjects that have had relatives or friends with COVID-19	27,2
Subjects that believe they or that relatives and friends had COVID-19	24,8
Subjects knew people close to them who did not survive COVID-19	19,8

Over half of the sample came into contact with COVID-19 (62.8%), of whom 6.7% had it directly, 27.2% had relatives and friends, 24.8% believed they had it, or that relatives and friends had it, but they were not sure because no swab tests were done, and 19.8% knew people close to them who did not survive COVID-19.

## RESULTS

The descriptive statistics of each variable used to measure the psychological well-being impact are presented in **Table 2**. It included mean and standard deviation in relation to gender and the categorical variable “people with the subject lives.”

The SHS revealed a mean score above the theoretical average, with average scores practically equal between males and females. The respondents’ mental health levels, measured using the GHQ, revealed mean scores near the theoretical average for both males and females with slightly higher malaise scores for females. For the Loneliness scale (UCLA), participants had a mean score near the theoretical mean score.

Specific analyses on gender differences did not show statistically significant differences for either SHS or GHQ scale, while for UCLA scale, significant gender differences emerged, with women showing significantly higher mean scores ( $M = 5.67$ ;  $DS = 1.97$ ) than the males of the sample ( $M = 5.23$ ;  $DS = 1.70$ ) [ $t(319.9) = -2.73$ ,  $p < 0.05$ , Cohen’s  $d = 0.24$ ]. Furthermore, there were no significant differences in the variables considered between those who had direct contact with the COVID-19 (themselves, relatives, or friends) and those who did not.

Also, as regards living alone, with partner, and with partner and children, in all three scales considered, the scores were always close to the theoretical averages. Furthermore, no significant differences emerged in SHS and GHQ regarding the variable “People with the subject lives”; significant differences emerged instead for UCLA. In fact, there was a significant difference between those living alone and those living with partner or with partner and child in the level of loneliness,  $F(2,681) = 3.83$ ,  $p < 0.05$ , and  $\eta^2_p = 0.011$ . *Post hoc* testing revealed a significant difference between those living with partner ( $M = 5.50$ ,  $SD = 1.87$ ) and who live with partner and children ( $M = 5.43$ ,  $SD = 1.85$ ) having a lower level of loneliness than those living alone ( $M = 5.98$ ,  $SD = 2.11$ ). These finding indicated that there was a higher level of loneliness among those living alone than those living with partner or with partner and children.

Moreover, comparing the SHS data of the participants with those obtained on the Italian validation scale (Iani et al., 2013), the analysis of the means for a single sample showed that our participants presented significantly lower average happiness scores, measured in relation to the COVID-19 emergency (**Table 3**).

**TABLE 2** | Descriptive statistics of variables of the sample ( $N = 721$ ).

Sociodemographic variables	Subjective happiness SHS		Mental health GHQ-12		Loneliness UCLA				
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>t(df)/F</i>	<i>p</i>	Cohen’s <i>d</i> / $\eta^2_p$
<i>Gender</i>							-2.73 (672)	0.007	0.24
Male	4.51	0.85	17.51	5.63	5.23	1.70			
Female	4.44	0.92	18.23	6.13	5.67	1.97			
<i>People with the subject lives</i>							3.83	0.022	0.011
Alone	4.42	0.85	17.29	6.24	5.98	2.19			
With partner	4.45	0.98	18.20	5.64	5.50	1.87			
With partner and children	4.47	0.91	18.12	6.21	5.43	1.85			

**TABLE 3 |** Subjective Happiness Scale (SHS) comparison between the average values of the participants and the average values of the Italian normative sample.

	SHS				
	Participants	Italian normative sample	t (df)	p	Cohen's d
	M (SD)	M (SD)			
Male	4.51 (0.85)	4.74 (1.22)	-3,414 (166)	0.001	0.22
Female	4.44 (0.92)	4.80 (1.21)	-8,791 (500)	0.000	0.33

As regards the GHQ scale, respondents scored significantly higher than the Italian normative sample (Giorgi et al., 2014) indicating a “worse degree” of mental well-being (Table 4).

The scores on the UCLA scale (Table 5), on the other hand, compared with the Italian normative sample (Caputo, 2017) showed significant differences only in males, who obtained higher loneliness scores than the normative sample, while the females, though having slightly higher scores than the males, did not present differences with the normative sample considered.

A next level of analysis was the correlations between the constructs considered in the study. All the constructs considered correlate with each other. There was a moderate positive correlation between GHQ scale and UCLA scale ( $r = 0.32, p = 0.01$ ), while there was a moderate negative correlation between SHS and GHQ scale ( $r = -0.40, p = 0.01$ ) and SHS and UCLA scale ( $r = -0.32, p = 0.01$ ).

Based on the main correlations highlighted, further investigation highlighted the factors affecting mental health, happiness, and loneliness. The stepwise model selection in multiple linear regression analysis, which considered GHQ scale as a dependent variable, is presented in Table 6.

The model had an  $R^2 = 0.20$ , which means that 20% of the variance in the GHQ scale is explained by the model. The  $R^2$  value was statistically significant. SHS seems to be the biggest predictor

**TABLE 4 |** Mental health comparison between the average values of the participants and the average values of the Italian normative sample.

	GHQ-12				
	Participants	Italian normative sample	t (df)	p	Cohen's d
	M (SD)	M (SD)			
Male	17.51 (5.63)	9.8 (4.9)	17,633 (165)	0.000	1.47
Female	18.23 (6.13)	11.1 (5.7)	25,647 (485)	0.000	1.20

**TABLE 5 |** Loneliness Scale: comparison between the average values of the participants and the average values of the Italian normative sample.

	UCLA				
	Participants	Italian normative sample	t (df)	p	Cohen's d
	M (SD)	M (SD)			
Male	5.23 (1.71)	4.94 (1.92)	2.002 (165)	0.047	0.14
Female	5.68 (1.97)	5.58 (2.08)		NS	

( $\beta = -0.31, p < 0.001$ ), while UCLA ( $\beta = 0.21, p < 0.001$ ) and the size of the home ( $\beta = 0.12, p < 0.05$ ) were moderate predictors.

Table 7 presents the stepwise model selection in multiple linear regression analysis, in which SHS was used as a dependent variable.

The model had an  $R^2 = 0.23$ , which means that 23% of the variance in SHS is explained by the model. The  $R^2$  value was statistically significant. The GHQ scale seemed to be the biggest predictor ( $\beta = -0.36, p < 0.001$ ), while UCLA scale ( $\beta = -0.23, p < 0.001$ ) seemed to be moderate predictors.

Table 8 presents the stepwise model selection in multiple linear regression analysis, in which the UCLA scale was used as a dependent variable.

The model had an  $R^2 = 0.16$ , which means that 16% of the variance in the UCLA scale is explained by the model. The  $R^2$  value was statistically significant. SHS seemed to be the biggest predictor ( $\beta = -0.23, p < 0.001$ ), while GHQ scale ( $\beta = 0.23, p < 0.001$ ) with People with the subject lives ( $\beta = -0.13, p < 0.05$ ), and the qualification ( $\beta = -0.11, p < 0.05$ ) were moderate predictors.

## DISCUSSION

Italy has been hit by a sudden traumatic situation linked to the COVID-19 pandemic that has led the population to a forced lockdown. This situation, as shown by the data of the present study, had a significant psychological impact on its inhabitants.

The data underline how this event has canceled gender differences in the perception of happiness (SHS) and mental health (GHQ-12). In these variables, women usually have a significantly lower score than men. The data, however, show that men and women had similar and significantly lower scores than the pre-pandemic condition; as far as subjective happiness

**TABLE 6 |** Regression model: Mental Health (GHQ) as dependent variable.

Variables	B	SE	Beta	t	R <sup>2</sup>
SHS	-2.110	0.354	-0.314	-5.968	0.195
UCLA	0.640	0.162	0.208	3.955	
Home	-1.409	0.607	-0.116	-2.321	

**TABLE 7 |** Regression model: Happiness (SHS) as dependent variable.

is concerned, the emotional well-being (Iani et al., 2013) scores were significantly higher than mental health (Giorgi et al., 2014), highlighting a worsening of the mental psychological component. These data are also confirmed by recent literature which highlights how the epidemic that has hit the whole world has a negative impact on the perception of happiness (Yang and Ma, 2020) and on mental health in general (Ahmed et al., 2020). Unlike what could be expected, however, no significant differences emerged regarding the level of happiness and mental health between those who had direct contact with the virus and those who did not have it, as if the pandemic condition was so pervasive as to make everyone more vulnerable regardless of whether they are personally affected or not. As regards, however, the data relating to the dimension of loneliness showed significantly higher scores for women than for males. Although comparing our data with the normative sample, significant differences emerge only for males who scored significantly higher than the pre-pandemic condition, as if compulsion at home had increased the perception of loneliness more in men than in women. In practice, the perception of loneliness of women that is normally higher than men did not change during the pandemic compared to the pre-pandemic condition. The male gender therefore seems to have worsened this dimension by perceiving more the dimension of loneliness due to forced isolation at home. These data could be interpreted by the fact that men are probably less used to spending time in the house as opposed to women who are more used to living the domestic dimension. This reflection is supported by the literature (Carriero and Todesco, 2016) which highlights how Italian women are more dedicated to caring for the home, even during the pandemic period (Rania et al., 2020), while men are more used to carrying out activities outdoors. Although technologies, like Facebook and other social networks, have certainly contributed to making people feel more connected, contrasting the feelings of loneliness as highlighted by some recent works (Cho, 2015; Knausenberger and Echterhoff, 2018), the data showed that those who lived alone perceived greater loneliness than those who lived with partner or with partner and children. This can be explained by the fact that those who lived alone had a more intense perception of the lack of social contacts, caused by compulsion at home. In fact, as Tull et al. (2020) argue, the reduction of contacts due to the emergency leads to increased feelings of loneliness and social isolation.

The variables considered are all related to each other, highlighting that with the decrease in happiness, due to the situation experienced by people in this period, a worse perception of mental health increases. The GHQ, in fact, evaluates both the perception of anxiety and depression and the well-being and social functioning dimensions that were both put in crisis by the forced lockdown. Furthermore, there are also positive relationships between the perception of loneliness and mental malaise and negative relationships between loneliness and happiness as also found in the literature (Cacioppo et al., 2010; Lee et al., 2019; Chang et al., 2020).

In support of these results, the regression analyses highlighted the dimensions that influence the perception of mental health in the lockdown period. The lower level of happiness and the greater perceived loneliness as well as the size of the home had

effects on the participants' perception of mental health. In fact, Yang and Ma (2020) found that sharing a limited space for long periods of time could have had an impact on a couple's relationship, and therefore on psychological well-being. On the other hand, regarding the construct of loneliness, the predictors are happiness, mental health, the persons with the subject lives, and education. Obviously living alone makes you perceive the condition of loneliness more in a period in which compulsion at home does not allow you to experience external relations. Indeed, Killgore et al. (2020) found that having to stay home because of the pandemic has a negative impact on the perception of loneliness and social disconnection. Porcelli (2020) also found that loneliness combined with anxiety and fear is one of the most dangerous consequences of the condition of social isolation that has been forced on us for a very long period. The variable education also affects the level of loneliness. This figure is in line with the literature which highlights how low levels of education can lead to a significantly higher level of psychological symptoms (Tian et al., 2020).

These data must make researchers, policymakers, and psychologists working in the field reflect on the fact that the data were collected 2 weeks after the lockdown and for the next 10 days, and therefore it is presumable that with the passing of the lockdown, this perception of malaise could also be accentuated.

## IMPLICATIONS FOR PRACTICE

These data should be brought to the attention of political decision-makers: although it is true that the medical health dimension remains a particularly relevant and essential aspect, it nevertheless seems appropriate to also take into account the dimension of psychological well-being of the population, which at this moment appears to be particularly strained. Considering that these data were collected in the first quarantine period, it would be appropriate to collect further data at a later date given the prolonged situation in order to track the trend of the psychological variables severely tested by the lockdown period and by the climate of medical and economic uncertainty being faced.

Therefore, it is important to monitor the progress of these psychological dimensions to intercept any alarm signal for both the population affected by COVID-19 as highlighted in the literature (Bo et al., 2020), both for the general population and to prevent long-term consequences.

We therefore believe that our data could be useful for hypothesizing future and diversified interventions to be applied in situations comparable to the current one: considering the psychological dimension of the subjects from the outset could allow participants to more effectively face mandatory lockdown at home and to feel more involved in political decisions and not to experience them as impositions. This is especially important since it is very likely that there may be a resurgence of this virus as has already happened in the past with similar viruses (Pathan et al., 2020). As highlighted by Yang et al. (2020), the lessons learned during the SARS epidemic and now during the SARS-CoV-2 pandemic may provide elements of reflection and help build a

response capacity for future situations in order to be ready for future epidemics. Moreover, at the moment, there is no scientific evidence that people who have had COVID-19 have developed antibodies and are therefore protected from reinfection (World Health Organization, 2020b). Therefore, a possible resurgence of the virus cannot be excluded, also linked to the failure to reach herd immunity, as sustained in some countries.

This research has some limitations. In fact, it can be easily seen from the sociodemographic data that most of the participants have a high level of education, which is not very representative of the general population even if the questionnaire was distributed through various social networks accessible to all groups of the population. Therefore, another limit can be linked to the online administration of the tool used, which despite the researchers' efforts could have influenced the involvement of some target populations. However, due to the contextual situation that involved forced physical distancing, the online questionnaire method seemed the only possible strategy to reach a large number of subjects and has already been used by other researchers in relation to the COVID-19 epidemic (Wang Y. et al., 2020). Finally, another limit is represented by the gender of the participants; in fact, although the data emerged regarding the gender difference are interesting, it should be emphasized that 75.5% of the participants are female.

Nonetheless, the data have revealed interesting aspects to consider in order to face with greater awareness critical situations and forced quarantine due to new waves of COVID-19 or future viruses (Yang et al., 2020). Despite the weaknesses highlighted, the study's strengths include the fact that it is one of the first carried out on the lockdown period linked to the COVID-19 pandemic in Italy that aims to investigate the psychological dimensions of individual well-being.

- Although the quarantine measures adopted in several countries have reduced deaths, the impacts of the COVID-19 pandemic are not limited only to the medical aspects, but its sociological, psychological, and economic effects at a global level will have repercussions not only in the immediate short term but also in the following months. Therefore, the longitudinal approach of our study is undoubtedly a strength that will allow us to monitor the well-being and mental health aspects of the general Italian population.

Symptoms of Anxiety and Depression  
in Students With Developmental  
Disabilities During COVID-19  
Lockdown in Poland.  
*Front. Psychiatry* 12:576867.  
doi: 10.3389/fpsy.2021.576867

**Background:** In this study we aimed to assess symptoms of anxiety and depression in persons with developmental disabilities during COVID-19 lockdown.

**Method:** Soon after school closures related to the pandemic, we conducted telephone interviews with 64 vocational school students with developmental disabilities, the majority of whom had mild intellectual disability, and their parents. The parents were asked about stressful events experienced during lockdown. The students were assessed with screening measures for anxiety (GAD-7) and depression (PHQ-8).

**Results:** Over one third of the tested students reported mild or more severe symptoms of anxiety and depression, and girls were more affected than boys. The number of experienced lockdown inconveniences predicted the severity of depression symptoms in girls.

**Discussion:** The high prevalence of symptoms of anxiety and depression in persons with developmental disabilities indicates the need for screening studies and the provision of psychological help in situations such as the COVID-19 lockdown.

**Keywords:** COVID-19, developmental disabilities, intellectual disability, anxiety, depression, lockdown

## INTRODUCTION

Since the new coronavirus disease (COVID-19) was first identified in Wuhan, China, in December 2019 (1) it has rapidly spread to other regions of China and other countries, thus becoming a major concern for global public health (2). The first cases of COVID-19 in Europe were reported in February in Italy, and this country is one of the most seriously affected by the disease in the region (3). The first case of COVID-19 in Poland was identified at the beginning of March 2020 (4), a week before the WHO's director-general declared a state of pandemic (5). The precautions officially introduced in March by the Polish government included closures of schools and universities, closures and limitations in trade and services, and significant movement restrictions for citizens (6). After the 1st of April, persons under the age of 18 could leave home only in the presence of a parent or caregiver. The restrictions also concerned persons with developmental disabilities and their families. However, in the context of the problems that affected everyone in the country, little attention seemed to be paid to the situation of this particular group.

The study presented in this article aimed to investigate the symptoms of anxiety and depression in vocational school students with developmental disabilities who stayed home during the pandemic situation due to school closures. The studied group consisted of persons with developmental disabilities, the majority of whom had intellectual disabilities; this is a vulnerable group whose risk of psychopathology is ~4–5 times higher than in the general population (7), and three to four times higher for persons with intellectual disability (8). The higher prevalence of mental health issues also applies to symptoms of anxiety and depression (9). The sex differences in general population indicate that women are at significantly greater risk of anxiety and depression than men (10). Findings related to persons with ID also suggest a higher prevalence of depression in girls (11), and that girls with ID are significantly more fearful and experience more worry than boys (12). We assumed that the burden related to the pandemic situation may exacerbate emotional difficulties in this group. Similar assumptions in regard to general population were made and confirmed in a study conducted in Ireland during the pandemic (13). The study allowed us to obtain information about these difficulties and to identify persons with developmental disabilities in need of psychological or psychiatric help.

## METHOD

### Ethical Considerations

The study was approved by the ethical committee at the Pedagogical University of Krakow and by the school board of the special education center in which it was conducted. During school enrolment, the parents or primary caregivers of all the participants in the survey gave their written consent to receive an invitation to participate in scientific research. Detailed information about this study was given during telephone conversations and consent was obtained orally from the participants. The participants were informed that they could withdraw from the study at any time. The data was kept and used in accordance with the General Data Protection and Regulation Law in force (14).

### Participants

We assessed 64 students (30 boys) from a vocational school for persons with developmental disabilities ( $M_{age} = 18.5$  years;  $SD = 2.25$ ) along with their parents or primary caregivers. Included in our study were 62 students with a diagnosis of mild intellectual disability, seven persons with a diagnosis of intellectual disability comorbid with a physical disability, and one with visual impairment. Two students had a diagnosis of an autism spectrum disorder. In each case, the diagnoses were provided by a psychological-pedagogical counseling center. The mild intellectual disability was diagnosed based on the ICD-10 (15) criteria. The results of a priori analysis of statistical power for two independent Pearson's coefficients with effect size defined as  $q = 0.75$  showed that for error probability set as  $\alpha = 0,05$  and power set as  $1-\beta = 0.8$  the minimum required sample size was 62, when equal sizes of both subgroups were assumed.

## Measures

### Interview Regarding the Lockdown Situation

The interview comprised seven questions that required a “yes” or “no” answer about difficulties that persons experienced during the last 2 weeks of COVID-19 lockdown. The parents or primary caregivers were asked how often they had sought information regarding the outbreak, whether they had experienced trouble accessing the internet or buying basic food products, hygiene products, or regularly used medications, as well as if they had any difficulties in dealing with official matters. The participants were also asked if anyone at home during the last 2 weeks had lost employment or the opportunity to do their job, and if anyone had felt ill or experienced a substantial worsening of their medical condition.

### Generalized Anxiety Disorder 7

Generalized Anxiety Disorder 7 (GAD-7) is a brief questionnaire developed for screening purposes by Spitzer et al. (16). This tool is intended to measure the severity of symptoms of anxiety. We used a Polish translation of the questionnaire available on the Patient Health Questionnaire website (17). This measure has been linguistically validated by the MAPI Research Institute (18) in accordance with the international standards of cultural adaptation methodology described in the Linguistic Validation Manual for Health Outcome Assessments (19) and ISPOR guidelines for the cross-cultural adaptation (20).

### Patient Health Questionnaire – 8

Patient Health Questionnaire – 8 (PHQ-8) is a brief questionnaire based on the widely used PHQ-9 screening measure for depressive symptoms (21). The only difference between PHQ-8 and PHQ-9 is that the former questionnaire does not include the last question regarding suicidal ideation. The PHQ-8 has been suggested as a better measure than PHQ-9 since the item regarding suicidal ideation is considered inaccurate (22). Also, the PHQ-8 is suggested as a screening measure when a study is conducted *via* telephone due to ethical reasons (23). The items in the Polish version of the questionnaire have been linguistically validated (18) and were obtained from the official site (17).

## Procedure

The study was conducted in Krakow in March and April 2020, after school closures due to the pandemic outbreak. We obtained the approval to conduct this research from the school board of a special education center for adolescents and young adults with intellectual disabilities. The data was gathered by two school psychologists who contacted the students and their parents or primary caregivers by phone. Before the pandemic, the psychologists were familiar with all the students they contacted. After giving consent, the parent or primary caregiver answered the questions regarding inconveniences experienced during lockdown, and the students answered questions included in GAD-7 and PHQ-8. When the participants reported that they had experienced symptoms of anxiety or depression, the psychologists conducting the

**TABLE 1 |** Descriptive statistics for age, GAD-7, PHQ-8, and sum of reported inconveniences.

Variable	Gender	Mean	Median	Std. Deviation	Minimum	Maximum
Age	Boys	18.60	18.5	2.39	16	23
	Girls	18.38	18.0	2.16	15	23
GAD-7 raw scores [sum of points]	Boys	2.33	1	3.51	0	14
	Girls	5.15	3	5.25	0	19
PHQ-8 raw scores [sum of points]	Boys	1.80	0	3.76	0	18
	Girls	3.91	2	4.75	0	16
Sum of reported inconveniences	Boys	2.17	2	1.62	0	5
	Girls	2.15	2	1.91	0	7

interview offered them counseling and help in setting up a psychiatric consultation.

## Statistical Analyses

Due to the skewness of the distributions of the total scores in GAD-7 and PHQ-8, the Mann-Whitney  $U$ -test was used to examine the gender differences in the total scores in both scales with the rank-biserial correlation as a measure of the effect size. The moderated regression analyses based on the ordinary least squares linear model were performed to verify whether the impact of the pandemic-related inconveniences on the total GAD-7 and PHQ-8 scores differed between girls and boys. The sum of these inconveniences, gender, and their interaction were specified as the predictors in the regression models. The dependent variables were transformed by taking the square root of their initial value to avoid the skewness of the distribution of the residuals in the regression models.

The non-parametric tests and regression analyses were computed using the free and open-source statistical platform jamovi (24), based on the R programming language for statistical computing (25) with the GAMLj jamovi module (26). The plots were prepared using the sjPlot R package (27).

## RESULTS

The frequencies for the pandemic-related inconveniences experienced by anyone in the subjects' households are presented in **Figure 1** and additional descriptive statistics are presented in **Table 1**. Trouble accessing the internet (42.2%), loss of employment or ability to work (42.2%), and trouble in dealing with official matters (29.2%) were the inconveniences most frequently reported by the respondents.

The results of the Mann-Whitney  $U$  test showed that the total scores in GAD-7 were higher in girls than in boys,  $U = 345$ ,  $p = 0.024$ ,  $r_{rb} = 0.324$ , with 95% confidence intervals from 0.050

**FIGURE 2** | Counts and within-group percentages for females and males classified in diagnostic categories of degrees of the severity of symptoms measured by GAD-7 and PHQ-8.

to 0.552. Girls also obtained higher total scores in PHQ-8 than boys,  $U = 359$ ,  $p = 0.031$ ,  $r_{rb} = 0.296$  with 95% confidence intervals from 0.020 to 0.531. The raw total scores in GAD-7 and PHQ-8 were re-coded according to the criteria specified in the diagnostic manual (17) into categories representing degrees of symptom severity. The sample distribution for each of the categories is depicted in **Figure 2** for boys and girls separately.

The overall model  $F$  test for the multiple regression conducted to predict the square root-transformed GAD-7 total scores from gender, sum of the experienced pandemic-related inconveniencies and their interaction was insignificant,  $F_{(3,60)} = 2.48$ ,  $p = 0.070$ ,  $R^2 = 0.110$ ,  $R^2_{adj} = 0.066$ . The overall model  $F$  test for the linear model that predicts the square root transformed PHQ-8 total scores from gender, sum of the experienced pandemic-related inconveniencies and the interaction of both was significant,  $F_{(3,60)} = 6.09$ ,  $p = 0.001$ ,  $R^2 = 0.223$ ,  $R^2_{adj} = 0.195$ . The results of the omnibus tests revealed that the interaction of gender with the sum of the experienced pandemic-related inconveniencies was the only significant effect,  $F_{(1,60)} = 4.16$ ,  $p = 0.046$ ,  $R^2 = 0.109$ ,  $\eta_p^2 = 0.065$ . This indicates that gender moderates the impact on the total PHQ-8 scores of experienced inconveniencies. As can be inferred from the regression lines and confidence intervals bands shown in **Figure 3**, in boys the level of predicted total PHQ scores are similar for varying values of the sum of experienced inconveniencies,  $b = 0.029$ , with  $CI_{95\%}$  from  $-0.238$  to  $0.297$ ,  $t_{(28)} = 0.220$ ,  $p = 0.826$ , whereas in girls as the sum of the experienced inconveniencies increases, the predicted total PHQ scores gradually increase,  $b = 0.378$ , with  $CI_{95\%}$  from  $0.165$  to  $0.590$ ,  $t_{(32)} = 3.55$ ,  $p < 0.001$ .

## DISCUSSION

In our study, we aimed to investigate the symptoms of anxiety and depression during the COVID-19 lockdown in students with developmental disabilities, the majority of whom have been diagnosed with mild intellectual disability. We

also interviewed the students' parents or caregivers about the difficulties experienced by the members of their household in the last two weeks. The most-often reported difficulties included trouble with accessing the internet and a household member's loss of employment or opportunity to work. However, it is also worth noting that almost one-fourth of participants' household members reported they experienced the onset of an illness or worsening of their health condition. These results indicate the strong negative influence of COVID-19 lockdown on the health of family members and the financial situation of households of persons with developmental disabilities.

The severity of symptoms of anxiety and depression was higher in girls than in boys with developmental disabilities, which is consistent with results from previous studies (11). Over one-third of girls experienced mild or stronger symptoms of anxiety and depression, whereas <15% of boys experienced symptoms of anxiety, and 20% experienced symptoms of depression. We did not find significant differences between girls and boys in terms of the impact of the sum of experienced inconveniences on anxiety. However, the effect of interaction between gender and inconveniences was close to statistical significance ( $p = 0.070$ ). This indicates that lockdown-related anxiety should be investigated further in larger samples. In our study, we also found that the number of lockdown-related inconveniences associated with depression symptoms affected participants differently depending on their gender. In girls, the number of difficulties related to lockdown considerably impacted their symptoms of depression. This result may indicate that girls with developmental disabilities are particularly vulnerable when it comes to coping with difficulties that arise in unexpected and burdensome situations, such as the COVID-19 lockdown. The sex differences in levels of anxiety and depression occur typically in general population (10), and also in persons with intellectual disability (9). The possible explanations why the boys presented less symptoms in our study may concern social expectations regarding the male role in society, which may lead to underreporting of emotional problems (12), or variety of biological factors (10). In our study a small number of boys seemed to show increase in emotional symptoms as a function of pandemic-related inconveniences. In future studies differences between boys who do and boys who do not develop emotional symptoms should also be an object of an in-depth analysis.

The study has some limitations. First, the sample of the students is relatively small, and further studies should be conducted on larger samples of persons with developmental disabilities. Second, the baseline level of depression and anxiety symptoms before the pandemic occurred was not assessed in our study, thus, there is a possibility that there are other factors,

except the pandemic-related difficulties, which influence the results. Third, the exact IQ scores for all the participants could not be obtained due to the pandemic situation. In future similar studies IQ scores should be included in regression analyses. Finally, we tested the participants only once, soon after the lockdown began. In future studies it seems important to assess emotional symptoms several times since it is possible that symptoms of depression and anxiety may relate to the amount of time spent in lockdown and may change in respect of further experienced inconveniences.

The results of our study indicate that symptoms of anxiety and depression occur frequently in persons with developmental disabilities (especially in girls). These results stand in accordance with the results of studies conducted in Ireland during the pandemic in which women also presented higher rates of anxiety and depression (13). Although in our study we were not able to verify whether the severity of the symptoms has changed compared to the period before the lockdown, the increase in the symptoms of anxiety and depression in persons with developmental disabilities should be expected in situations of school closures, limitations in trade, services, and mobility, and other troublesome restrictions. Therefore, we recommend conducting screening assessments for symptoms of anxiety and depression that are carried out similarly to those described in this paper; we also recommend the provision of psychological and psychiatric support to persons with intellectual disability and other vulnerable groups.

**Background:** The outbreak of COVID-19 occurred in 2020 which resulted in high levels of psychological stress in both the general public and healthcare providers.

**Purpose:** The study aimed to address the mental health status of people in China in the early stage of the COVID-19 outbreak, and to identify differences among the general public, frontline, and non-frontline healthcare providers.

**Method:** A cross-sectional study was used to identify the mental health status of the general public and healthcare providers between Jan 29 and Feb 11, 2020. Data were collected using an online survey from a convenience sample. The instruments used included: Patient Health Questionnaire, Generalized Anxiety Disorder scale, Insomnia Severity Index, and Impact of Event Scale-Revised. Descriptive statistics were used to describe the data. Kruskal-Wallis H tests were performed to assess differences in measurements among the three groups;  $P < 0.05$  (two-sided) was considered to be statistically significant.

**Results:** Results showed that a majority of participants experienced post-traumatic stress (68.8%), depression (46.1%), anxiety (39.8%), and insomnia (31.4%). Significant changes in the mental health status of frontline providers was found as compared to those of the other groups ( $P < 0.001$ ). Interestingly, the scores of the general public were significantly higher than those of the non-frontline healthcare providers ( $P < 0.001$ ).

**Conclusion:** These findings provide information to evaluate outbreak associated psychological stress for the general public and healthcare providers, and assist in providing professional support and actionable guidance to ease psychological stress and improve mental health.

**Keywords:** COVID-19, healthcare providers, general public, mental health distress, depression, anxiety

## INTRODUCTION

The outbreak of Coronavirus Disease (COVID-19) occurred in Hubei province in December 2019, resulting in more than 82,165 confirmed cases, and 3,298 deaths in China (1). The pandemic then spread quickly world-wide as countries rolled out measures to curb the effects of the novel coronavirus (2). In the face of this large-scale public health event, both healthcare providers and the public have been experiencing psychological pressure. The surge of confirmed cases and deaths stressed the entire healthcare system, and many healthcare providers were recruited from multiple departments to control the epidemic. About nine million residents of Wuhan (the provincial capital) were under home quarantine for 2 months because of the lock-down policy, and their life was significantly disrupted (3). The development and implementation of mental health assessment, treatment and services are vital goal in the health response to the COVID-19 outbreak (4).

Following the major outbreaks of severe respiratory syndrome (SARS) in 2003 and Middle East respiratory syndrome (MERS) in 2015, a series of mental health disorders of healthcare workers were reported, including depression, anxiety, delirium, post-traumatic stress disorder (PTSD), and even suicidality (5, 6). The risk factors for these mental health disorders included exposure to trauma, such as witnessing and caring for patients who were severely ill, the deaths of healthcare professionals, substantial mortality and bereavement, perceived life threat, orphaning of children, food and resource insecurity, discrimination against affected families, and stigma (7). Although the outbreaks of SARS and MERS stimulated related research, there has been minimal focus on the psychological impact of infectious diseases on persons in the initial stage of the outbreak.

This study aims to understand the changes in the mental health status of the general public and healthcare providers in the early stage of the COVID-19 outbreak. The findings of this study will provide insight into the development of psychological interventions aimed to support people affected by a pandemic.

## METHODS

### Settings and Participants

Due to the strict lockdown and quarantine policy, this national, cross-sectional study was conducted between Jan 20 and February 11, 2020 using an online survey. Ethical approval for this study was received from the institutional review board at Renmin Hospital of Wuhan University (No. WDRY2020-K004). Eligibility criteria of participants included: (1) frontline healthcare providers: a licensed healthcare professional who worked in a hospital designated to care for COVID-19 patients; (2) non-frontline healthcare providers: a licensed health professional who worked in a health care facility that did not directly care for COVID-19 patients; (3) members of the general

public: residents of the community who were >18 years of age. Staff from the COVID-19 designated hospitals were contacted by the research team and asked to invite members of their work group to complete an online survey. This survey was distributed *via* WeChat, a commonly used social media platform in China. Meanwhile, information about the study and the online survey link were posted on WeChat to recruit participants from the general public. In this way, the online survey was open to a large population of healthcare providers and the general public. Respondents were asked to complete an online informed consent, prior to completing the survey. A total of 915 frontline healthcare providers, 1,659 non-frontline healthcare providers and 490 members of the general public were recruited and completed the survey.

### Demographic and Mental Health Questionnaires

Demographic questionnaires collected data on gender, age, marital status, educational background, profession, and professional titles.

#### Depression

Depression was evaluated by the Patient Health Questionnaire (PHQ-9), which has nine items measuring self-assessed depressive symptoms experienced during the previous 2 weeks. It uses a 4-point Likert-type scale (0 = never, 1 = sometimes, 2 = more than once a week, and 3 = almost every day). The total score ranges from zero to 27, and higher scores indicate more depressive symptoms. Scores of 5, 10, and 15 represent cutpoints for mild, moderate, and moderately severe depression, respectively. The PHQ-9 has shown good psychometric properties (8, 9).

#### Anxiety

Anxiety was measured by the Generalized Anxiety Disorder scale (GAD-7), a self-report tool developed by Spitzer et al. (10) that follows the criteria from the Diagnostic and Statistical Manual-IV (DSM-IV). The seven items included continuous variables and verification questions. These items describe the typical symptoms of generalized anxiety disorder (GAD) and are rated on a 4-point scale, from “not at all” to “nearly every day”. The scores on the nine items are summed for total scores that range from zero to 27; a higher score represents higher anxiety severity. Scores of 5, 10, and 15 represent cutpoints for mild, moderate, and moderately severe anxiety, respectively. Psychometric evaluations of the GAD-7 suggest that it is a reliable and valid measure of GAD symptoms in the psychiatric patient (11, 12).

#### Insomnia

The Insomnia Severity Index (ISI) is a brief instrument that assesses insomnia according to the criteria from the DSM-IV and the International Classification of Sleep Disorders (13). The ISI is a 7-item self-report questionnaire assessing the nature, severity, and impact of insomnia in the past month. A 5-point Likert scale (0 = none; 4 = very severe) is used to rate each item, with total scores ranging from zero to 28. A higher total score

**Abbreviations:** PHQ-9, patient health questionnaire, GAD-7, generalized anxiety disorder; ISI, insomnia severity index; ISE-R, impact of event scale-revised.

indicates more severe sleep difficulties. Scores of 8, 15, and 22 represent cutpoints for subthreshold, moderate, and moderately severe insomnia, respectively. Adequate psychometric properties for both the English and Chinese versions have been reported in previous studies (14, 15).

### Post-traumatic Stress

The Impact of Event Scale (IES), a self-report questionnaire, is the most widely used measure of PTSD symptoms in critical care outcomes research (16). The IES-R which is the revised version of the scale measures reexperiencing (intrusion) symptoms, avoidance/numbing symptoms, and hyperarousal symptoms of PTSD (17). With the IES-R, respondents are asked to report how distressed or bothered they have been by particular difficulties in the past seven days: “not at all” (item score 0), “a little bit” (score, 1), “moderately” (score, 2), “quite a bit” (score, 3), or “extremely” (score, 4), with total scores ranging from zero to 88 for the 22 items of the scale. Scores of 9, 26, and 44 represent cutpoints for mild, moderate, and moderately severe PTSD symptoms, respectively. The IES-R has good reliability and validity in both the English and Chinese versions (18–20).

### Statistical Analysis

Descriptive statistics including frequency and percentages were used to describe the demographic characteristics of the participants. Since the data were not fit the normal distribution, Kruskal-Wallis H tests were performed to assess differences in the characteristics and severity of mental health distress between frontline, non-frontline healthcare providers and the general public and  $P < 0.05$  (two-sided) was considered to be statistically significant. Furthermore, Kruskal-Wallis H tests were performed to assess the differences in the total score of the mental health measurements between the three groups of participants. Dunn-Bonferroni *post-hoc* tests were utilized to compare the group differences when the result of the Kruskal-Wallis H tests indicated a statistical significance.

## RESULTS

### Comparison of Demographic Characteristics Between the General Public, Non-frontline, and Frontline Healthcare Providers

A total of 3,064 participants (915 frontline healthcare providers, 1,659 non-frontline healthcare providers, and 490 members of the general public) completed the online survey. Most were female (75.8%) and the majority (76.1%) were <40 years of age. Significant statistical differences were found in gender, age, marital status, and educational background between the general public, non-frontline, and frontline healthcare providers. Additionally, there was a significant difference in professional titles between non-frontline and frontline healthcare providers (see **Table 1**).

### Comparison of Depression, Anxiety, Insomnia, and Impact of Event Scores Between the General Public, Non-frontline, and Frontline Healthcare Providers

In this study, a majority (68.8%) of participants experienced post-traumatic stress and some reported symptoms of depression (46.1%), anxiety (39.8%), and insomnia (31.4%). When comparing participants in the three groups, more frontline healthcare workers had depression (58.8%), anxiety (52.6%), insomnia (42.2%), and post-traumatic stress (76.1%) than participants in the other groups. The results showed significant differences in the occurrence of depression, anxiety, insomnia, and post-traumatic stress in these groups ( $P < 0.001$ ) (see **Table 1**).

Results in **Table 2** show that a statistically significant difference was found among the three groups of participants (general public, non-frontline health professionals, and frontline health professionals) in regard to four aspects of mental health status. The frontline healthcare providers had significantly higher median scores for depression, anxiety, insomnia, and post-traumatic stress than the general public and non-frontline healthcare providers ( $P < 0.001$ ). The general public had significantly higher median scores for depression, anxiety, and insomnia than non-frontline healthcare providers ( $P < 0.001$ ).

## DISCUSSION

Most of the participants were under 40 years of age. This might be due to the fact that the social media platform used to distribute the survey is more often accessed by young adults. The results indicated that the frontline healthcare team is younger (<age 41), and many were single, with junior-level professional titles. This is consistent with the fact that hospitals are the traditional location of employment of recent healthcare graduates. More nurses (69.9%) were in the frontline team in Hubei province and this is consistent with nurses comprising 68% of the frontline team throughout China due to the intensive care needs of patients with COVID-19. Therefore, the sample in this study was representative of the healthcare providers.

The results of this study indicated that during the initial stage of the COVID-19 outbreak, healthcare providers who provided direct care for patients with COVID-19 had significantly higher scores on depression, anxiety, insomnia, and post-traumatic stress. This result was consistent with the findings of previous research during the outbreaks of SARS and MERS, as most of the healthcare providers experienced severe emotional distress (21–23). When the coronavirus appeared, frontline providers were managing this unknown infectious disease and adapting their expertise to stop its rapid spread. They were faced with a myriad of physical and psychological challenges, including intensive work for long hours, an entirely new disease, shortages of equipment and supplies, high risk of occupational exposure, fear of spreading the virus to their families or colleagues, caring for patients who were critically ill, and witnessing the sudden loss of lives (4). All these physical and psychological stressors make frontline healthcare providers particularly vulnerable to mental

health distress. To curb this global public health crisis, healthcare providers are the most valuable resources for every country. It is crucial to assess their mental health status regularly, and provide comprehensive support to protect their well-being, including establishing a safe working environment and reasonable work schedules, providing sufficient personal protective equipment and continuous monitoring, and supervision of infection prevention strategies. Professional psychological counseling and

crisis management interventions should be made available when necessary.

This study also showed that the outbreak of COVID-19 impacted everyone. At the end of January, most of the provinces and municipalities launched level I emergency responses, the highest level for a public health emergency. In Hubei province, the epicenter of the outbreak, cities were on lockdown and public transport was suspended. Residents were required to conduct

self-quarantine at home to contain the spread of COVID-19. They had more time to view information about the epidemic on television and online social media. The increased availability of information made the general public more aware of the situation, but it also added to their fear and anxiety. The surge in confirmed cases and deaths, the deaths of infected healthcare personnel, as well as the need for individuals to monitor their temperature and maintain strict quarantine policies, raised the public's awareness but also sent out alarm signals. Indirect exposure to extreme events through repeated presentation and overloaded information from the news media, might create distress and elevate risks for common mental health disorders (24). Meanwhile, myths and misinformation were often driven by news reports and inaccurate public health messaging. For example, rumors circulated that eating fish would increase the risk of infection because they feed on waste products of poultry and livestock which could be infected; the virus could be transmitted by a mosquito bite, etc. The overwhelming media reporting and not knowing how to discern what information is relevant can lead to panic, fear, and anxiety.

The quarantine requirement for the general public was another major issue to consider. Individuals lacked diversity in their support from others, social interactions to validate their personal perspectives and a means of expressing their concerns. They may experience boredom, loneliness and anger (4). This can increase the risk for a high prevalence rate for symptoms of psychological distress (e.g., depression, stress, insomnia, irritability, and post-traumatic stress) (25). To decrease the public's sense of uncertainty and fear in a public health crisis, government officials and the media need to provide timely, accurate and transparent information about the epidemic, emphasize the importance of self-quarantine, explain how long it will continue, provide meaningful indoor activities and practical advice on coping and stress management, ensure the

availability of basic supplies, and suggest professional support when necessary (4, 25).

The non-frontline healthcare providers also experienced psychological stressors, due to the severe shortage of personal protective equipment, which was mainly supplied to the frontline. They were worried about inadequate protection and increased risk of infection, because their patients might be in an incubation period without manifesting any symptoms of COVID-19, or hide their history of exposure to confirmed, suspected cases or epidemic areas (26). A study in Wuhan found that out of 40 infected healthcare workers, 31 (77.5%) worked on general wards (27). To prevent cross-contamination in hospitals, non-frontline departments were temporarily closed. Therefore, the workload of non-frontline healthcare providers was decreased compared with that of the frontline teams. The results also indicated that non-frontline healthcare workers had less mental health distress compared with the general public group. This may be due to the educational background of the non-frontline health providers who were able to distinguish facts from rumors compared with the general public. As a result, the providers were more likely to adapt in the midst of this public health crisis.

## STRENGTHS AND LIMITATIONS

This study described and compared the mental health status of the general public, non-frontline, and frontline healthcare in China in the early stage of the COVID-19 outbreak. It provided a wealth of information and gain a representative picture of the psychological response from a large group of population in this stress-coping period.

There are two major limitations in this study that could be addressed in future research. First, a cross-sectional study does not explore the causal relationship. Second, sampling bias

is a concern when using convenience sampling methods. The sample recruited may be systematically different from the general population, which may cause the study to be biased and limit the generalizability of the results. But gender distribution of general public participants was nearly even between males and females, and the majority of healthcare providers who responded were nurses, which in China, is almost exclusively a female occupation. Thus, the participants were still representative in this study regarding the general public and healthcare provider groups. Therefore, a longitudinal large-scale study which enrolls more male healthcare providers is necessary to explore the impact of an infectious disease outbreak and to explore possible predictors of changes in mental health status.

## CONCLUSION

The general public, frontline, and non-frontline healthcare providers experienced different changes in their mental health status. The frontline healthcare providers reported more manifestations of depression, anxiety, insomnia, and post-traumatic stress. Effective prevention and response measures are essential to address the mental health issues associated with population-wide exposure during the early phase of the COVID-19 crisis. It is necessary to assess for early outbreak associated psychological stressors in both the general public and healthcare providers, and provide professional support and actionable guidance to ease their pressures and improve mental health.

This study investigated how young Italian people experienced the period of peak spread of COVID-19 in their country by probing their emotions, thoughts, events, and actions related to interpersonal and community bonds. This approach to the pandemic will highlight social dimensions that characterized contextual interactions from the specific perspective of Community Psychology. The aim was to investigate young people's experiences because they are the most fragile group due to their difficulty staying home and apart from their peers and because they are, at the same time, the most potentially dangerous people due to their urge to gather in groups. The research involved 568 university students, 475 females, and 93 males, with an average age of 21.82 years (SD = 4.836). The collected data were analyzed with the Grounded Theory Methodology, using the Atlas 8.0 software. From the textual data, representative codes were defined and grouped into 10 categories, which reflect the individuals' prosocial attitudes, behaviors, and values. These categories formed three macro-categories, called: "Collective Dimensions," which includes Connectedness, Solidarity, Italian-ness, Social Problems, and Collective Mourning; "Prosocial Orientation," which includes Trust and Hope; and "Collective Values," which includes Values of Freedom, Respect of Social Rules, and Civic-Mindedness. All these macro-categories are indicative of the shared feelings experienced by Italians during the first time of the pandemic. Further practical implications of these results will be discussed, including a consideration of the risk of developing distress and improving well-being, as well as promoting preventive behaviors.

**Keywords:** emotional and action connectedness, solidarity, trust, collective mourning, COVID-19, civic-mindedness

## INTRODUCTION

This article will examine the perceived burden of the Covid-19 lockdown on the lives of young people from the specific perspective of Community Psychology.

Lewin (1936) perspective situated this discipline at the boundary between individual and social events (Amerio, 2000; Kagan et al., 2007; Orford, 2008). Therefore, its hallmark is an ecological

approach capable of analyzing the interplay of individual, relational, and social experiences (Prilleltensky, 2008; Di Napoli et al., 2019a).

We examined the COVID-19 lockdown considering individual emotions and thoughts as well as actions and significant events of individual life. In our model, we aimed to detect perceptions and representations of individuals in all their emotional and cognitive dimensions as well as the events which influence their experience, together with—for them—significant actions and behaviors (Arcidiacono, 2016). In line with this, we propose a narrative setting, capable of depicting their experience in four individual dimensions (emotions, thoughts, actions, and events). From the ecological perspective, we considered the individual domain of feelings and thoughts, that is, we took a cognitive and emotional perspective. Meanwhile, following Amerio (2000) and Ajzen and Kruglanski (2019), we considered actions as the best individual expression of the interaction with the external world; furthermore, events concern the experiences that occur around people and are the expression of the contexts in which people are immersed.

## THE LITERATURE

Lewin stated that “groups come into being not only because of perceived similarity, but because members realize their fates depend on the fate of the group as a whole” (Lewin, 1948; Brown, 1988; Townley, 2017). This certainly also applies to a community. A community can be considered in terms “of the emotional and psychological connections that exist between people and the groups they form and the means by which people communicate the idea of community—it exists through shared meaning” (Kagan et al., 2007, p. 75).

A community is characterized by the presence of some collective dimensions such as emotional connectedness and solidarity, trust, and civic values, and these assume different meanings as circumstances change. It is worth mentioning that Walker (2020) emphasizes the role of *we-ness* and of the need to create shared ties specifically in times of emergency.

### Emotional Connectedness and Solidarity

In times of crisis and social trauma such as Covid-19, individuals and families change their relationship with the social world and the community.

The journal *Nature* recently published an article on social and behavioral response to Covid-19 asserting that fighting a global pandemic requires large-scale cooperation (Van Bavel et al., 2020). In this pandemic, there are several collectives (for example, family, community, national, and international) which can make decisions to cooperate when faced with such an unexpected social event.

The awareness, fostered by fear (Pulcini, 2002), of being united with other human beings through the perception of vulnerability and weakness leads people to feel a renewed desire for bonding and generates and reinvigorates the desire for community and the need to organize themselves in forms of shared sociality, in other words, the need/desire for coexistence and for a sense of

community (Di Maria, 2000; Marta et al., 2016; Procentese and Gatti, under review).

Recent research showed that sense of community is central to a program of protecting citizens' well-being during pandemic conditions (Lie et al., 2020). Also, O'Neill (2004) stated that, as in conditions of disaster, the sense of community favors the protection of communities and that it increases when citizens are taken into consideration by their community (Lau et al., 2008).

The dimensions of the collective refer to the sense of community (SoC) defined as that “feeling that the members feel they belong, to be important to each other and to the group, a shared trust that the needs of the members can be satisfied through commitment to be all together” (McMillan and Chavis, 1986, p. 9).

The four fundamental elements that make up the sense of community are evident in this definition. The first element is the sense of belonging, which refers to a feeling of being part of a community and to the experience of emotional security that derives from this. A second concept involving the sense of belonging is identification with the community, that is, the experience of feeling adequate and well-integrated into it. Finally, the sense of belonging includes the sharing of a system of symbols, which has the main purpose of initially creating and then maintaining the sense of community.

The second element that makes up the sense of community is influence: it is a two-way concept as it is understood both as influence of the community on members and vice versa.

The third fundamental element is the integration and satisfaction of needs, that is, the members' certainty that their needs will be met thanks to belonging to the group since within it there is a sharing of the needs themselves as well as of purposes, beliefs, and values.

Studies have shown that the psychological sense of community is an important component in community initiatives. It is positively related to higher levels of well-being and associated with pro-social behaviors, civic participation, and promotion of social capital (Chavis and Wandersman, 1990; Prezza et al., 1999; Roussi et al., 2006; Pozzi et al., 2014; Ornelas et al., 2019).

In other words, community members who join together will have better chances of satisfying both their personal and their collective needs. The fourth and final element is a shared emotional connection, that is, the presence of strong emotional bonds between the members.

Coexistence is therefore favored by the sense of community that is configured as a catalyst for active, shared, and visible social participation in the entire community of belonging (Chavis and Wandersman, 1990; Hughey et al., 1999; De Piccoli et al., 2004; Christens and Lin, 2014).

Literature has effectively confirmed that SoC is associated with community participation (Florin and Wandersman, 1984; Chavis and Wandersman, 1990; Brodsky, 1996). Both community participation and SoC are interrelated key factors that promote community development and improve the chances that communities will solve problems, enhancing their internal human resources and promoting social empowerment (Talò et al., 2014).

## Trust

In a pandemic situation, social trust and institutional trust are very important issues for overcoming the crisis, as literature has widely demonstrated. Indeed, trust assumes a central role in the acceptance of recommended measures (Paek et al., 2008; Vaughan and Tinker, 2009).

Several studies have examined the role of trust during the H1N1 influenza, highlighting the importance of building public trust for promoting compliance with recommended behaviors (Gilles et al., 2011; Prati et al., 2011; Quinn et al., 2013; Freimuth et al., 2014). Moreover, Van Der Weerd et al. (2011) highlighted the fact that during the influenza pandemic (H1N1), trust in institutions increased, but trust does not always assure adherence to proactive measures. Recently, Sibley et al. (2020) reported that during the COVID-19 pandemic and lockdown, institutional trust and attitudes toward the nation and the government increased, as did trust in science, and trust in the police.

Conversely, in Italy, Stanzani (2020) observed that at the end of the lockdown, institutional trust decreased among Italians, and they only experienced high levels of trust toward activities carried out by NGOs.

This is to say that institutional trust (Lewis and Weigert, 1985; Barbalet, 2009; Luhmann, 2018) expresses judgments about the performance of institutions such as government (e.g., Hetherington, 2005).

Moreover, Rönnerstrand (2016) observed that contextual, generalized trust has been linked to immunization, in line with the literature that argues that being a trustful individual and residing in a community characterized by trust among members influences health and health behavior (Kawachi et al., 1999; Rose, 2000; Hyyppä and Mäki, 2001; Subramanian et al., 2003; Di Napoli et al., 2019b).

Finally, generalized social trust refers to trust toward generalized others who are not directly known (Bjørnskov, 2006; Nannestad, 2008), which occurs when “a community shares a set of moral values in such a way as to create regular expectations of regular and honest behavior” (Fukuyama, 1995, p.153).

Furthermore, a recent study (Imai, 2020) conducted among health workers during the Covid-19 emergency, showed that trust between organizations and workers is essential for improving work motivation and social interaction and cooperation.

## Civic Values

During a pandemic, the sharing of values has a strong impact on social shared identities.

Social values play an important role in addressing the pandemic emergency (Jarynowski et al., 2020), and one's individual perception that others share one's own social values enhances the adherence to norms and behaviors for curbing the spread of the virus (Wolf et al., 2020).

Specifically, Flanagan (2003) and Flanagan et al. (2007) introduced values with respect to civic attitudes: They defined engagement values to explain the position taken and the relative importance attributed by people to issues of a social or political nature. In their view, a constitutive element of civic values is the experience of group membership together with the experience of socialization in one's family and community in general (Sherrod

et al., 2002; Marta et al., 2010; Marzana et al., 2012; Alfieri et al., 2014). Wolf (2007) conducted a meta-analysis of civic values and found that civic values are, in order of the most widely studied to the least: political tolerance, understood as the desire to extend civil rights to all, even to groups we do not like; volunteerism, understood as the contribution of one's time to support the activities of community organizations; political knowledge, understood as the awareness of the political system, current events, and political leaders; social capital, as the extent to which a person is networked within their community; civic skills, understood as the experience in and familiarity with activities used to influence the political process; and patriotism, understood as a visceral positive connection to one's country and respect for its national symbols and rituals.

## THE RESEARCH

Giving voice to people and allowing people to express their needs and desires as well as acquiring awareness about their world are among the most significant goals of community psychology (Rappaport, 1995), rooted in Freire's conscientization 1970 and Martín-Baró's community actions 1994. It should also be recalled that in this discipline, well-being is not only an individual matter; it concerns community interactions and well-being (Di Martino et al., 2018; Di Napoli et al., 2019a). Therefore, social emotional connectedness, community interactions (Prati et al., 2016, 2020), conviviality (Procentese et al., 2019a,b), and participation (Albanesi et al., 2015; Cicognani et al., 2015; Arcidiacono et al., 2016; Churchman et al., 2016; Pozzi et al., 2017) are social pillars for understanding the psychic life. They enrich the merely individual dimensions, compounded by individual emotions and interpersonal relations that act on a family and friendship level.

Thus, at the onset of COVID-19, we decided to explore these dimensions in a group of Italian students. Specifically, we were interested in probing the inner world of young people faced with this unexpected event.

In line with the discipline's vision regarding individual well-being, we investigated how people express these dimensions.

## MATERIALS AND METHODS

### Aims and Scope

The main goal of this study was to acquire information about the lockdown experience during the pandemic and to understand its meaning and symbolization at individual, local, and national levels.

Framed within the community psychology approach, our interest was to analyze social interactions between individual and social levels during this time. Therefore, we asked our participants to talk freely about emotions, thoughts, events, and actions that they considered significant to share. They were asked to refer to their own personal experience or to feelings and actions related to their relatives, friends, or more generally attributed to this global pandemic.

The aim was to investigate young people's experience because they are the most fragile group due to their difficulty staying

home and apart from their peers and because they are, at the same time, the most potentially dangerous people due to their urge to gather in groups. Therefore, storytelling was used as a tool to collect their stories and to probe their meaning and symbolization, developing their reflectivity (Esposito et al., 2017; Salvatore et al., 2018). In fact, in our case, in line with the mission of community psychology to give voice to young people, among the most affected people by the pandemic's social implications, we asked our students to freely express their thoughts and emotions related to their lockdown experience.

Two companion papers will carefully describe their online teaching experience (Novara et al., forthcoming) and their individual feelings and thoughts (Marzana et al., forthcoming; Migliorini et al., 2021).

Here our aim is to probe emotional connectedness and shared actions undertaken by people during the lockdown.

## Participants

The recruitment of the participants took place through the mediation of lecturers in the field of community psychology at five universities in different Italian regions in the north, center, and south. Each instructor invited the students in their own course to participate in the research, filling out an online questionnaire created and distributed through the SurveyMonkey digital platform.

Data collection took place from March 24 to April 1, 2020, i.e., during the week in which the number of cases of COVID-19 contagion reached its peak in Italy.

Participants consisted of 568 university students, 475 females and 93 males, with an average age of 21.82 years ( $SD = 4.836$ ). For all participant characteristics, see **Table 1**.

## Methods and Procedures

Students were asked to describe meaningful events and actions related to their lockdown experience. In a sort of focalized approach (Arcidiacono, 2016), we gave them an open stimulus, but, at the same time, we asked them to delve into specific dimensions: in this case, emotions, thoughts, actions, and events. The text of each single student could be expressed in only a few words, totaling no more than 10,000 characters.

When filling in the form on the SurveyMonkey platform, students were asked to provide informed consent.

Those students were also offered the opportunity to receive individual actions to express social support and the take care of their own student community.

## Data Analysis

The textual material written on the online platform was analyzed by means of the Grounded Theory Methodology (GTM) (Corbin and Strauss, 2008; Charmaz and Belgrave, 2018), using the ATLAS.ti 8.0. Grounded theory, “at the most basic level (...) remains an approach in which researchers use data to develop theory from the bottom up” (Rasmussen et al., 2016, p. 23).

The process of data analysis starts after the first texts provided were analyzed. The aim was for the entire research team to share common meanings to be attributed to the written material. The preliminary coding phase started with a bottom-up approach by

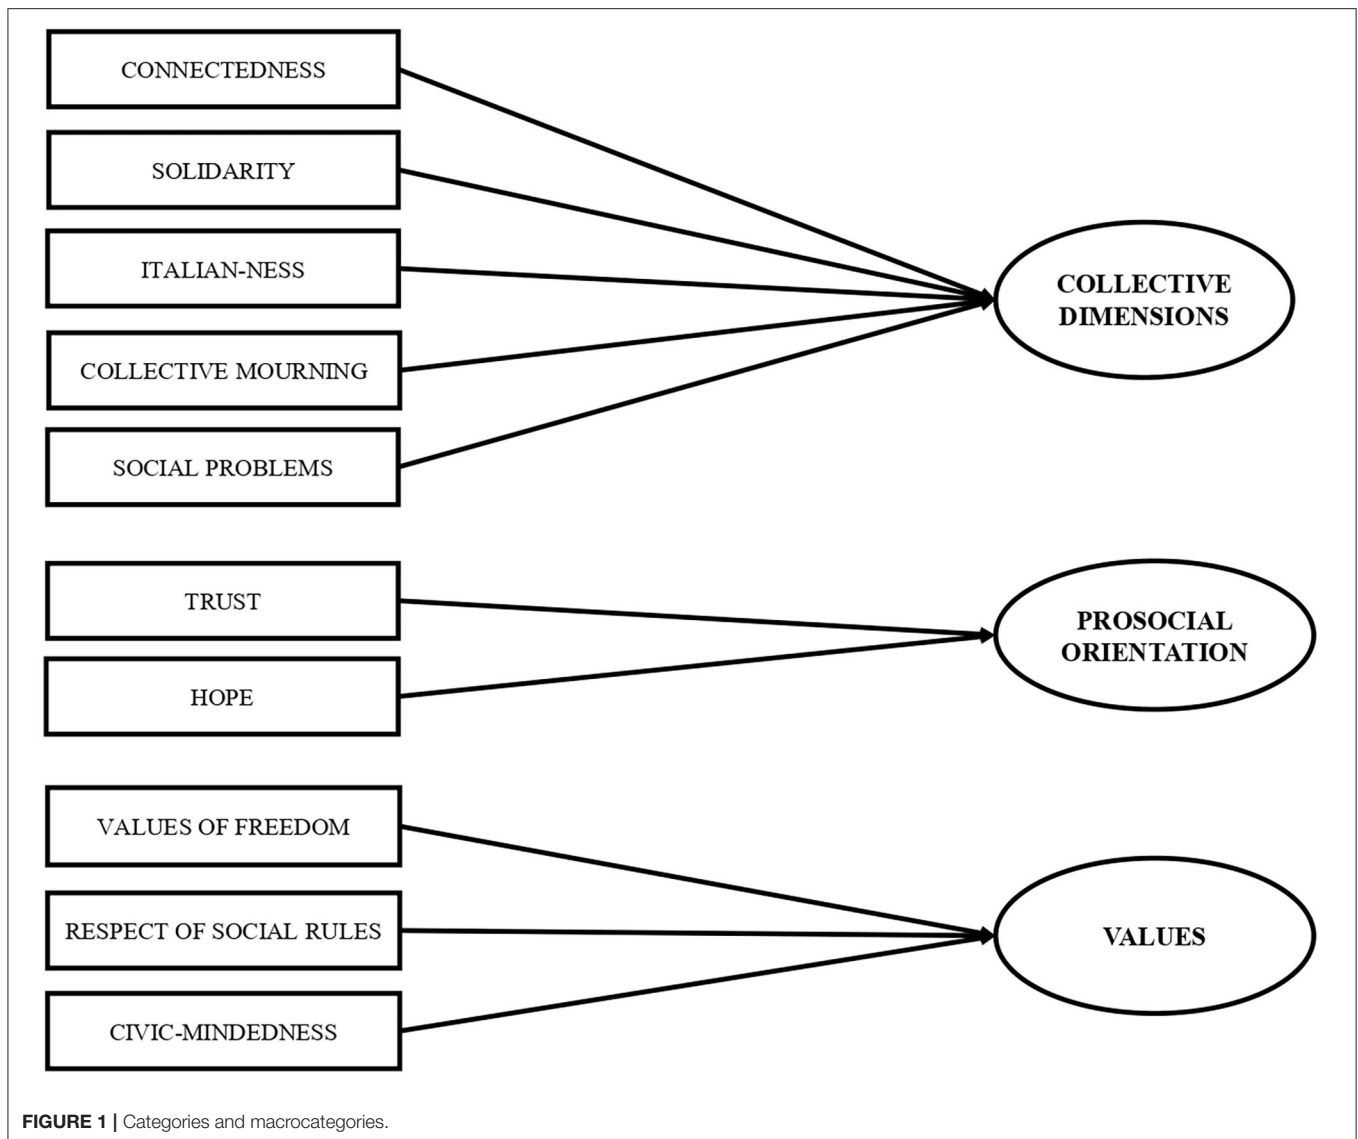

**TABLE 1 |** Characteristics of the participants.

Age	M = 21.82 %	SD = 4.836 N (568)
<b>Sex</b>		
Male	16.4	93
Female	83.6	475
<b>Territorial area</b>		
North	28.0	159
Center	10.7	61
South	61.3	348
<b>Sexual orientation</b>		
Heterosexual	91.0	517
Homosexual	3.0	17
Bisexual	5.3	30

<b>Housing condition</b>		
With one or both parents	85.0	483
Alone	2.8	16
With a partner	4.4	25
With one or more roommates	3.3	19
With other family members	4.4	25
<b>University</b>		
University of Valle d'Aosta	11.4	65
Università Cattolica del Sacro CUore Milan	17.3	98
University of Florence	9.9	56
University of Naples Federico II	51.6	293
University of Palermo	9.2	52
Other Italian universities	0.7	4

coding significant words and sentences. They were then shaped into larger code groups and framed in wider categories.

Several online meetings took place, usually with the participation of 10–17 researchers. A reflexivity-based iterative process was undertaken among all team members. Notes, theoretical memos, and preliminary codes for identifying conceptual categories that shared common meanings were discussed. A reflective procedure (Esposito et al., 2017) was undertaken, in fact, researchers were asked to question themselves to better interpret the findings as they emerged from the texts. The heterogeneity of the research team—particularly in terms of age, professional background, and prior experience with GTM—was used as a resource to better interpret the content and the meaning of the texts. This shared procedure produced several subsequent coding frames, reaching a final shared categorical frame by a consensual strategy. This activity was parallel to the text coding activity that each unit brought to its material. Finally, all codes framed in the shared categories were collected in a common repository (Google Drive folder) and used to start writing the final report. After this, categories, codes and quotations were re-discussed again, and the team reached the definition of the final missing aspects. Last but not least, students of some universities were asked to share in the results.

A preliminary discussion on the collected texts was shared with the students during the course of the study. The preliminary

results were also shared with groups of students not directly involved in the research during seminars to which the researcher's team was invited.

A brief report will be provided to all students involved in the research, highlighting the principal results as well as all references to published articles through docent websites and/or Facebook pages.

## RESULTS

The results showed the presence of some sensitizing concepts in the student's storytelling (Blumer, 1969): in other words, "thoughts and hunches" that researchers have as they get started doing research.

The texts were then categorized into collective dimensions such as connectedness, solidarity, social problems, and collective mourning, but the coding also encompassed some specific

unexpected thoughts concerning national belonging that were named "Italian-ness".

The *Collective dimensions* macro-category included several different categories (**Figure 1**):

**Connectedness.** A peculiar aspect—consistent with a situation characterized by "*being in the same boat*," or, better, "*in the same storm*"—refers to sharing the same destiny: the wider community perceives, especially at the peak of the contagion, a close relationship, a "*feeling of unity when facing misfortunes*." The interdependence of fate, in the lesson learned from Lewin's contributions, is a powerful mechanism in building groups' cohesion. Especially in small local communities or in regions more heavily affected by the infection, such an aspect quickly became the high road toward achieving a great—and, sometimes, unexpected—level of social cohesion.

Other interviewees refer to aspects related to everyday life, such as sharing useful information or exchanging recipes, because

cooking was one of the favorite pastimes during the lockdown, with the sense both of expressing one's creativity and of enriching the new ritual of enjoying meals together, at the same table.

In addition, other shared suggestions concerned exercise and workouts due to the discomfort caused by the forced inactivity and the lack of movement perceived particularly in the first days of confinement, and, above all, the most important topic is the sharing of emotions: fear, worry, and uncertainty about the future.

Participants thus wrote about connectedness. They wrote about their own perceptions related to micro- and macro-belonging, and, consequently, about the cohesion experienced in their proximal networks such as their neighborhood, partner, and family: *"the value of having meals all together, around the table, at home."*

Singing and playing popular songs and hymns on balconies, toasting one another from one side of the street to the other as well as playing traditional bingo (*tombola*) socially together while standing at windows overlooking the same courtyards suddenly became the most relevant ways to express the value of *"being together."* Shared community emotional connectedness became a new social issue.

At the community level, it is then interesting to note the importance attributed to the *social cohesion* perceived in the local community, *"a great sense of community never perceived before COVID,"* even by the students who were used to spending most of their time outside the home. Social networks were an important way to feel *"far, but, at the same time, close to significant others."*

Solidarity. A possible outcome of such feelings was the growth of solidarity: *"In my opinion, people may rediscover solidarity, unselfishness, stop thinking about our own interests."*

Interviewees referred to community solidarity: even if at times it did not involve all the residents, these feelings were widely shared anyway. Solidarity was often defined as *"rediscovered humanity,"* generally referring to the local community, and was also detailed by specifying the more fragile inhabitants: the elderly, people with disabilities or previous illnesses, and those who felt *"lost in an adverse event"* or sometimes *"worthless."*

Particular attention was paid to healthcare workers and professionals: participants highlighted both the solidarity shown by them toward the whole local community and the inhabitants' appreciation for their work as *"heroes"* in pandemic times.

In addition, similar praise was expressed toward volunteers engaged in providing meals or other basic necessities, or individual protection devices, often lacking in the first phase of lockdown.

Another aspect—emerging with particular emphasis in some contexts—must be underscored: this refers to international solidarity, demonstrated by physicians coming from abroad to help the areas of Italy most seriously affected by the virus or by providing medical devices and financial support. People—and particularly some young people—generally think about other countries as producers of goods or places worth visiting and not as possible helpers.

In "normal" life participants seem to have considered solidarity as a dimension coming from lucky (healthy, medium-high income, and privileged) people toward the most

deprived individuals. During the lockdown they experienced the meaning of loss and lack of resources, rediscovering peer-to-peer solidarity.

Italian-ness. The social relationships we experience in daily life also satisfy the need to feel like full members of a community that is territorially recognized and confined in a specific physical and mental space. This feeling of being Italian, and being recognized by others as such, is what we called "Italian-ness." It includes those anthropological, cultural, and territorial characteristics that connote being Italian. It is not only a question of characters that are objectively unique to a nation, such as a symbol, a geographical border, or a founding myth; a fundamental aspect is, in fact, the common feeling which is that of being part of something bigger and more important that is independent of individual stances and, at the same time, includes them (Reicher and Hopkin, 2001).

What emerges from the research is that the pandemic connected people to the nation—and to some extent to the populace—in a renewed feeling of Italian-ness. Among the symbols, the "tricolor flag" displayed at windows and the "Italian national anthem" sung in unison from the balconies of the houses, or other songs grounded in national memory, all recurred in the texts.

Even the posters displayed on the facades of the houses, with the words "everything will be alright," had a consoling if not proactive effect. These were the actions through which the population felt less alone or rather, less isolated (probably also from the world) and "closer to all Italian citizens, as never before."

As one participant wrote: "People who get excited and sing with you in a moment of collective pain can generate reflected joy," a collective action that outlines an action of "national coping."

In summary, the pandemic bonded people to the nation in a renewed feeling of "Italian-ness," highlighting how "in an emergency there are no borders."

Social Problems. From the social perspective, the description of the problems seems to generate a certain polarity. In some cases, an intrinsically social and collective vision of the problem prevailed: *"... the current situation of many Italian families left without work and in poverty...;" "... how complicated the situation is in general...;" "... in the elderly in the family, progressively more and more alarming data have generated a strong fear for the future of the country...;" "Isolation, necessary for physical health issues, in the long run risks damaging people's mental health."*

On the other hand, there were many expressions of identification with others, where social concern focused on the individual suffering of the other; therefore, the summative character of the sufferings of the individual emerges as social. In this regard, the texts collected presented a great deal of narrative expressing attention to social problems: *"Yesterday in my city's hospital, an elderly man committed suicide because he had been infected and was afraid of having infected someone else. I'm afraid these episodes will occur again;" "This made me think of how many people are now alone and at greater risk."*

The variety and intensity of this meaning can also be encapsulated entirely within this single statement: *"Anxiety from*

*multiple points of view, for people who are in hospitals and therefore disabled by the virus, for doctors, nurses, healthcare and law enforcement workers, for my grandparents who are elderly, for all those people who unfortunately do not have the means to be safe and for our Italy which has been brought to its knees.”*

Collective Mourning. The Social Mourning dimension seems above all to emphasize the emergence of the community meaning of death, as opposed to the contemporary tendency to consider death as a private event and mourning as a personal elaboration. What is represented in participants' texts, therefore, is not only a fact in itself, but above all the novelty, the surprise, the difference compared to usual living conditions.

In this sense, some aspects appear to be significant. One of these is the frequency with which participants speak about the death of strangers. Fortunately, this is also probably related to a low incidence of family mourning, but the recurrence of this theme underlines the impact at a community level including for the many people not directly involved: “...seeing all these people die so much that they no longer have room in cemeteries...;” “...the pain of all of us sitting on the sofa and hearing the number of deaths every day took away our desire to speak, to smile, people were dying...;” “The line of military vehicles leaving the Bergamo hospital.”

An interesting feature of these statements is that, although they are about strangers, the categories of meaning and the discursive styles of the private dimension of mourning and personal pain are mainly used, as if attuning to the families of the deceased strangers. In the discourse, there is therefore a point of contact between the collective entity of events and the affective and family sphere for the attribution of meaning: “...he was in a coffin ready to be cremated without family members having the opportunity to say farewell to him and to be celebrated with dignity...;” “The impossibility of saying goodbye to the deceased for those who have lost someone.”

Another element that seems to refer to the community dimension of mourning is the frequency with which the images of the coffins and the line of military vehicles in Bergamo are recalled in the various cities, even distant ones. This refers to a visual representation of experiences conveyed by the mass media. However, this aspect can also be taken for a better definition of the experiences of mourning, because sometimes addressing loss appears in the private dimension, linked to the direct experience of the participants: “Death of a friend of my mom;” “One event that surely struck me was the news of the death caused by the coronavirus of a neighbor of my grandmother’s.” In other cases, the absence of mourning in a social sense and of a community ritual concerning “stranger” mourning, portrayed in the images of military trucks in Bergamo, seems to be emphasized. In this sense, it can be assumed that there is a subtle dissonance between amplified public representations, such as those conveyed by the media, and underestimated individual experiences or direct experiences of mourning.

Finally, in some cases, the speed of contagion transmission number was associated with the Social Mourning macro-category. This occurrence may suggest the profound impression aroused not only by the extent of the losses, but above all by the occurrence, a rampant emergency, coming so fast as

to cause anxiety with respect to our practical possibility to combat it.

Collective values. The *Collective values* macro-category includes different categories that refer to behaviors, attitudes, or values related to respect for other people, the rules of living in a community, respect for the rules and responsibility as well as Values of Freedom and civic-mindedness. Civic sense, for example, collects the codes referring to “*staying at home*” as a form of respect for the rules such as adherence to restrictions required by institutions: “*An action that emerges as crucial in this period I believe is respect for the rules and decrees issued. Respecting rules and decrees, being selfless while staying at home.*” Participants, therefore, stated opinions concerning a sense of justice. They referred to the failure of some people to comply with the rules, an injustice toward those who, conversely, did not transgress them. The lack of collective values is connected to this aspect of justice, and it is expressed as individualism, selfishness, and a lack of responsibility.

This refers to an attitude of focusing on oneself and one's needs while ignoring those of others: “*Different people can't help putting their personal needs before collective needs,*” which is reflected in behaviors that denote a lack of respect for the community and negligence in people's behavior.

Some examples of these behaviors are escaping lockdown by train to return home, moving from the so-called “red zones” of Italy, which were considered highly contagious, and irresponsible shopping in supermarket to get as many items as possible. “*The selfishness of these people makes me understand that there is no emotional bond that holds. Faced with the fear of dying these people would also sell their soul to the devil; egoism has never brought benefits to society and to the individual lives of people. I cannot understand how all this can happen without thinking in the least about who is on the other side.*”

An important value on which the interviewees focused was freedom. During this period of lockdown, this assumed the connotation of “*rediscovered value.*” Freedom became a fundamental dimension in daily life, very often taken for granted; it took on great importance when it was taken away from us.

Last, particular attention was paid to the dimension of the environment. Many participants wondered about the effect that the pandemic would have on nature, often speaking of “*the world that is being purified*” and “*planet earth that is reborn,*” coming to the conclusion that “*the negative experience for human beings is becoming positive for nature.*”

## Prosocial Orientation

The *prosocial orientation* macro-category contains two different categories: trust and hope. As far as trust is concerned, the interviewees declared that this state of emergency had increased their confidence and has made them conscious of the importance of trusting their fellow citizens, humanity, and, above all, the public institutions: “*Increasing trust in others is a fundamental premise for moving forward and overcoming the crisis situation.*”

Trust in fellow citizens is basically considered as very important for empowering everybody to adopt precautionary behaviors to protect themselves and other people: “*We really need*

*this type of trust which is trust in others. To believe that people really realize what we are currently experiencing.”*

Moreover, the students refer to an increased confidence in public institutions, above all in the Prime Minister, thanks to the closeness and understanding that the institutions showed toward the citizens: *“Then, leaving aside any political opinion, I’ve been impressed—positively this time—by the governmental promptness in sending out a message of strength, safety, and trust.”*

Great confidence and recognition were expressed for the Italian lockdown model since it displayed an emphasis on care: *“I felt relieved and a little bit reassured because I had the feeling that the state was putting in place actions and that we as a people were not alone at the mercy of the disease.”*

Trust in the authorities also increased gratitude for the presence of checks on compliance with the lockdown: *“Something positive that I have noticed is the high number of checks that the police are carrying out. In my neighborhood I see police cars passing continuously and stopping passers-by and cars.”*

However, there is a portion of the students who show distrust toward fellow citizens and authorities regarding the management of the emergency. The distrust is mainly toward careless attitudes adopted by other inhabitants and institutions: *“Ignoring the rules imposed by the authorities regarding the coronavirus emergency, it makes me lose esteem and trust in our society.”*

For some of the interviewees, a symbol of hope is represented by the drawings that Italian children made, recognized as symbols of positivity toward the future; children’s drawings were also represented as a trigger for serenity, relieving the worries and sadness of the lockdown period.

The saying *“#andràtuttobene”* (#everything will be alright) became a symbol of an individual and collective hope of recovering and returning to normality.

The *hope* category, as an emotional future-directed network, describes what the subjects desired right after the emergency phase.

Hope, however, carries different attributes for the interviewees. Some of the interviewees hope for a revolution compared with what existed before the onset of COVID-19, that is, the possibility of adopting new and different ways of living in the future. Thus, hope for the revolution means importing new ways of establishing interpersonal relationships, taking care of the most vulnerable, having greater care for the environment: *“To rebuild a new a world. More creative. More responsible. More aware. More true. More united. I do not want normality anymore. I want a masterpiece;” “... I wish that this moment would bring a real revolution. Inside and outside ourselves. I want to learn the lesson of this hard moment. I do not want to ever lose any bit of what was taught.”*

For some youth, hope will return when they can resume living as in prior everyday life, before the COVID-19 emergency: *“I hope this moment will pass soon. Panta rei that is “everything flows” as an important ancient Greek philosopher used to say, so I wish that the stress that our country is suffering will weaken soon;” “Hope that everything will end soon is strong.”*

Then some of the interviewees refer to the lack of hope as the inability to imagine themselves in the future. Inability to

foresee when the emergency will end makes the interviewees afraid and discouraged.

## DISCUSSION

The coffins left behind in the Bergamo morgue continuously broadcast by media for several days was the image also reported by the frequent dreams (Iorio et al., 2020) that best expressed the dimension of collective mourning; conversely, people talking to each other from balconies was the voice of connectedness. Here visual representations give us the symbolic meaning shared by our respondents. We can, therefore, consider this two-fold image as a core category encompassing shared meaning attributed to this pandemic at the community level. The lines of coffins and people singing and toasting from balconies, respectively express this emotional sharing of collective mourning and the need to express shared feelings of connectedness. In this case, we assumed as a core category not a sentence or a word but two visual images reported by the texts, and it is worth mentioning how visual communication expresses feelings and thoughts (Arcidiacono et al., 2016). At the beginning of the lockdown, this aspiration to share and stay connected was the first spontaneous reaction to the media reports of deaths and infections. Signs of reciprocal solidarity were also expressed and described.

According to Walker (2020), “Psychological research suggests that being in an emergency can create a common identity amongst those affected. Emergencies appear to at least temporarily dissolve social division as the development of this identity facilitates a degree of cooperative altruism even when amongst strangers in life-threatening situations” (p. 4).

Confirming what was reported in the introduction, in the words of the participants, the renewed desire for bonding and community was evident in response to the situation of collective trauma (Ntontis and Rocha, 2020). In fact, unity strengthens the belief in a greater ability to cope with the emergency. It is not trivial to point out that this rediscovered unity also occurred through the recovery of some traditions (social games, cooking, etc.), which represent an anchor to something known, something that does not change (even down through generations) in a time when lives are turned upside down. It is interesting that at a time when the need for freedom and escape is curtailed, tradition retains its consoling meaning for the community, which is to cling onto certainties while adapting them to new needs, even when these are completely unusual and unpredictable.

We have also found this renewed interest in bonds in what we could define as behavioral solidarity toward humanity. In particular, it places the most isolated social categories (such as the elderly, the homeless, etc.) or professional categories less valued by government policies (i.e., doctors, nurses, and the whole health system) at the center of attention and collective sensitivity.

We also found that the epidemic led individual citizens to have a shared emotional experience and to develop a social identity that we have called Italian-ness. In fact, in line with the Intergroup Emotions Theory (Smith and Mackie, 2015), this dramatic event, even if it involved the Italian regions to a different degree, triggered group-based emotions in Italians.

These common emotions were independent of the individual level and were linked by a sense of belonging to a common identity. As studies of people exposed to emergencies suggest (Drury et al., 2016, 2019), sharing the crisis situation fostered a sense of belonging among individuals, which was managed to overcome the profound differences that characterize the different regions of the national territory.

This identity was also strengthened by the fact that Italy was at that time the only European country to be severely affected by the epidemic. In fact, during the period in which the data were collected, there was an image, fueled by fear and by social media, of Italians as spreaders of the virus. As postulated again by the Intergroup Emotions Theory (Smith and Mackie, 2015), this discriminatory experience favored social identity thanks to opposition to an outgroup represented by other European countries.

In addition, as Dovidio et al. (2020) argue, the delocalization of the virus that has affected the entire globe and configured itself as a global threat has exported the threat out of the ingroup of belonging, lowering the level of intra-group conflict. This could explain the generalized and newly found trust in the “Other,” which at a higher level of categorization creates a common ingroup identity to which one belongs (Gaertner et al., 2016). In this way, respondents “recognize people are the solution, not the problem” (Jetten et al., 2020, *ivi*, p. 11). In fact, they become the problem when they do not respect the civic norms that protect the global community, of which everyone—during the pandemic—feels they can be part. The Other, then, can also be a source of mirroring and not just identification (Novara et al., 2019), awakening an empathic capacity that we find in the feeling of collective mourning, in the concern for the economic difficulties of some families, for the risk that workers in the field run, for the community. All these things—as some say—will need to be taken better care of in the future, including reawakening environmental responsibility.

Moreover, in line with literature (Rönnerstrand, 2016; Sibley et al., 2020), there is an increased sense of trust in political institutions in which the interviewees recognize an attitude of care and attention, as well as toward other citizens. Therefore, trust for interviewees is a necessary condition for overcoming the crisis situation.

Finally, it is interesting to note the feeling of hope (Solnit, 2020) in the results regarding not only the prospective image of how we will live together after COVID-19 but also the retrospective image of how we will live in the future based on what has been in the past: conscious collective learning.

Indeed, hope, despite being little explored in its implications in a pandemic situation, is a very important issue, moreover considering it as a socially constructed emotion connected to the quality of life (Scioli, 2007).

This was probably also the benefit of the storytelling method that we used in the research: It allowed the interviewees not only to report their experiences but to narrate them in the psychological sense, accessing an emotional and meaningful elaboration of their experiences, and we know how much this can promote preventive and caring behavior during mass emergencies.

Finally, this study confirms that young people are attentive and sensitive to social issues, as elsewhere described (Alfieri et al., 2019) and have developed a concern for community.

## Limits

This research is not without limits. This study collected experiences of students, and in the classes we included, there was a greater number of females. The number of participants also differs among various universities, but it is quite balanced among the northern, southern, and central regions of Italy. Furthermore, the participants are university students studying in humanities departments; therefore, the sample does not represent all Italian university students and young Italians, more broadly.

In a future study, it would be interesting to develop situated differences among young Italians of different social contexts and to compare the results with youth from other countries facing the pandemic with different strategies.

## CONCLUSION

This study reveals the initial emotions, thoughts, and actions undertaken at a collective level by students of the North, South, and Center of Italy. Its value is to grasp the primary reaction to the lockdown emergency. It highlights how around Italy, people undertook actions aimed at maintaining continuity among people and overcoming the forced closure of society. For us, as community psychologists, this need for connectedness expresses how community interactions are the pillar of social life.

In this vein, Italian-ness may be understood as a form of shared national identity that makes possible a common identity. Furthermore, the many references to the whole world and environmental needs demonstrate a wider social identification with our planet and all human beings.

Referring to the Elaborated Social Identity Model (ESIM) of crowd behavior developed by Cocking et al. (2009), Carl Walker suggests that it is a “common identity that can result in people helping and supporting each other, even if they are complete strangers. Coronavirus functions in a similar way, positioning groups of people as being under attack from a common and indiscriminate enemy” (2020 p, 4). Therefore, it is not surprising that connectedness actions were among the first collective reactions for our students.

Similarly, solidarity occupied a significant place in collective descriptions of our respondents: “Evidence from a range of different disasters in different countries (Drury et al., 2019) confirms the link between a sense of shared fate and shared social identity, and also between emergent social identity and solidarity” (p. 104).

Narratives coming from the data collected show communities at first astonished and then frightened by the persistence of the contagion. Suddenly, disease and death pervaded everyday life. The psychosocial and collective response, in order to restore an acceptable threshold of well-being—according to Nelson and Prilleltensky (2010) and Prilleltensky (2008)—was to make sense of the whole experience and to undertake all the behaviors needed to care for mental and social health. In the face of social distancing, affecting the opportunities for closer and physical

relationships, alternative measures were imagined: virtual connectedness, sense of cohesion expressed by shared rituals (playing, singing, toasting, etc.), organization of community and neighborhood support, first of all, addressed toward the most fragile citizens, such as—for opposite reasons—young people who wished to meet peers and elderly people, heartbroken by the loneliness and by the perceived risk of infection. Creativity advanced in order to provide unusual and effective actions for increasing mutual caregiving, individual and community health and well-being, and sense of community (Chavis and Wandersman, 1990; Talò et al., 2014) in adverse events.

The complexity and depth of these data show the potentiality of storytelling as a tool that offered the students the opportunity to re-think and reprocess traumatic events, a space to rework them. It has proved to be a tool that not only has value in itself but also for the effects it had. Storytelling helped the young people build a meaning into their experiences, to elaborate fears but also to give voice and creative expression to those experiences. Storytelling empowered young people and was a powerful way to improve their overall wellbeing.

From a community psychology perspective, in line with the COVID-19 Statement of EFPA ECPA, 2020, we hope that some collective feelings described by our young Italian respondents during the pandemic will build “new ways of understanding the networks of communities we are part of.” Building trust and solidarity is a long-term process, involving public and private sectors (Capone et al., 2020; Procentese et al., 2020). Communities in many countries are amazingly active in

strengthening their feeling of belonging and building new forms of community. Helping to preserve the treasure of engaged, creative, and home-grown ideas and “popup”-solutions will be important if we want to maintain the sense of community and co-creation, which is emerging in our societies.

Therefore, it is to be hoped that these preliminary considerations on the COVID-19 lockdown experience will reach a larger audience and therefore become a lever for social change as the special issue proposed by Castelnuovo et al. (2020) intends to do.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by University Federico II, Department of Humanities, Ethics Board for Research in Psychology. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

All authors listed have made a substantial, direct and intellectual contribution to the work, and approved it for publication.

Mood Disorder in Cancer Patients  
Undergoing Radiotherapy During the  
COVID-19 Outbreak.  
Front. Psychol. 12:568839.  
doi: 10.3389/fpsyg.2021.568839

**Introduction:** Novel coronavirus (COVID-19) is having a devastating psychological impact on patients, especially patients with cancer. This work aims to evaluate mood disorders of cancer patients undergoing radiation therapy during COVID-19 in comparison with cancer patients who underwent radiation therapy in 2019.

**Materials and Methods:** We included all the patients undergoing radiation therapy at our department in two-time points (once a week for a month in May 2019) and during the COVID-19 outbreak (in April 2020). All the patients were asked to fulfill a validated questionnaire (STAI-Y1, State trait anxiety inventory scale), the Symptom Distress thermometer (SDT) (from 0 to 10 score), and the Beck Depression Inventory v.2 (BDI-2). We took into account the COVID-19 outbreak and also sex, age, week of radiation treatment, and disease.

**Results:** We included 458 patients (220 males and 238 females), with a median age of 64 years. STAI-Y1 median score was 40 (mean 41,3, range 19–79), whereas the median score of SDT was five and BDI-2 median score was 11. STAI-Y1, SDT, and BDI-2 were significantly correlated with the COVID-19 outbreak ( $p < 0,001$  for all the tests), sex ( $p: 0,016$  for STAI-Y1,  $p < 0.001$  for SDT,  $p:0.013$  for BDI-2), week of treatment ( $p: 0.012$  for STAI-Y1 and  $p: 0.031$  for SDT), and disease ( $p:0.015$  for STAI-Y1,  $p < 0.001$  for SDT and  $p:0.020$  for BDI-2).

**Conclusions:** The prevalence of mood disorders in patients undergoing radiation therapy is higher than expected and even higher during the COVID-19 outbreak. These measurements could be useful as a baseline to start medical humanities programs to decrease these scores.

**Keywords:** mood disorders, COVID-19, radiotherapy, cancer, anxiety, depression

## INTRODUCTION

Since WHO announced the novel coronavirus (COVID-19) outbreak as a pandemic on 11th March, the virus has reached more than 4 million cases and 300,000 deaths all over the world (Laghi and Grassi, 2020; Neri et al., 2020).

Notably, the psychological effects of COVID-19 on both patients and healthcare workers could be serious and deserves a systematic investigation (Belfiore et al., 2020; Huang and Zhao, 2020; Tsamakidis et al., 2020).

A cancer diagnosis often implies extensive emotional, physical, and social suffering, therefore current cancer management should incorporate different psychosocial interventions to improve patients' quality of life (Zimmermann-Schlegel et al., 2017; Senf et al., 2019).

In this context, it is easy to imagine the potential threats of the COVID-19 outbreak on the psychological well-being of cancer patients.

Currently the radiotherapy community is focused on providing responses to face the different issues of this critical period (Coles et al., 2020; Grassi et al., 2020; Guckenberger et al., 2020; Rinaldi et al., 2020; Scorsetti et al., 2020; Zaorsky et al., 2020), but the management of psychological disorders has not been evaluated yet.

This work aims at the prevalence of mood disorders (anxiety, distress, and depression) for cancer patients undergoing radiation therapy during the COVID-19 outbreak in comparison with patients treated in 2019.

## MATERIALS AND METHODS

### Population

The Institutional Review Board (IRB) approved the survey and protocol.

Patients undergoing RT were prospectively enrolled in the present study in two-time points (once a week for a month in May 2019) and during the COVID-19 outbreak (once, in April 2020).

Inclusion criteria were as follows: written informed consent concerning treatment risk, psychological test agreement, and age > 18 years.

### Procedure

In the two time periods chosen, all the patients that underwent radiotherapy on the days when the tests were collected (once a week for a month for time point 1 and once for period 2) were included in the present evaluation. During treatment all the patients are visited every week from the clinician, in order to evaluate acute toxicity and radiotherapy side effects. Before the visit, the patients performed a self-administered psychological evaluation according to the described instruments. Demographic and clinical variables registered were sex, age, disease, and week of radiation treatment.

### Instruments

Three validated patient-reporting tests were used: the State version of anxiety inventory scale (STAI-Y1), the Symptom

**TABLE 1 |** Characteristics of the two cohorts of timepoints.

Parameters	Time point 1 (Pre Covid-19)	Time point 2 (Covid-19 Outbreak)	Statistical analysis (Chi-square test)
<b>Sex</b>			
Males	181 (47.6%)	39 (50%)	$p:0.711$
Females	199 (52.4%)	39 (50%)	
<b>Age</b>			
<50 years	50 (13.2%)	13 (16.7%)	$p < 0.001$
50–70 years	192 (50.5%)	58 (74.4%)	
>70 years	138 (36.3%)	7 (9%)	
<b>Disease</b>			
Gastrointestinal	51 (13.4%)	6 (7.7%)	$p:0.543$
Brain	39 (10.3%)	6 (7.7%)	
Breast	121 (31.8%)	30 (38.5%)	
Lung	15 (3.9%)	6 (7.7%)	
Prostate	58 (15.3%)	13 (16.7%)	
Head and Neck	66 (17.4%)	12 (15.4%)	
Other/Palliative	30 (7.9%)	5 (6.4%)	
<b>Week of treatment</b>			
First week	87 (22.9%)	20 (25.6%)	$p:0.659$
Other	293 (77.1%)	58 (74.4%)	

Distress Thermometer (SDT), and the Beck Depression Inventory vers.2 (BDI-2).

The STAI-Y1 is a self-report measure with 20 items to assess state anxiety, with each item evaluated on a 4-point Likert scale. A cutoff point of 40 has been suggested to detect clinically significant symptoms for scale (Knight et al., 1983; Julian, 2011).

The SDT is an 11-point scale with endpoints labeled “no distress” (0 points) and “extreme distress” (10 points) (Distress Management, 2003).

For SDT, a cutoff point of 4 was chosen, based on the scores of the Hospital Anxiety and Depression Scale and Brief Symptom Inventory 18 (Jacobsen et al., 2005).

The BDI-2 is a validated tool for patient mood assessment and has been developed to investigate the presence and degree of depressive symptoms.

The BDI-2 is a 21-item self-administered questionnaire, with each response scored on a scale of 1–3. All the scores are summed to give the BDI score. A BDI-2 score of 0–13 indicates minimal symptoms, 14–19 mild symptoms, 20–28 moderate symptoms, and 29–63 severe symptoms (Beck et al., 1996).

### Statistical Methods

Differences in patients' characteristics (sex, age, disease, week of treatment) between the two time points were evaluated with the Chi-square test in order to compare the two cohorts of patients (see Table 1).

### Univariate Analysis

The three scales were analyzed as continuous data. Student's *t*-test was used in univariate analysis to assess differences in

scales according to patient-specific variables (sex, age, week of treatment) and between the two timepoints (pre and during COVID-19).

A sensitivity analysis was performed considering the three scales as categorical items with cut-offs corresponding to those indicated for each instrument. Chi square test was used to assess association with the two timepoints.

### Multivariate Analysis

All the parameters (sex, age, week of treatment, COVID timepoint) were considered in a linear regression analysis with a stepwise method. For the linear regression analysis, the nominal parameter “disease” was categorized as a dummy variable.

The three scales were considered dependent variables and the parameters sex, age, week of treatment, disease, and timepoints were considered as independent variables.

A two-tailed  $p$ -value  $< 0.05$  was considered statistically significant.

All the statistical analysis was performed on SPSS v.23.0.

## RESULTS

### Population

We included 458 patients (220 males and 238 females), with a median age of 64 years (mean 63,9 years, range 29–88 years), tested before COVID-19 (380 patients, 83%) and during the COVID-19 outbreak (78 patients, 17%) (see **Table 1** for the characteristics of enrolled patients).

The two cohorts of patients showed a significant difference in terms of age, probably due to the selection of patients during the COVID-19 outbreak.

### Instruments

STAI-Y1 mean score was 41.3 (standard deviation 10.89), with 227 patients (49.6%) showing a STAI-Y1  $< 40$ .

SDT mean score was 4.6 (standard deviation 2.55), with 211 patients (46.1%) showing a low anxiety score on SDT ( $< 4$ ).

BDI-2 mean score was 13.8 (standard deviation 10.10). A total of 297 patients were categorized as minimal score (64.8%), 80 as mild score (17.5%), 46 as moderate score (10%), and 35 as severe score (7.6%).

Differences were found in all three scores between the two timepoints, highlighting the worsening of mood disorders during the COVID-19 pandemic (see **Table 2**).

### Univariate Analysis

A linear regression model was used to evaluate the association between each instrument and the other variables considered.

STAI-Y1 was correlated with the COVID-19 outbreak ( $p < 0.001$ ) being higher post COVID-19 outbreak, sex ( $p:0.016$ ) being higher for female patients, and week of treatment ( $p:0.012$ ) being higher in the first week of treatment.

SDT, similarly, was correlated with the COVID-19 outbreak ( $p < 0.001$ ), sex ( $p < 0.001$ ), and week of treatment ( $p:0.036$ ).

BDI-2, finally, was correlated with the COVID-19 outbreak ( $p:0.005$ ) and sex ( $p: 0.013$ ).

**TABLE 2 |** Differences among the three tests in the two cohorts of timepoints.

Parameters	Time point 1 (Pre Covid-19)	Time point 2 (Covid-19 Outbreak)	P-value*
<b>STAI-Y1</b>			
<b>(Continuous data)</b>			
Mean	40.24	46.51	$p < 0.001$
Standard Deviation	10.39	11.82	
<b>SDT</b>			
<b>(Continuous data)</b>			
Mean	4.35	5.88	$p < 0.001$
Standard Deviation	2.50	2.42	
<b>BDI-2</b>			
<b>(Continuous data)</b>			
Mean	13.27	16.7	$p:0.005$
Standard Deviation	10.02	10.06	
<b>STAI-Y1</b>			
<b>(Categorical)</b>			
$< 40$	216 (56.8%)	29 (37.2%)	$p: 0.0015$
$\geq 40$	164 (43.2%)	49 (62.8%)	
<b>SDT</b>			
<b>(Categorical)</b>			
$< 4$	184 (48.4%)	27 (34.6%)	$p: 0.025$
$\geq 4$	196 (51.6%)	51 (65.4%)	
<b>BDI-2</b>			
<b>(Categorical)</b>			
Minimal score	262 (68.9%)	35 (44.9%)	$P < 0.001$
Mild score	57 (15%)	23 (29.5%)	
Moderate score	33 (8.7%)	13 (16.7%)	
Severe score	28 (7.4%)	7 (9%)	

\*P-value was relative to Student's t-test for continuous variables and chi-square test for categorical items.

### Multivariate Analysis

Multivariable linear regression analysis showed that all the significant parameters associated with STAI-Y1 also maintained their significance when considered in the same model: COVID-19 outbreak ( $p < 0.001$ ), week of treatment ( $p: 0.001$ ), and sex ( $p: 0.015$ ).

For SDT, similarly, the only significant parameters are COVID-19 ( $p < 0.001$ ), disease ( $p:0.001$ ), and sex ( $p:0.004$ ). The diseases that showed a higher SDT were brain cancer, head and neck cancer, and lung cancer, whereas all the remaining cancer diseases showed a lower SDT (see **Figure 1**).

For BDI-2 the only significant parameters remain COVID-19 outbreak ( $p: 0.004$ ) and sex ( $p:0.011$ ) (see **Table 3; Figure 1**).

## DISCUSSION

The psychological distress related to the diagnosis of cancer can be devastating for the patients and their relatives (Lim et al., 2013), with responses that include denial of the diagnosis, fear of death, fear of recurrence of cancer, concerns about body image,

**TABLE 3** | Linear regression analysis was used to correlate all the variables with the test STAI-Y1, SDT, and BDI-2.

Dependent (Linear regression)	Parameter	p-value	B
<b>STAI-Y1</b>	(constant)		
	<b>Covid-19</b>	<b>&lt;0.001</b>	0.24
	<b>Week of treatment</b>	<b>0.001</b>	-0.15
	<b>Sex</b>	<b>0.015</b>	0.10

	Disease	0.565	-0.03

*Bold values are significant parameters.*

as well as impacts on sexuality, relationships, and lifestyle (Zabora et al., 2001; Schouten et al., 2019).

A mood disorder may be part of the reaction to the news of a cancer diagnosis, but in many patients it will persist, causing an additional burden of disease (Hopwood and Stephens, 2000).

Conversely, the illness itself or the cancer treatments may lead to a radical modification of patients' everyday life activities, especially in cases of advanced illness (Zaza et al., 2005). These conditions can have a relevant impact on patients' quality of life (Tang et al., 2017) and eventually induce mood disorders such as psychological distress, anxiety, and depression (Andersen et al., 1984; Andersen and Tewfik, 1985; Stiegelis et al., 2004; Bradt and Dileo, 2010).

Cancer patients undergoing radiotherapy represent an even more fragile population that is associated with increased levels of anxiety and depression that is often under-detected and undertreated (Stiegelis et al., 2004), as frequently this population of patients has not regained the optimal psychological and physical conditions from previous treatments (de Graeff et al., 2000; Monga et al., 2005). A significant percentage of radiotherapy patients, in fact, is subjected to different types of therapies in the previous months (such as surgery possibly followed by chemotherapy in a subset of breast cancer patients, induction chemotherapy in a subset of lung or head and neck cancer, and so on).

At the same time, early alarming reports have suggested that patients with cancer seem more likely to develop severe COVID-19 (Liang et al., 2020), and patients undergoing radiotherapy are also required to make daily visit hospitals for some weeks, with an increased risk of contagion.

Salari et al. have recently performed a meta-analysis to investigate the prevalence among the general population of

stress, anxiety, and depression (Salari et al., 2020). The authors found that the prevalence of these disorders was, respectively, 29.6, 31.9, and 33.7%, so it is essential to develop psychological interventions to improve the mental health of the population during the pandemic. Xiong et al., in a similar study, found that the risk factors associated with the mood disorders include female gender, younger age (<40 years), presence of chronic illnesses, student status, and frequent exposure to press news concerning COVID-19 (Xiong et al., 2020).

Vindegard et al., conversely, investigated the consequences of COVID-19 on mental health and found lower psychological well-being and higher scores of anxiety and depression vs. before the pandemic, with no differences among the initial phases of the outbreak to a month later (Vindegard and Benros, 2020). Poor self-related health was, again, recognized as a risk factor with higher risk of mood disorders.

The points just discussed can shed light on our results which show that during the critical period of the COVID-19 outbreak patients undergoing RT develop increased depression, anxiety, and distress, according to all the tests used.

The incidence of depression in cancer patients varies considerably among the different studies, ranging from 7 to 49% (Derogatis et al., 1983; Jenkins et al., 1998; Kai-hoi Sze et al., 2000; Pascoe et al., 2000).

Hahn et al. performed a routine screening for depression in radiation oncology patients and they found that only 15% of patients endorsed significant depressive symptoms (Hahn et al., 2004). Conversely, Kawase et al. investigated a homogeneous cohort of 172 patients with early-stage breast cancer and found that 42% of the patients showed depressive disorder (Kawase et al., 2012).

Alacacioglu et al. also investigated depression and anxiety levels in cancer patients and discovered that nearly half of the patients showed mild and severe depression (respectively 29.1 and 18.2%) (Alacacioglu et al., 2013). Both depression and anxiety were higher in women, in people with low socioeconomic level, and in patients with a relapsing disease.

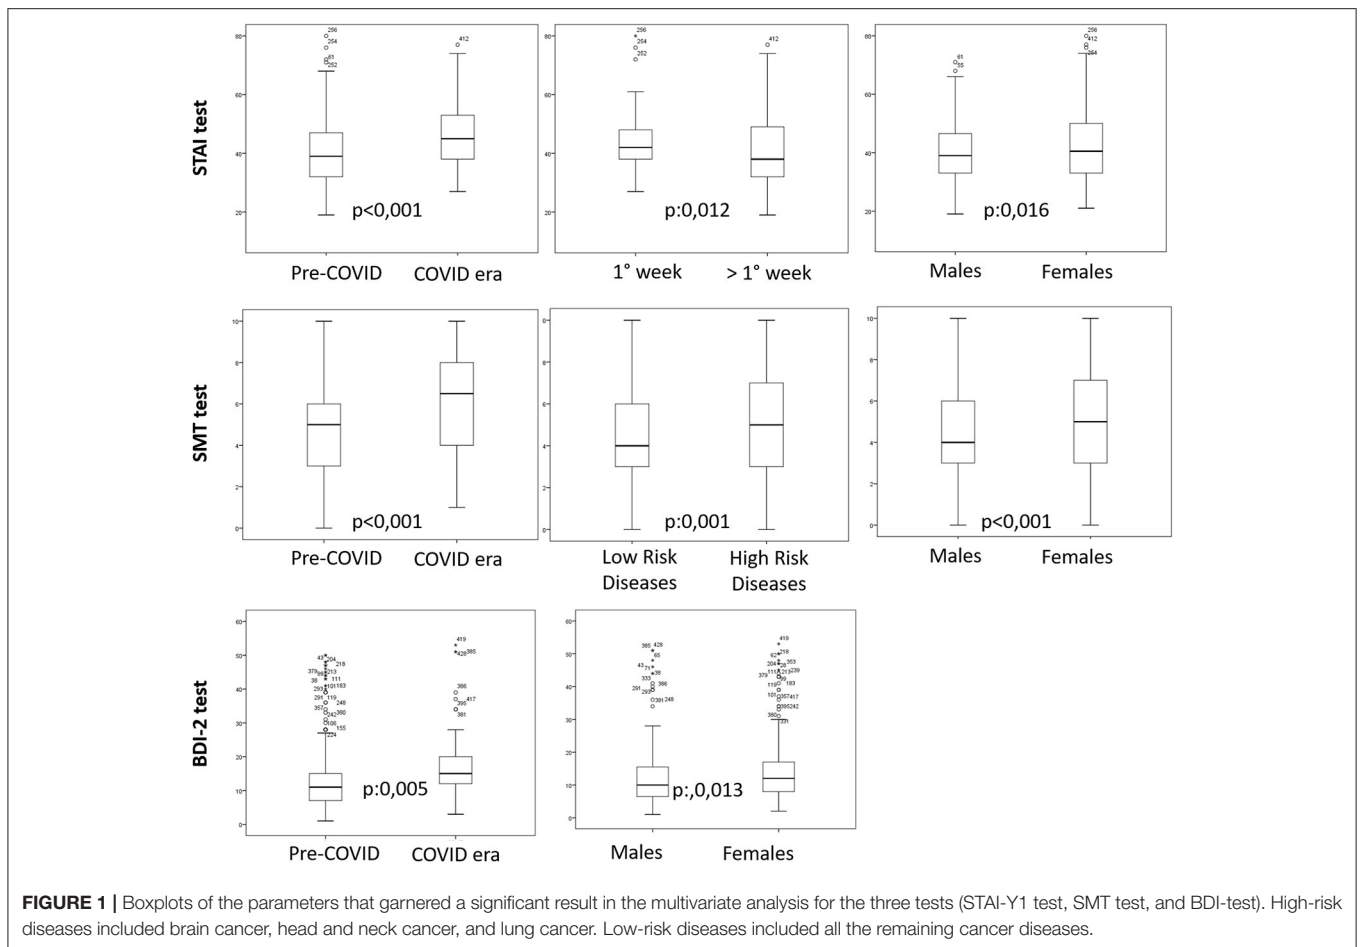

Katz et al., conversely, investigated the depression in head and neck cancer patients undergoing radiotherapy and found that the prevalence of Major and Minor Depression was 20% (Katz et al., 2004).

The RTOG 0841 trial has recently investigated the use of screening for depression in cancer patients receiving radiotherapy in a multi-institutional setting (Wagner et al., 2017). The cohort of patients included 455 patients with different diseases; 75 patients (16.5%) exceeded screening cut-offs for depressive symptoms and were further investigated.

Our results, thus, are consistent with the literature, although the prevalence of depression among cancer patients is variable among the different studies, due to the choice of tests adopted and the differences in the cohorts of analyzed patients.

In regard to anxiety, a review of RT studies indicated that a significant percentage of patients showed clinically significant levels of anxiety at the initiation of RT (Stiegelis et al., 2004; León-Pizarro et al., 2007; Halkett et al., 2016).

Literature has also demonstrated that anxiety due to RT is ranked first among the factors influencing patients' adherence

to treatment (Dragomir and Fodoreanu, 2013; Ho et al., 2013; Hyphantis et al., 2013).

Voigtmann et al. have investigated anxiety in a cohort of 240 patients undergoing RT, and found that 28% of the patients scored in the pathological or borderline anxiety range (Voigtmann et al., 2010).

Nixon et al. have recently investigated the anxiety due to the immobilization mask used for RT in head and neck cancer patients and found that females were more likely to experience higher mask anxiety (Nixon et al., 2019). The population of the patients analyzed in our study show a big proportion of patients with brain cancer and head and neck cancer (123 pts, 26.8%), thus explaining the high anxiety levels in the study.

Marital status, conversely, is not correlated with the development of anxiety (Nieder and Kämpe, 2018), whereas Shimotsu et al. have classified specific types of anxiety, respectively due to adverse effects of RT, the environment of RT, and treatment effects of RT (Shimotsu et al., 2010).

In this regard, Mullaney et al. have correlated the department's psychosocial climate and treatment environment on patients' anxiety during radiotherapy, and found that both these aspects significantly impact anxiety levels (Mullaney et al., 2016).

The other parameters that are correlated with mood disorders are sex, week of treatment, and disease.

Female patients show more anxiety than male patients, in accordance with previous studies (Dunn et al., 2012). Increased anxiety levels in some specific diseases (head and neck cancer, brain cancer, and lung cancer) may be due to the more severe conditions and to the use of immobilization systems such as masks, as previously reported.

Finally, patients show increased anxiety at the beginning of the RT, whereas the anxiety levels tend to decrease in the following week. This trend is in line with the literature (Dunn et al., 2012).

## Limitations

This study must recognize several limitations. First of all, the study utilized a small group from a single institution. In addition, worries about identification and potential medical insights may have induced participants to score low on tests.

All cancer patients were tested before the COVID-19 outbreak to obtain basal values and to explore different strategies with the aim to improve radiation therapy workplace cultures, such as medical humanities programs and music therapy (Vinciguerra et al., 2019; Nardone et al., 2020).

The basal test has allowed a first and unprecedented measurement of the real effects of COVID-19 outbreak in cancer patients.

Finally, it is important to underline that this study was conducted after the peak period of the COVID-19 outbreak, at the end of April. Future research is required in different institutions at different time points. At the same time, it is pivotal to follow up with the analyzed population.

## CONCLUSIONS

Cancer patients have shown a significant increase in anxiety and depression due to the COVID-19 outbreak.

Multi-institutional prospective evaluation is needed to confirm these data and to develop proper strategies in order to mitigate the increase.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

Nation-wide community quarantines and social distancing are part of the new normal because of the global COVID-19 pandemic. Since extensive and prolonged lockdowns are relatively novel experiences, not much is known about the well-being of individuals in such extreme situations. This research effort investigated the relationship between well-being elements and resiliency of 533 Filipino adults who were placed under the nationwide enhanced community quarantine (ECQ) during the COVID-19 pandemic. Participants comprised of 376 females (70.56%) and 157 males (29.45%). The median and mode ages of the participants is 23 years, while 25 is the mean age. PERMA Profiler was used to measure participants' well-being elements, while Connor-Davidson Resiliency Scale-10 (CD-RISC-10) was used to measure their resiliency. Collected data were analyzed using the regression model and necessary condition analysis. This study corroborated that all the five pillars of well-being are significant positive correlates of resiliency ( $p < 0.00$ ) in quarantined adults. The results shown accomplishment ( $\beta = 0.447$ ,  $p < 0.01$ ) positively predicts resiliency, while negative emotions ( $\beta = -0.171$ ,  $p < 0.00$ ) negatively predict resiliency. Lastly, the five pillars of well-being are necessary-but-not-sufficient conditions (ceiling envelopment with free disposal hull, CE-FDH  $p < 0.00$ ) of resiliency. Our results cast a new light on well-being elements as constraints rather than enablers of resiliency. This novel result shows that optimum resiliency is only possible when all the five pillars of well-being are taken care of and when a person is at least minimally contented with their physical health. The present findings underscore the importance of a holistic as against an atomistic approach to maintaining good mental health, which suggests that deficiencies in certain areas of well-being may not be fully addressed by overcompensating on other areas, as all five pillars of well-being are necessary-but-not-sufficient conditions of resiliency. The study ends with the recommendation for the use of necessary condition analysis to study both classical and novel psychological research problems.

## THE IMPORTANCE OF WELL-BEING ON RESILIENCY OF FILIPINO ADULTS DURING THE COVID-19 WHO ARE COMMUNITY QUARANTINED

The infectious Coronavirus disease (COVID-19), which causes respiratory illness includes flu-like symptoms such as cough, fever, and in more severe cases, breathing difficulties. COVID-19 is mainly spread through contact with an infected person who sneezes or coughs. It can be acquired when a person touches their eyes, nose, or mouth after touching objects or surfaces that have the virus on it (World Health Organization, 2020). Starting December 2019, countries imposed travel bans and asked individuals who have possibly been exposed to the contagion to isolate themselves in a dedicated quarantine facility or at home (Brooks et al., 2020) at an unprecedented scale. The Philippines reported its first case of COVID-19 on January 30, 2020. Since then, the number of reported cases exponentially increased by the day (ABS-CBN Investigative and Research Group, 2020). As of December 12, 2020, 447,039 infected cases were reported throughout the country. Of the total number of cases, 409,329 have recovered, and 8,709 have died (Department of Health, 2020).

As a response to the growing threat of the pandemic, the entire Luzon was placed under enhanced community quarantine (ECQ; Medialdea, 2020). Shortly, both Visayas and Mindanao followed suit. The said measure involves draconian restrictions: that include the establishment of checkpoints in most cities; the suspension of classes in all levels; the prohibition of mass gatherings; the temporary shutting down of non-essential businesses; the banning of public utilized utility vehicles; and the strict implementation of home isolation. Although it was initially planned to end on April 12, 2020 (Abueg, 2020), several subsequent recommendations both from the national and local governments extended the nationwide community quarantine until December 31, 2020 (CNN Philippines Staff, 2020). As the nation's Gross Domestic Product (GDP) shrank 16.5% in the second quarter of 2020, the Philippines officially entered recession as an effect of the extended quarantines (Agence France-Presse, 2020). While quarantine is often among the initial responses against an emerging infectious disease (Parmet and Sinha, 2020), it is often unpleasant for those who are required to submit to it and may lead to several harmful conditions for some persons (Hawryluck et al., 2004; Brooks et al., 2020). Hence, the psychological effects of quarantine have received considerable attention. Barbisch et al. (2015) reported that losing autonomy, isolation away from loved ones, uncertainty, and boredom could lead to adverse effects on an individual's well-being. Following the imposition of cordon sanitaire in previous outbreaks, substantial anger, anxiety and even an increase in suicide rates have been reported (Brooks et al., 2020). Similarly, the National Center for Mental Health (NCMH) in the Philippines reported that depression and other mental health issues were on the rise after imposing ECQ in different provinces in the country (Tenorio, 2020).

## WELL-BEING AND ITS ELEMENTS

It is important to note that while quarantines are often unpleasant, their effect on people diverge. While there are individuals who experience mental health issues, there are also those who are more resilient and can move on with their lives. This highlights the importance of studying not only how individuals suffer in light of community quarantines, but also how they cope, and even flourish in the face of such challenging times. Seligman (2011) argued that even in difficult situations, human beings are motivated to thrive and not just merely survive. According to Fredrickson and Losada (2005), flourishing means living "within an optimal range of human functioning, one that connotes goodness, generativity, growth, and resilience." Based on this definition, resilience appears to arise from flourishing. Well-being predicts resiliency. For clarity, the terms "flourishing," "thriving," and "well-being" are used interchangeably in the literature (Butler and Kern, 2016). Therefore, we also use the terms interchangeably here.

Well-being Theory of Seligman (2011) advocates that flourishing arises from five well-being pillars-Positive Emotion, Engagement, Relationships, Meaning, and Accomplishment, hence PERMA. It is important to note that no single element defines well-being, but each contributes to it. Positive emotions include an extensive variety of feelings, which include excitement, satisfaction, pride, and awe. Previous reviews highlight the important role of these emotions in positive life outcomes (Butler and Kern, 2016). Engagement involves activities that stimulate and develop upon an individual's interests. Csikszentmihalyi (2009) argues that true engagement leads to a state of deep and effortless involvement where an individual is completely absorbed in an activity that often leads to a sense of joy and lucidity. Relationships are social connections important in stimulating positive emotions. They can either be work-related, familial, romantic, and even platonic. The experiences that contribute to well-being are often amplified through our relationships. Positive relationships have been linked to positive outcomes such as better physical health, healthier behaviors, less psychopathology, and lower mortality risk (Tay et al., 2013). A sense of meaning is derived from having a direction in life, belonging to a cause larger than the self, and serving a purpose greater than one's immediate needs (Steger, 2012). Such activities provide a sense that life is valuable and worthwhile. Various societal institutions such as religion, politics, justice, and community social causes enable a sense of meaning. Accomplishments are pursuits toward and reaching goals, mastery, and efficacy to complete tasks (Butler and Kern, 2016) in various domains such as the workplace, in sports and games, and even in hobbies and interests. Seligman (2011) argued that people pursue accomplishments even when they do not result in positive emotions, meaning, or relationships. Although PERMA was developed mainly within the Western context, several researches found that PERMA is experienced in culturally consistent manners in non-Western societies such as the United Arab Emirates (Lambert and Pasha-Zaidi, 2016), Hong-Kong (Lai et al., 2018), and the Philippines (Nebrida and Dullas, 2018).

## DEFINING RESILIENCE

Over the past decade, resilience has become a popular concept in both research and clinical practice (Kumpfer, 2002; Walsh-Dilley and Wolford, 2015). Despite the lack of consensus in how it is defined (Vella and Pai, 2019), it is accepted that resilience involves the positive adaptation following a stressful or adverse experience (Porterfield et al., 2010). Most definitions acknowledge two key points about resilience (Herrman et al., 2011). First, is that various factors interact with it. For example, personal characteristics such as personality traits (Oshio et al., 2018), self-esteem (Karatat and Cakar, 2011), and even age (Diehl and Hay, 2010) influence resilience. Social and community factors (Harms et al., 2018) such as secure attachments, the presence of a role model (Levine, 2003), family stability (Grubman, 2018), and culture (Ungar, 2008) affect the ability to cope with daily struggles. Second, resilience is time and context-specific and may not be present across all life domains. Resilience appears to be receptive to the influence of specific situations (Hayman et al., 2017) such as unique stressors (Jex et al., 2013) like war and other happenstances (Besser et al., 2014).

While the aforementioned literature provides key insights into the definition, factors, and contexts of resilience, most research focuses on factors are outside the control of the individual. While these researches are important in explaining the development of resilience, they lack emphasis on positive mechanisms, which are behaviors a person can perform to facilitate resilience. While resilience has been studied both in daily and unique stressors, none focused on the novel situation of wide range community quarantines. Therefore, despite the abundance of resilience-related research, the question remains “What positive mechanisms are involved in the resilience of people who are subjected to quarantine?”

## THE PRESENT STUDY

In this paper, we introduced a novel approach in understanding the necessary but not sufficient nature of the aforementioned positive aspects of well-being in predicting resiliency. We used Dul (2016) Necessary Condition Analysis (NCA), which seeks to identify necessary-but-not-sufficient conditions in data sets (Dul, 2018). A necessary condition is a crucial factor in an outcome. If it is not in place, the outcome will not be achieved, but its sole presence does not guarantee that the outcome will be obtained. Without the necessary condition, however, there is a certain failure, which may not be compensated by other determinants of the outcome. Necessary (but not sufficient) conditions widely exist in real-life. For example, the novel SARS-CoV-2 coronavirus is a necessary-but-not-sufficient condition for COVID-19 (World Health Organization, 2020). Without SARS-CoV-2 coronavirus, an individual will not acquire COVID-19. However, even with SARS-CoV-2 coronavirus, an individual may or may not acquire COVID-19. In the same light, a college student who wants to pass the course, Introduction to Psychology (the outcome) needs to attend 80% of lecture hours (necessary conditions). However, attending class regularly does not guarantee

passing the course as other requirements (examinations, seat-works, research work, and journal critique paper) play a role in a student's grade. Yet, if the student incurs too many absences and tardiness, failure is guaranteed. As seen in the aforementioned examples, necessary causes are not automatically sufficient. They can be seen as constraints, barriers, or obstacles one needs to deal with to arrive at the desired outcome.

While well-being and resiliency are closely related concepts (Hu et al., 2015) *Flourishing* model of Seligman's (2011) perceives resiliency as the result of both “surviving” and “thriving” psychological characteristics. This theoretical relationship between well-being and resilience has gained empirical support in recent years (Harms et al., 2018). For example, Martínez-Martí and Ruch (2017) and Burns and Anstey (2010) demonstrated that measures of well-being are not simply redundant with self-report scales of resilience. At the same time, while the relationship between these two concepts are robust, it is rarely straightforward (Harms et al., 2018). Interestingly, some researchers (Fredrickson et al., 2003; Tugade and Fredrickson, 2004; Ong et al., 2006, 2010; Kuntz et al., 2016) argued that optimal levels of PERMA elements predict resilience in normal sample.

In the light of the foregoing, the present study aims to investigate how PERMA predicts the resiliency of community quarantined individuals. An explanation of possible necessary-but-not-sufficient conditions of resiliency during quarantine may have both theoretical and practical value. Theoretically, an investigation of this sort allows the advancement of our understanding of how a multitude of variables coalesces to produce resiliency in times of quarantine and social isolation. This is significant as wide-range and prolonged quarantines are relatively novel experiences. Hence, not much is known about its psychological implications for human beings. Psychological interventions may target different necessary-but-not-sufficient variables jointly. Because of NCA's ability to identify *bottleneck* variables (Dul, 2019a), conditions that must be present for resiliency to be possible, interventions may prioritize bottleneck variables of resiliency to maximize the use of limited resources. Lastly, identifying necessary-but-not-sufficient conditions for resiliency may also help individuals who are quarantined to develop their understanding of the behaviors they need to engage to have resiliency. Following this logic, we hypothesize that:

*H<sub>01</sub>*: PERMA elements predict the resiliency of the community-quarantined individuals.

*H<sub>02</sub>*: PERMA elements are necessary, but not sufficient conditions, for the resiliency of the community-quarantined individuals.

## METHODOLOGY

### Research Design

To test the assumption that PERMA elements are both sufficient and necessary conditions of resiliency in community quarantined individuals, sufficiency and necessity observational design were used concurrently. In these designs, the conditions (PERMA)

and the outcome (resiliency) are observed in real-life context and without the manipulation of the condition. While sufficiency and necessity observational research designs follow the same data gathering procedures, they diverge in data analysis. Dul (2016) argued that NCA is a complement to traditional approaches to analyze relations. As in our research, by using multiple regression we could spot determinants that contribute to resiliency, whereas NCA allowed us to spot critical determinants (constraints) that prevent resiliency from developing. These bottlenecks, when present, prevents resiliency from occurring even when we increase the values of other determinants unless we take away the bottlenecks by increasing the value of the critical determinant. NCA lead us to discover critical determinants that were not part of the determinants identified with the regression model. Using both approaches is critical in adequately understanding the resiliency of individuals who are subjected to the extended ECQ.

## Research Participants

Because of the restrictions in both mobility and social interactions as direct consequences of the nationwide ECQ, we used purposive – convenience sampling to recruit Filipino Facebook users who reside in communities placed under the ECQ. The survey was promoted through social media, primarily on Facebook. A total of 541 participants responded to our online survey *via* Google Form. The minimum age reported was 16 years old, while the maximum age was 64 years old with a median of 23. Because resiliency scores are contingent to age, only those whose ages ranged between emerging adulthood to early middle adulthood (18–40) were included in the study.

## Inclusion Criteria

Participants that were considered to partake in the research met the following criteria: first, a participant must be aged 18 to 40 years old. Second, he/she resides in a quarantined area in the Philippines. Third, a participant must be a Filipino citizen as social and cultural factors influence resiliency.

## Exclusion Criteria

A participant was excluded in the research because of the following conditions: first, a participant aged less than 18 years old and over 40 years old, a participant who refused to completely answer the online survey questionnaires, and a participant who does not reside in a quarantine area in the Philippines.

## Ethical Considerations

In dealing with the participants, respect and protection of the privacy of the participants were prioritized. Thus, privacy and anonymity was of paramount importance. Also, voluntary participation of the chosen participants for said the study was important. Participants had the right to withdraw from the study at any phase of the research if they wished to do so.

Potential participants were fully informed regarding the research, full consent was essential and obtained from the participants. The first page of the online questionnaire required

participants to check a box to show consent before having access to the survey. The principle of informed consent involved the researchers providing sufficient information and assurances about taking part to allow potential participants to understand the implications of participation and to reach a fully informed, considered, and freely decided about whether to do so, without the exercise of any pressure or coercion. No incentives were provided in return for their participation.

In collecting data through online surveys, we minimized intrusions on privacy, anonymity, and confidentiality. Before data collection, an adequate level of confidentiality of the research data was ensured to the participants to make them feel secured and protected with the information they shared or contributed. Also, any communication about the research was observed with respect and transparency. Ultimately, research participants are not subjected to harm.

## Research Instruments

Google Forms was used to gather sociodemographic variables from the sample and deliver the following self-administered scales, which were used to measure the variables of the current study. Specifically, we used the Connor-Davidson Resiliency Scale-10 (CD-RISC-10) to measure their resiliency, and the PERMA Profiler to measure participants' well-being elements.

## Connor-Davidson Resiliency Scale

The CD-RISC-10 is a 10 item scale that is used to measure resiliency, operationally defined as the ability to “thrive in the face of adversity” (Connor and Davidson, 2003). The unidimensional CD-RISC-10 evaluates several components of psychological pliability: the abilities to adapt to change, manage what comes along, handle stress, stay focused and think clearly, avoid getting discouraged in the face of failure, and handle unpleasant emotions such as pain, sadness, and anger (Campbell-Sills and Stein, 2007). Each item is rated on a five-point range of responses. The total score is computed by getting the sum of all the responses whereby higher scores show high resilience (Scali et al., 2012). Campbell-Sills et al. (2009) maintained that CD-RISC-10 has a median score of 32 with lowest to highest quartiles of 0–29 (Q1), 30–32 (Q2), 33–36 (Q3), and 37–40 (Q4) in general sample. As a widely used scale, CD-RISC-10 has achieved remarkable internal consistency of 0.89 in general population samples. It is both valid and reliable within the context of different cultures, including Filipino samples (Campbell-Sills and Stein, 2007).

## PERMA Profiler

The PERMA Profiler is a brief scale that measures the five pillars of well-being: positive emotion, engagement, positive relationships, meaning, and accomplishment, together with negative emotions and health (Butler and Kern, 2016) along a 10-point Likert type scale. Of the 23 items, 15 correspond to the five core elements of well-being (three items per PERMA domain). In addition, eight items were included to test negative emotions (three items), physical health (three items), loneliness (one item), and overall well-being (one item). All items are

expressed positively and higher scores denote better well-being except for negative emotions. Subscale scores are calculated by getting the mean of the three items on each subscale, except for loneliness. Overall well-being is calculated by averaging all items except those from the negative emotions subscale. The measure has been used in various samples and was found to have sufficient psychometric properties (Cobo-Rendón et al., 2020). Butler and Kern (2016) reported that adequate reliability is observed for overall well-being and all subscales,  $\alpha$  range from 0.71 to 0.94 across eight studies ( $N = 31,966$ ). According to Nebrida and Dullas (2018), the Tagalog version of the PERMA Profiler has a Cronbach's alpha of 0.842 in 101 Filipino participants.

In the current study ( $n = 533$ ), both PERMA Profiler ( $\alpha = 0.927$ ) and CD-RISC-10 ( $\alpha = 0.915$ ) have an "excellent" internal consistency. These results confirm that the scales are reliable tools for measuring elements of Well-being and Resiliency, respectively, in our sample.

## Data Gathering Procedures

Data gathering lasted from March 23 to April 10, 2020, during the first reset of the nationwide extended ECQ. After securing individuals' interest to take part in the study, we sent potential participants a link to the survey *via* Facebook Messenger. The first section of the Google Form shows the title of the research and an overview of the current study. After giving consent, participants could fill out the survey. Participants cannot answer the scales without explicitly agreeing to partake in the study. After securing informed consent, each participant was asked to provide their sociodemographic characteristics and then answer the PERMA Profiler and the CD-RISC-10. Answering both scales did not take the participants more than 20 min. After completing the questionnaire, each participant was virtually debriefed.

At any point, should a participant decide not to proceed with the research, they were free to do so with no implications. All the participant has to do was to close the Google Form window and any previously provided data were not recorded.

Data from Google Form were exported to IBM's Statistical Package for Social Sciences (SPSS) and NCA Software for data analysis.

## Data Analysis

Frequency and percentage were used to analyze the sociodemographic characteristics of the participants. We used Cronbach's alpha to determine the internal reliability of the measuring scales. Correlation and multiple regression analyses were conducted to examine the relationship between PERMA elements and potential predictors of resiliency. Lastly, we used NCA to analyze whether the core elements of well-being are necessary but not sufficient conditions of resiliency.

There are two steps in NCA (Dul et al., 2019), determining ceiling lines and bottleneck tables are the first. Unlike traditional regression models where a line is drawn through the middle of the data in an XY-plot, a ceiling line is created in NCA. This line distinguishes between areas with cases and areas

without cases, the zone found in the upper left-hand corner of the plot. However, exceptions such as outliers and errors may be present in a sample so that the empty zone above the ceiling is not empty (Karwowski et al., 2016). The ceiling line is a non-decreasing line (either a linear step function or a straight line) that shows which level of  $x$  (well-being elements) is necessary but not sufficient in producing the desired level of  $y$  (resiliency).

Dul (2016) identified two techniques in drawing the ceiling line. The first is the non-parametric Ceiling Envelopment with Free Disposal Hull (CE-FDH), which is a piecewise linear line. It is the default ceiling envelopment technique for NCA because it is flexible and intuitive and applies to dichotomous, discrete, and continuous conditions. The second technique is the parametric Ceiling Regression with Free Disposal Hull (CR-FDH), unlike the CE-FDH, this technique smoothens the piecewise linear lines by using a straight line. Because of this, CR-FDH usually has some observations above the ceiling line. Whereas CE-FDH does not. In further comparing the two techniques, CE-FDH is preferred when a straight line does not represent the data because smoothing reduces the size of the ceiling zone as with dichotomous variables and for discrete and continuous variables with relatively low small data sets. CE-FDH is 100% accurate in drawing the demarcation between observations above and observations below the ceiling line.

Quantifying the accuracy of ceiling lines, effect size, and statistical significance of the necessary conditions and necessary inefficiency are the second and final step (Dul et al., 2020). The area of the empty zone above the ceiling line divided by the area where cases would be possible given the minimum and maximum values of  $X$  and  $Y$  is the effect size of a necessary condition (Karwowski et al., 2016). Therefore, large effect size shows lower ceiling line and greater limitations that well-being elements have on resiliency. On the other hand, if there is a lack of empty space in the scatter plot then well-being elements are not contingents of resiliency. The effect size of a necessary condition can take the values between 0 and 1 where 0–0.1 corresponds to a small effect, 0.1–0.3 a medium effect, 0.3–0.5 a large effect, and  $d$  that is greater than 0.5 a very large effect (Tynan et al., 2020). An R package that allows the calculation of various effect size indicators and inferential statistics useful for hypothesis testing is provided by Dul (2016). The NCA null hypothesis is that the observed effect size is the same as the effect size calculated using random data (Dul, 2019b). An estimation of the probability that the observed necessary condition effect size results from comparing two unrelated variables, otherwise known as permutation test, is used to determine statistical significance in NCA (Dul et al., 2020). Observed values of the  $x$  and  $y$  variables are randomly paired without replacement. Such pairing continues until the sample size is reached and the process is repeated at least 10,000. The resultant value of  $p$  is interpreted using traditional thresholds such as  $\alpha = 0.05$  or  $\alpha = 0.01$ . Depending on the context of the research, both significance testing and effect size are useful in determining the theoretical and practical importance of an observed outcome (Tynan et al., 2020). We focus our attention on conditions with both  $d > 0.5$  and  $p < 0.05$ .

SPSS was used to analyze the frequency and percentage of various sociodemographic variables, the scales' reliability, and for generating the Regression Model. R Statistical Software with NCA Package was used to conduct NCA.

## RESULTS

### Profile of the Participants

Participants comprised 376 females (70.56%) and 157 males (29.45%). The median and mode ages of the participants are 23 years, while the mean age is 25. Among the participants 189 (35.46%) were college students, 293 (54.97%) are employed, and 51 (9.57%) are out of work. Lastly, seven (1.31%) participants reported that they had direct contact with someone who was infected with COVID-19, while 100 (18.76%) reside in communities with known COVID-19 cases and 426 (79.92%) have no exposure to the disease.

### PERMA as Predictors of Resiliency

**Table 1** summarizes the descriptive statistics and analysis results of the study. Results revealed that the mean resiliency score of the participants is 24.83, with a SD of 7.22. PERMA elements including overall well-being are positive and significantly correlated with resiliency. Interestingly, a subjective sense of health (feeling good and healthy each day) showed only a weak, albeit significant positive correlation with resiliency. Negative emotions and loneliness are negatively correlated with resiliency.

The multiple regression model with all nine predictors produced  $R^2 = 0.368$ ,  $F(9, 523) = 33.83$ ,  $p < 0.001$  with adjusted  $R^2 = 0.357$ . This means that 36.8% of the variance in resiliency scores is because of the PERMA elements. As seen in **Table 1**, accomplishment ( $\beta = 0.447$ ,  $p < 0.01$ ) and negative emotions ( $\beta = -0.171$ ,  $p < 0.00$ ) are the only elements of PERMA with significant regression weights, showing scores on these elements predict resiliency. However, negative emotions have significant negative weight as compared to with standardized coefficients of  $-0.171$  vs.  $0.477$ .

**TABLE 1 |** Summary statistics, correlations, and coefficient results for regression analysis of study variables.

Variables	Mean	SD	R	Rp	$\beta$	B	p
Resiliency	24.83	7.22					
Positive Emotions	7.13	2.03	0.54	0.00	0.271	0.963	0.25
Engagement	7.36	1.85	0.40	0.00	0.142	0.556	0.44
Positive Relations	7.31	2.06	0.46	0.00	0.126	0.440	0.57
Meaning	7.27	2.10	0.53	0.00	0.239	0.820	0.29
Accomplishment	7.04	1.86	0.55	0.00	0.447	1.85	0.01
Overall Well-being	7.27	1.55	0.57	0.00	-0.583	-2.72	0.54
Health	7.41	1.58	0.261	0.00	0.143	0.66	0.42
Negative Emotions	5.62	2.17	-0.03	0.516	-0.171	-0.57	0.00
Loneliness	5.23	2.87	-0.07	0.96	-0.028	0.573	0.57

R, Pearson correlation coefficient with resiliency; Rp, p value of R; Loneliness and health  $R = -0.211$ , where  $p = 0.001$ .  $\beta$ , standardized beta; B, unstandardized beta; p, probability value of PERMA elements as predictors of resiliency.  $R^2$  of five original PERMA elements including four additional subscales = 0.368.

The multiple regression model of the four confounders between the relationship of PERMA elements and resiliency produced  $R^2 = 0.036$ ,  $F(4, 528) = 4.90$ ,  $p < 0.001$  with adjusted  $R^2 = 0.028$ . It shows that the spread of the confounders is 3.6% between the relationship of the variables. As seen in **Table 2**, only employment status (student, unemployed, and employed) with  $\beta = 0.14$ ,  $p < 0.00$  is a significant predictor of resiliency.

### PERMA as Necessary-But-Not-Sufficient Conditions of Resiliency

The results of NCA on Resiliency show that all five elements of the original Seligman (2011) PERMA are necessary but not sufficient conditions of Resiliency among individuals who are community quarantined as showed by the size of the empty zone in the XY-plots in **Figure 1**. This means that to score 35 in the CD-RISC-10, a score of 1 for positive emotions and engagement, a score of 2 for Positive Relationships, Meaning, and Accomplishment are necessary.

**Figure 2** contains the scatterplots of the four supplementary subscales of Butler and Kern (2016) PERMA Profiler. Only the xy-plot of Overall Well-being (x) and Resiliency (y) has a “moderately sized” empty zone in the upper left corner of the plot. This is not surprising considering that Overall Well-being is the composite score of the five PERMA elements and health score. The scatterplots of Health (x) and Resiliency (y), and Negative Emotions (x) and Resiliency (y) contain discernibly small empty zones. Lastly, the empty zone is absent in the Loneliness (x) – Resiliency (y) scatterplot. This assumes that Loneliness is not a necessary condition of Resiliency as the presence and size of an empty zone is a sign that a necessary condition is present (Dul, 2016).

We summarized the results of the multiple NCA in **Table 3**. The observed accuracy of all variables exceeds arbitrary benchmark of Dul (2018) for the desired accuracy of 95%. Dul suggests the use of CR-FDH for interpreting variables with accuracies above 95%. However, since our variables do not follow a normal distribution ( $p = 0.00$ ) based on One-Sample Kolmogorov-Smirnov Test, we used the non-parametric CE-FDH ceiling line technique. Necessary-but-not-sufficient relationships between Resiliency and the five original PERMA elements and the auxiliary components are observed. The NCA effect size range between  $d = 0.09$  and  $0.12$  based on CE-FDH for the original PERMA elements and  $d = 0.04$  to  $0.12$  on the supplementary elements, excluding Loneliness. According to recommendations, Positive Emotions, Meaning, Accomplishment, and Overall Well-being of Dul (2016) have medium effect

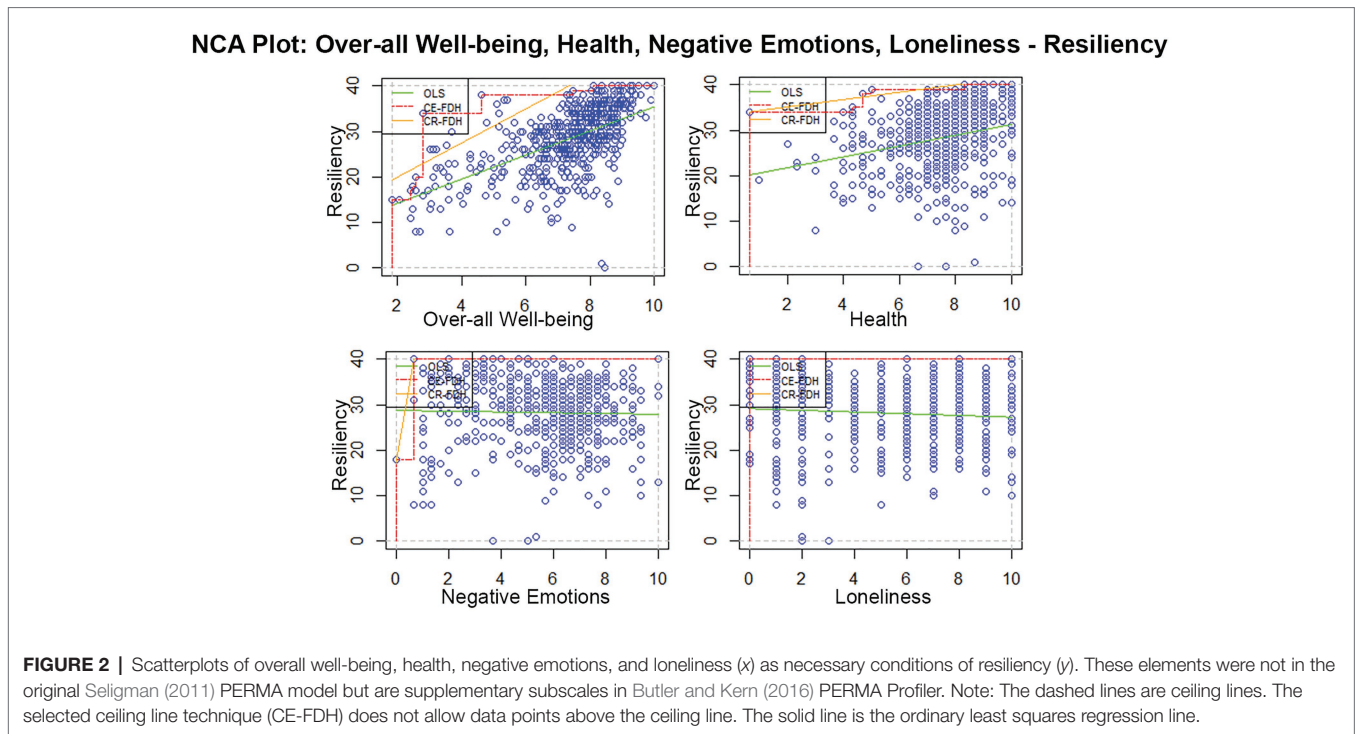

**TABLE 2 |** Confounders between the relationship of PERMA and Resiliency.

Variables	R	$\beta$	B	p
Resiliency				
Gender	0.01	0.02	0.24	0.73
Age	0.14	0.08	0.09	0.08
Exposure to COVID-19	0.01	0.00	0.06	0.93
Employment status	0.17	0.14	1.09	0.00

R, Pearson correlation coefficient with resiliency;  $\beta$ , standardized beta; B, unstandardized beta; p, probability value of confounders with  $p < 0.001$ .

**FIGURE 1 |** Scatterplots of the original PERMA elements (*x*) as necessary conditions of resiliency (*y*). Note: The dashed lines are ceiling lines. The selected ceiling line technique (CE-FDH) do not allow data points above the ceiling line. The solid line is the ordinary least squares regression line.

**FIGURE 2 |** Scatterplots of overall well-being, health, negative emotions, and loneliness (*x*) as necessary conditions of resiliency (*y*). These elements were not in the original Seligman (2011) PERMA model but are supplementary subscales in Butler and Kern (2016) PERMA Profiler. Note: The dashed lines are ceiling lines. The selected ceiling line technique (CE-FDH) does not allow data points above the ceiling line. The solid line is the ordinary least squares regression line.

sizes on Resiliency. Engagement, Positive Relationships, Negative Emotions, and Health have small effect sizes on Resiliency. The NCA significance test is powerful enough to rule out an effect being the product of randomness (Dul et al., 2020). Lastly, there is no necessary-but-not-sufficient relationship between Loneliness and Resiliency.

The ability to identify bottleneck variables (constraints) is a useful feature of NCA, especially for interpreting

multivariate necessary conditions (Dul, 2019b). **Table 4**, which is read horizontally, shows for which level of resiliency, which level of PERMA elements is necessary. For a desired value of resiliency, in the first column, it shows the minimum required values of the PERMA elements in the next columns. Levels are expressed in percentage ranges so that 0 is the minimum value, the maximum is 100, and 50 is the point between these two values.

**TABLE 3 |** Necessary conditions effect size and significance test for PERMA Profiler subscales predicting Connor-Davidson Resiliency Scale-10 (CD-RISC-10) scores.

	CE-FDH	CE-FDH <sub>p</sub>	CR-FDH	CR-FDH <sub>p</sub>	Accuracy (%)	Skewness	Skewness p
Positive Emotions	0.12	0.001	0.15	0.001	98.5	-1.18	0.00
Engagement	0.09	0.001	0.09	0.001	99.4	-1.56	0.00
Positive Relations	0.09	0.001	0.12	0.001	98.9	-1.19	0.00
Meaning	0.12	0.008	0.10	0.008	99.4	-1.21	0.00
Accomplishment	0.12	0.001	0.13	0.001	98.7	-1.37	0.00
Overall Well-being	0.12	0.001	0.17	0.001	97.7	-1.32	0.00
Health	0.07	0.21	0.06	0.27	99.4	-0.45	0.00
Negative Emotions	0.04	0.23	0.02	0.52	100	-0.81	0.00
Loneliness	0.00	1.00	0.00	1.00	100	-0.23	0.00

CE-FDH, ceiling envelopment with free disposal hull; CR-FDH, ceiling regression with free disposal hull. The p value reported was estimated with 10,000 permutations and are treated as significant if <0.05. The threshold for statistical significance is arbitrary but commensurate with the example given by Dul et al. (2020). Accuracy refers to the percentage of observations under the CR-FDH ceiling line. Skewness p is based on One-Sample Kolmogorov-Smirnov Test. Skewness of resiliency scores is -0.78.

**TABLE 4 |** Bottleneck table of PERMA elements as necessary conditions of resiliency based on CE-FDH.

100	75.9	66.7	70.3	83.3	77.8	76.8	6.7	82.1	NN

Re, resiliency; P, positive emotions, E, engagement; R, positive relationships; M, meaning; A, accomplishment; OW, overall well-being; H, health; N, negative emotions; L, loneliness; NN, not necessary.

The bottleneck table shows that no minimum value of any PERMA element is necessary to score 30% in Resiliency. This means that at 30% no PERMA element is a bottleneck for resiliency. However, for a resiliency level of 40%, the minimum required level of Positive Emotions is 6.9%, the necessary level of Accomplishment is 3.7, 7.1% for Overall Well-being, and none of the over PERMA elements are necessary. As observed in the bottleneck table, when Resiliency increases from 0 to 100%, more PERMA elements become necessary, and required levels of the PERMA elements become higher. At 90% level of Resiliency, the necessary level of Positive Emotions is 34.5%, Engagement is 18.6%, Positive Relationships is 25.9%, Meaning is 26.7%, Accomplishment is 25.9%, Overall Well-being is 34.2%, Health is 6.7%, and Negative Emotions is 42.9%. No level of Loneliness is necessary for any level of Resiliency. Not achieving any of these minimum levels means that attaining a 90% level in resiliency is impossible. Since each condition is a bottleneck, scoring higher in other elements does not compensate for the deficiency in others.

## DISCUSSION

Wide range community quarantines and social distancing are elements that are increasingly becoming the new normal as

a result of the global COVID-19 pandemic. Previous research (Hawryluck et al., 2004; Barbisch et al., 2015; Brooks et al., 2020; Parmet and Sinha, 2020) offer invaluable insights into the psychological consequences of restrictions. Moreover, while there has been an interest in the psychological impact of COVID-19 and community quarantine in the Philippines (for example, Nicomedes and Avila, 2020; Tee et al., 2020), most focus on the negative psychological impact of COVID-19. This raises the question of what protective factors are important in the midst of prolonged community quarantines. To test this properly, we used a combination of the traditional regression model and the novel multivariate necessary-but-not-sufficient conditions analysis to investigate how resiliency is contingent on well-being elements in Filipinos who are community quarantined.

Participants of this study were predominantly female, around the age of 23 and who are employed. While, we specifically targeted individuals between the ages of 18–40, most of our sample are emergent adults (mean age = 25, median, and mode ages = 23). The disproportional representation of young adult females can be attributed to several factors. First, previous studies (Smith, 2008; Yetter and Capaccioli, 2010; Slauson-Blevins and Johnson, 2016) have reported that young adult females take part in online surveys at a higher frequency compared with their male counterparts. There are more female Facebook users than males (Lee et al., 2016), which is significant because we invited potential participants through Facebook. Lastly, the Philippines has a young population. The median age in the Philippines is 25.7 (United Nations Statistics Division, 2019; Plecher, 2020). Taken together, it can be assumed that the sociodemographic characteristics of our study are similar to the Filipino Facebook population.

Based on the CD-RISC-10 quartiles for community sample provided by Campbell-Sills et al. (2009), the mean resilience score (24.83) of the current sample belongs to the lowest 25%. This implies that the participants of the current study have lower resiliency scores than the general population. This result ties well with the notion that resilience is stress-context specific (Jex et al., 2013; Wood and Bhatnagar, 2015; Hayman et al., 2017) and that the nature of the sample influences resiliency scores (Connor and Davidson, 2003). Specifically, people with psychiatric problems and those who are experiencing significant

stress score lower than the general population (Li et al., 2012; Ye et al., 2017). In the context of COVID-19, Nicomedes and Avila (2020) found that Filipinos in community quarantine experience significant stress and scored high on both health anxiety and panic.

While resiliency and well-being have become commonplace terms and construct central in positive psychology (Jeste et al., 2015), they are often studied using correlational methods (Schultze-Lutter et al., 2016), and traditional approaches *via* the sufficiency paradigm. In line with previous studies (Souri and Hasanirad, 2011; Khawaja et al., 2017; van Agteren et al., 2018), we found that all elements of well-being are positively correlated with resiliency. Although the multiple regression test shows that among the original PERMA elements, only accomplishment is a significant predictor of resilience. This means that the subjective sense of competence, having a structure each day, i.e., identifying, setting, and achieving daily goals enable resiliency in individuals subjected to quarantine. We also observed that negative emotions significantly, although negatively predict resilience. This suggests the significant predicting function of individuals' tendency to experience anxiety and anger for lower levels of resilience. These findings support the previously reported (Tugade and Fredrickson, 2004; Chen et al., 2018) link between negative emotions and low levels of resilience.

In this paper, we identified elements of well-being that are necessary-but-not-sufficient for resiliency to occur in individuals who are community quarantined. Specifically, Positive Emotions, Meaning, and Accomplishment are significant and moderately necessary conditions of Resiliency, as suggested by their medium effect size. This finding suggests that positive feelings like interest, joy, and contentment and pursuing a daily purpose, and regularly experiencing a sense of accomplishment are essential to quarantined individuals' ability to thrive in their present predicament. Such necessary conditions not only allow individuals to enjoy everyday experiences (Abiola et al., 2017) but also provide a sense that life matter, which replenishes depleted energy from adverse experiences, and are required in the development of resiliency.

Engagement and Positive Relationships have small yet significant effect sizes on Resiliency. This infers that experiencing a state of "flow," or being absorbed in an activity (Nakamura and Csikszentmihalyi, 2014) and feeling loved, supported, and valued by others are also necessary to the quarantined individuals' capacity to recover quickly from their daily difficulties. This ties well with previous studies (Eaude, 2009; Svence et al., 2015; Abiola et al., 2017; Gerino et al., 2017; Roncaglia, 2017; Cobo-Rendón et al., 2020), where well-being elements were observed to be related with the occurrence of resiliency in individuals from a different context. Well-being elements allow quarantined individuals to focus their attention on alleviating harm, preventing negative mental health consequences, and finding positive outcomes in the presence of difficulty.

A unique finding, we encountered is that PERMA elements are bottleneck variables of resiliency. This highlights the little-known capacity of well-being to serve as a constraint to attaining higher levels of resiliency in community-quarantined individuals. This novel result shows two things. First, low levels of resiliency

(30% and less) do not necessitate even the slightest well-being elements. Second, higher levels of resiliency require certain levels of all the original PERMA elements and physical health. However, health remains a constant, albeit weak, necessary condition. This means that optimum resiliency is only possible when all the five pillars of well-being are taken care of and when one is at least minimally content with their physical health. When comparing our results to those of older studies (Sanders et al., 2015; Svence et al., 2015; Abiola et al., 2017). It must be pointed out that while the link between well-being and resiliency has been suggested in these studies, none could establish the necessary-but-not-sufficient relationship between the concepts. The present findings underpin the importance of holistic rather than an atomistic approach to mental health as noted by Mario (2012) and contradicts the compensation hypothesis of well-being. NCA revealed that deficiencies in certain areas of well-being may not be addressed by overcompensating in other areas, as all five pillars of well-being are necessary-but-not-sufficient conditions of resiliency.

Our findings show that loneliness is inversely correlated with the subjective perception of health. This basic result is consistent with the research (Balter et al., 2019) showing that loneliness predicts poor immune systems in healthy young adults. This is important since maintaining good health is vital amidst a growing viral pandemic. We observed that loneliness is a significant negative predictor of resiliency and not a necessary condition for any level of resiliency in individuals who are community quarantined. A similar conclusion was reached by Perron et al. (2014) where individuals who feel resilient also experience less loneliness. This further highlights the importance of the elements of well-being as necessary conditions of resiliency, which may lessen the effects of or serve as a buffer against loneliness and other negative psychological consequences of quarantine.

The overall results of our study have theoretical and practical implications. At a theoretical level, our results found clear support to PERMA concept of Seligman (2011) as necessary ingredients of resiliency even for socially isolated individuals such as those placed in ECQ. This goes beyond previous reports wherein PERMA elements were observed as predictors of resiliency, as only NCA can identify a necessary-but-not-sufficient relationship between the said variables. Despite experiencing segregation like lockdowns, the conditions that will allow people to thrive in the face of adversity are the same as when they are not undergoing such a predicament. Therefore, this finding can help us understand how the five elements of well-being constrain the negative psychological consequences of community quarantine by providing a buffer against these harms, reducing their effects, and promoting individual capacity to cope with such unsettling conditions. From this standpoint, we speculate that PERMA should be inversely correlated with negative indicators of mental health and correspondingly with other elements of positive psychological health, as noted by Hu et al. (2015). At a practical level, this opens an opportunity to develop evidence-based interventions such as telepsychology (Zhou et al., 2020) for quarantined individuals that help

clients understand behaviors they need to engage to have resiliency, and target multiple necessary-but-not-sufficient variables jointly, and not just focus on certain elements of well-being. This provides support for eclectic approaches to therapy especially the ones that incorporate positive psychology as Bolier et al. (2013) noted empirical support for the effectiveness of such interventions. Lastly, our findings agree with the call to a more inclusive psychology in the Philippines. This paradigm shift involves incorporating such approaches as critical (Paredes-Canilao et al., 2015) and positive (Datu et al., 2018) psychology to the prevailing traditional pathology-based perspective.

One fundamental limitation of this study is that the use of multiple regression and NCA cannot guarantee causality (Dul, 2016). While our data is consistent with the causal hypothesis, it is not evidence of a causal connection. Therefore, causal necessary-but-not-sufficient relations should not be inferred from our data. Another important caveat in interpreting our results is that we used the Facebook population as compared to the actual geographical population. It is not a perfect representative since Facebook users are usually younger females who have better educational attainment compared to the general population (Kosinski et al., 2015). Resiliency and well-being were measured during the ECQ, a far from normal situation. Therefore, although we took obligatory safety measures to increase the trustworthiness of the findings, we suggest that care be exercised when generalizing our findings into the general population and normal circumstances.

Many questions remain to be answered concerning the well-being of people who are community quarantined and the utility of NCA in psychological research. Further work is needed to identify the negative consequences of prolonged quarantine on individuals, especially those who have preexisting mental health problems and those who experience a disruption in access to their mental health-care providers. Moreover Odacı and Kalkan (2010) reported that internet use, specifically social media (Maglunog and Dy, 2019) exacerbates loneliness and that social media usage is expected to rise during the ECQ. Another important question, therefore, is how does the ongoing quarantine affects rates and levels of loneliness. Finally, while necessary conditions are traditionally studied using regression analysis in psychological research, NCA proved to be a more useful tool in understanding necessary-but-not-sufficient relationships because of its ability to

understand bottleneck variables. We, therefore, recommend the use of NCA in both classical and novel psychological research problems.

Resiliency grants us the capacity to flourish in the face of difficulty. For resiliency to result, the pillars of well-being are essential. Our research reveals, however, that well-being elements could be enablers or constraints. Accomplishment, for example, could predict resiliency. All pillars are necessary to attain it. Compensating in certain aspects cannot address the deficiency in others. Herein lies the importance and significance of holistic well-being. Those who can attain this are better equipped to thrive in the ECQ, a situation that affects the lives of so many Filipinos.

The COVID-19 pandemic and the quarantine undergone by children in many countries is a stressful situation about which little is known to date. Children and adolescents' behaviors to cope with home confinement may be associated with their emotional welfare. The objectives of this study were: (1) to examine the coping strategies used out by children and adolescents during the COVID-19 health crisis, (2) to analyze the differences in these behaviors in three countries, and (3) to examine the relationship between different coping modalities and adaptation. Participants were 1,480 parents of children aged 3–18 years from three European countries ( $n_{\text{Spain}} = 431$ ,  $n_{\text{Italy}} = 712$ , and  $n_{\text{Portugal}} = 355$ ). The children's mean age was 9.15 years ( $SD = 4.27$ ). Parents completed an online survey providing information on symptoms and coping behaviors observed in their children. The most frequent coping strategies were accepting what is happening (58.9%), collaborating with quarantine social activities (e.g., drawings on the windows, supportive applauses) (35.9%), acting as if nothing is happening (35.5%), highlighting the advantages of being at home (35.1%), and not appearing to be worried about what is happening (30.1%). Compared to Italian and Spanish children, Portuguese children used a sense of humor more frequently when their parents talked about the situation. Acting as if nothing was happening, collaborating with social activities, and seeking comfort from others were more likely in Spanish children than in children from the other countries. Compared to Portuguese and Spanish children, Italian children did not seem worried about what was happening. Overall, an emotional-oriented coping style was directly correlated with a greater presence of anxious symptoms, as well as to mood, sleep, behavioral, and cognitive alterations. Task-oriented and avoidance-oriented styles were related to better psychological adaptation (considered a low presence of psychological symptoms). Results also show that unaffected children or children with a lower level of impact were more likely to use strategies based on a positive focus on the situation. This study provides interesting data on the strategies to be promoted by parents to cope with the COVID-19 health crisis in children.

**Keywords:** quarantine, COVID-19, coping, stress, youth

## INTRODUCTION

In the first quarter of 2020, a serious public health crisis emerged worldwide due to the spread of the severe acute respiratory syndrome coronavirus (SARS-CoV-2) or COVID-19 (World Health Organization (WHO), 2020). To control the spread of the coronavirus, measures to reduce social contact were implemented in many countries, varying from only social limitation to voluntary or mandatory confinement. Spain and Italy, with, respectively, more than 28,700 and 32,700 deaths as of May 25 (European Centre for Disease Prevention Control, 2020) were among the most affected countries worldwide. Other countries such as Portugal managed to reduce the impact in the number of infections and deaths, reaching a comparatively low figure of 1,316 deaths on the same date. It is paradoxical that, in Portugal, confinement was voluntary, whereas, in Italy and Spain, where infections and deaths were much higher, mandatory confinement was imposed.

Although there is a history of epidemics in the past, this is the first time in our recent history that confinement has been imposed to control a pandemic. However, few available studies confirm the psychological impact of confinement due to COVID-19 on children and adolescents. In a sample of 2,330 school-age children in Hubei province, China, 23% reported depressive symptoms and 19% reported anxiety symptoms after 34 days of confinement, a higher prevalence than that found in previous studies (Xie et al., 2020). Orgilés et al. (2020), in a sample of 1,143 parents of Italian and Spanish children aged 3–18 years, found that 86% of them observed changes in their children's emotional or behavioral state compared to before the quarantine. When comparing the impact of confinement on the young population of Italy, Spain, and Portugal in a study that involved parents of 1,480 children and adolescents aged 3–18 years, Francisco et al. (2020) concluded that children from Italy were less affected than those from Spain, but also surprisingly less affected than children from Portugal, the country where the rules for confinement had been less restrictive. The authors conclude that, although Portuguese children could go outdoors and enjoyed a more normalized life, observing different behavior patterns in each family could be confusing and worrisome for them. Italian children, with mandatory confinement but allowed to go outdoors (a short walk with one adult near their home), were better adapted than Spanish and Portuguese children.

Confinement has brought about a major change in the lives of children and adolescents. School closure has changed their academic routines, social distancing has limited their social relationships with their family members, and the closing of the public spaces has modified their leisure, restricting it to their home. During any confinement, there are numerous stressors. Brooks et al. (2020), through a review of 24 studies, highlight that the main stressors of confinement are long duration, fear of infection, frustration and boredom, and the lack of adequate information from health authorities. However, the effect of the stressors of a confinement situation on people's well-being could depend on how they cope with the situation.

Coping behaviors can be defined as intentional and conscious responses to the demands and emotions of stressful events

(Lazarus, 1999; Compas et al., 2001). One of the most widely accepted classifications of coping behaviors is that of Lazarus and Folkman (1984), who distinguished between problem-focused and emotion-focused coping, as responses aimed at managing the problem that causes discomfort, and as regulating emotional responses to the problem, respectively. Subsequently, Parker and Endler (1992) observed that problem-focused coping strategies were associated with task orientation, whereas emotion-focused coping reflected an individual-focused orientation (Stanislawski, 2019). They included a third dimension called avoidance-oriented coping, which involved both task-focused and individual-focused strategies. The former is conceived as distraction (performing alternative tasks as a coping strategy), whereas the latter implies social amusement (instead of confronting the stressful situation). The ability to cope with stressful events and regulate emotions can play an important role in the explanation of why some children develop psychopathological symptoms while others not (Compas et al., 2017).

There is extensive literature on the behaviors that children and adolescents carry out to face stressful situations. Identifying coping behaviors in stressful situations can facilitate early effective interventions to reduce the risk of future psychological problems. Numerous studies have examined how certain coping behaviors can help to reduce stress whereas others have been associated with negative psychological symptoms. Specifically, coping behaviors of children and adolescents suffering from chronic diseases (e.g., Compas et al., 2012; Jaser et al., 2017), sexual abuse or mistreatment (e.g., Bal et al., 2009; Flett et al., 2012), war or post-war situations (e.g., Benson et al., 2011; Braun-Lewensohn et al., 2011), alcohol use (e.g., Catanzaro and Laurent, 2004), cancer (e.g., Compas et al., 2017), problems or conflicts between parents (e.g., Nicolotti et al., 2003; Shelton and Harold, 2008), terrorism (e.g., Rhoades et al., 2007), and natural disasters (e.g., Vigna et al., 2010; Zhang et al., 2010) among others, have been studied.

Psychological symptoms and behavioral changes in children and adolescents from European countries, including Italy, Spain, and Portugal, during the COVID-19 quarantine, have been described from the results of cross-sectional studies (Espada et al., 2020; Francisco et al., 2020; Orgilés et al., 2020; Xie et al., 2020). These studies conclude that a significant percentage of children have presented emotional and behavioral symptoms associated with the quarantine, and that a lower percentage of children have healthy habits (in terms of exercise, use of screens, and sleep patterns), compared to before the COVID-19 confinement. These findings are especially valuable to understand the impact of the early stages of the pandemic on children's well-being but the coping strategies they used to adapt to the pandemic have not yet been explored. Although much is known about children and adolescents' (coping strategies in numerous stressful situations, to date, little is known about how they are coping with the COVID-19 situation. As coping behaviors may significantly mediate children's mental health when facing the stress derived from the pandemic, knowing children and adolescents' specific coping strategies that are more closely related to psychological well-being would be very useful to prevent problems and

intervene early in cases of risk. The objectives of this study were: (1) to examine the coping behaviors carried out by children and adolescents during the COVID-19 health crisis; (2) to analyze the differences in coping behaviors in children from Spain, Italy, and Portugal; and (3) to examine the relationship between different coping strategies and adaptation to home confinement.

## METHOD

### Participants

Participants were parents of 1,480 parents from three European countries (Italy  $n = 712$ , Spain  $n = 431$ , and Portugal  $n = 335$ ). The average age of the participating parents was 42.26 years ( $SD = 5.92$ ) and 87.8% were females. Sixty percent reported earning from 1,000 to 2,999 euros monthly, 7.4% earned 5,000 or more, and only 6.6% earned less than 1,000 euros. That is, the sample was predominantly middle class. Children were aged between 3 and 18 years ( $M = 9.15$ ,  $SD = 4.27$ ), and 47.2%

were females. Participants were equivalent across countries in all sociodemographic variables, except for going outdoors, the number of people living at home, square meters per home, and children's age. Italian participants were more likely to have a garden than Spanish participants. The Spanish sample was more likely than the Portuguese sample to have a terrace. Participants from Italy and Portugal reported having a higher average number of people living at home during the confinement. Portuguese participants had larger homes than the Spaniards and Italians. Portuguese children were slightly older than the Spanish children. **Table 1** describes the characteristics of the sample and differences across countries.

### Procedure

Participants were recruited in each country *via* social media (Facebook, Twitter, Instagram, and WhatsApp), as face-to-face contact was not allowed. An online survey was created *ad hoc* and distributed using a snowball sampling strategy. The

data collection period was the same in the three participating countries (lasting 15 days, with the study starting 15 days after the lockdown). Parents from 94 Italian cities, 94 Portuguese cities, and 84 Spanish cities participated in the study. To create the survey, scientific literature related to the psychological impact of quarantines was reviewed, and questionnaires applied in previous studies with adult population were considered. The survey collected sociodemographic information of parents and children (see **Table 1**), parental perception of how the quarantine affected their children emotionally, and parental perception of the coping strategies that their children used during the quarantine. The children's psychological responses to the quarantine were assessed through 31 symptoms on a scale ranging from 1 (*much less compared to before quarantine*) to 5 (*much more compared to before quarantine*) and grouped into six categories: anxiety symptoms (e.g., he/she is worried or is anxious), mood symptoms (e.g., he/she is sad or cries easily), sleep problems (e.g., he/she is afraid of sleeping alone or has nightmares), behavioral alterations (e.g., he/she often argues with other members of the family or is uneasy), feeding problems (he/she eats more or has no appetite), and cognitive alterations (e.g., he/she is very indecisive or has difficulty concentrating). As part of the same study, Francisco et al. (2020) previously explored psychological symptoms and behavioral changes in Spanish children and adolescents during the early phase of the COVID-19 confinement. Coping behaviors were measured using a list of eleven items that included the three dimensions proposed by Parker and Endler (1992): task-oriented (e.g., "Highlights the pros of being at home"), emotion-oriented (e.g., "Talks often about how he/she feels"), and avoidance-oriented (e.g., "Changes the subject when you try to talk to him/her about the coronavirus or quarantine"). Instead of a known measure, a specific list of statements was chosen to assess coping so that the content was specific to the COVID-19 context. Before completing the survey, information about the objectives of the study was provided, and informed consent was requested. The approval of the Ethics Board of the authors' institution was obtained for the research.

## Data Analyses

Descriptive statistics were used to describe the characteristics of the sample. The normal distribution of the data was tested using the Kolmogorov–Smirnov test. Nonparametric procedures were used because of the absence of normality ( $p < 0.05$ ). A total of 31 children's immediate psychological reactions were evaluated. Parents who informed that their children presented any of these reactions to a greater extent during home confinement (compared to before this period) were coded as 1 ("affected"), whereas the rest was coded as 0 ("unaffected"). A new variable (level of disturbance) was created by adding the 31 dichotomous variables of symptoms (score ranging from 0 to 31). The continuous variable (level of disturbance) was categorized into four groups: "unaffected" (The children had not worsened in any of the symptoms), "low impact" (had worsened in 1–3 symptoms), "medium impact" (had worsened in 4–9 symptoms), and "high impact" (had worsened in 10 or more symptoms).

Kruskal–Wallis tests were performed to analyze differences in coping styles (task-oriented, emotion-oriented, and avoidance-oriented) across the four groups of impact, and Chi-squared tests to compare proportions of children using each coping strategy (yes/no) across the levels of impact (four categories). A  $p$ -value under 0.05 was considered a statistically significant difference. To reduce the risk of Type I errors in multiple-comparisons across groups, Bonferroni corrections were applied to  $p$ -values (Beasley and Schumacker, 1995). For continuous variables, Epsilon-squared ( $\epsilon^2$ ) was used as an effect size, where small effect sizes range from 0.01 to  $< 0.08$ , medium effect sizes range from 0.08 to  $< 0.26$ , and large effect sizes range from  $\geq 0.26$ . For categorical variables, Chi-squared *post hoc* tests using adjusted residuals were performed. The percentage of children using each coping strategy was calculated to determine which ones were most frequently used by preschool children (3–5 years), school-age children (6–12 years), and adolescents (13–18 years). Cramer's  $V$  was calculated as a measure of association between multi-categorical variables, and interpreted as follows:  $> 0.25$  very strong,  $> 0.15$  strong,  $> 0.10$  moderate,  $> 0.05$  weak, and  $> 0$  none or very weak (Akoglu, 2018). The relationship between coping styles and different areas of impact (anxiety, mood, sleep, feeding, behavioral and cognitive alterations) was explored using Spearman correlations. All analyses were performed using SPSS 26 for Mac.

## RESULTS

### Coping Strategies

**Table 2** shows the proportion of children using coping strategies during the home confinement due to COVID-19. The most frequently used coping strategy was acceptance, with more than half of the parents reporting that their children use it (58.9%). Other commonly used coping strategies (at least 30% of the children) were collaborating with social activities such as drawings on windows or collective applauses (35.9%), ignoring the problem and acting as if nothing was happening (35.5%), highlighting the advantages of being at home (35.1%), seeking comfort from others (31%), and not showing concern about what was happening (30.1%). According to age, the most used coping strategies (more than 30% of parents reported that their children used them) were similar among preschool children, school-age children, and adolescents, although their order could differ for each group. In preschool children (3–5 years), the most used coping strategies were: accepts what's going on (45.5%) (Task-oriented); acts as if nothing is happening (44.4%) (Avoidance-oriented); doesn't seem to care what is happening (40%) (Avoidance-oriented); and seeks affection from others (36.9%) (Emotional-oriented). In the school-age children (6–12 years), the most used coping strategies were: accepts what's going on (60.6%) (Task-oriented); highlights the advantages of being at home (41.3%) (Task-oriented); seeks affection from others (33.8%) (Emotion-oriented); and acts as if nothing is happening (32.3%) (Avoidance-oriented). In the adolescent group (13–18 years), the most used strategies were: accepts what's going on (69.9%) (Task-oriented); highlights the advantages of being at home (37.9%) (Task-oriented); and acts as if nothing is happening (32.2%) (Avoidance-oriented). When comparing the

However, differences that were significant at \*p < 0.05 and \*\*p < 0.01 were also indicated in the table.

three countries, and after applying for Bonferroni correction, Spanish children were more likely to collaborate in social activities than children from the other countries. Compared to the Italian children, those from Portugal were also more likely to collaborate in social activities. Spanish children were more likely to seek affection in others, compared to the rest of children. Italian children were more likely to act as if they were not worried about what was happening, compared to the rest. Compared to the Portuguese children, those from Spain were also more likely to seem worried about what is happening.

## Relationship Between Coping Strategies and Children's Immediate Psychological Responses

The psychological impact of the quarantine on children was measured through 31 symptoms grouped into six categories: anxiety symptoms, mood symptoms, sleep problems, behavioral alterations, eating problems, and cognitive alterations. Coping strategies were also grouped depending on whether they were task-, emotion-, or avoidance-oriented (Table 3).

Table 4 presents the Spearman correlations between task-oriented, emotion-oriented, and avoidance-oriented coping

Note. Values in square brackets indicate the 95% confidence interval for each correlation. The confidence interval is a plausible range of population correlations that could have caused the sample correlation (Cumming, 2014). \*indicates  $p < 0.05$ . \*\*indicates  $p < 0.01$ .

cognitive alterations. The relationships observed across these variables were small ( $\rho$  from  $-0.08$  to  $-0.17$ ). The use of an emotion-oriented coping style was related to a higher number of symptoms, more anxiety, mood disturbances, sleep, behavioral, and cognitive alterations. The relationships observed across variables were small ( $\rho$  from  $0.12$  to  $0.28$ ). The use of an avoidance-oriented coping style was related to fewer symptoms in all areas, including eating. The relationships observed across variables were small ( $\rho$  from  $-0.05$ ,  $-0.20$ ).

## Relationship Between Coping Strategies and Children's Level of Disturbance

Children were classified depending on their level of disturbance: "unaffected" (the children had not worsened in any of the symptoms), "low impact" (had worsened in 1–3 symptoms), "medium impact" (had worsened in 4–9 symptoms), and "high impact" (had worsened in 10 or more symptoms). **Table 5** shows the coping strategies used by children with different levels of disturbance. Of the 11 coping strategies, 8 were related to the level of disturbance. Children more psychologically affected by home confinement were more likely to use the following strategies: asking very often about coronavirus or quarantine, saying they were very angry about what was happening, seeking affection from others, and changing the subject when others tried to talk to them about the coronavirus or quarantine. Children with a lower level of disturbance due to home confinement were more likely to highlight the advantages of being at home, accept what was happening, act as if nothing was happening, and not seem worried about what was happening. The coping strategies "he/she uses humor when you talk about quarantine or coronavirus," "collaborates in social activities" and "often talks about how they feel" were unrelated to the level of disturbance due to home confinement in children's psychological reactions.

## DISCUSSION

The objective of the present study was to examine for the first time the strategies used by children and adolescents to cope with the quarantine imposed by governments to control the COVID-19. Another objective was to study the relationship between children's coping strategies and their emotional and behavioral responses to the home confinement to determine which strategy

is more useful to cope with the situation. Different rules of confinement were also analyzed, as three European countries participated in the study.

Results show that the most frequently used coping strategy was task-oriented (accepting what was happening), with 59% of parents reporting its use by their children. Also, at least 30% of the children collaborated in social activities, acted as if nothing was happening, highlighted the advantages of being at home, sought comfort from others, or did not seem worried about what was happening. Differences by countries show interesting results. Collaborating in social activities and seeking comfort from others were more likely in Spanish children than in children from the other countries. Compared to Portuguese and Spanish children, Italian children did not seem worried about what was happening. Although it is unclear, the different rules of confinement imposed by each country could explain these differences. Portugal followed voluntary confinement, so maybe children's routines did not change as much as in the other countries; the few cases of infections and deaths compared to Spain and Italy might have contributed to their not perceiving the situation as dangerous. Children from Spain used adaptive strategies to cope with the situation, such as collaborating in social activities, but they were also more likely to seek comfort from their parents. Spain had the most restrictive confinement rules, not allowing children to go outside until April 26th. Although more data are necessary to explain this finding, the interruption of all social contact and staying at home with the parents for such a long time could have encouraged Spanish children to seek more comfort than Portuguese and Italian children, who followed a less restrictive confinement. Also, Spanish children collaborated more in social activities, such as collective applauses from the balconies or windows, probably showing their need for social contact with others, which was limited indoors. Finally, Italian children seem less concerned about the situation than children from the other countries. Unlike Italy, Portugal used voluntary confinement, with habits and routines depending on each family's decision, so the children may have perceived inconsistent situations outdoors that might have worried them. Italian children were allowed to go outside before Spanish children, so Spanish children may have been more worried than Italian children because they had to follow the prohibition of going outside. Although

further research is needed, allowing Italian children to go outside while maintaining consistent rules for all the children (a walk with one adult near their house) may have reduced their concerns.

A main objective of this study was to analyze the relationship between coping strategies and children's behavioral and emotional symptoms reported by parents. As there is a lack of studies examining how children cope with home confinement, we tried to explore which strategies were more related to children's well-being, and thus more useful for them to cope with the situation. Results show that children who use an emotion-oriented coping style have more behavioral and emotional symptoms (more anxiety, mood disturbances, sleep, behavioral and cognitive alterations). Contrarily, those who use a task-oriented or an avoidance-oriented coping strategy have fewer emotional and behavioral symptoms, specifically, fewer symptoms related to mood, sleep, behavioral and cognitive alterations. These results are in line with previous studies finding that emotion-focused coping, in which attention is not directed to solving the problem but to one's emotional experience (Sears et al., 2000), is usually related to internalizing symptoms, such as

anxiety or mood, and externalizing symptoms, such as behavioral alterations (Carlo et al., 2012).

To define which strategy could be more useful to cope with the quarantine, children were classified as unaffected, low impact, medium impact, and high impact, as a function of the number of symptoms reported. Results show that unaffected children or children with a lower level of impact are more likely to highlight the advantages of being at home, accept what is happening, act as if nothing was happening, and not seem worried about what was happening. Although a unique type of coping strategy related to psychological symptoms has not been found in this study, these four strategies have in common a positive focus on the situation. Contrariwise, children considered more psychologically affected used one of these four specific strategies to cope with home confinement: asking very often about coronavirus or quarantine, feeling angry about what was happening, seeking comfort from other members of the family, and changing the subject when the parents tried to talk to them about the situation. These coping strategies have been related to psychopathological symptoms in previous studies. Avoidance and rumination have been frequently associated with

anxiety and depression, whereas acceptance has shown a negative relationship with those symptoms (Schäfer et al., 2017). Asking frequently about the stressful situation may be considered as a strategy of rumination, which showed a high positive association with anxiety and depression symptoms, among other problems, in a meta-analysis that included studies carried out with children (Aldao et al., 2010). Avoidance had a small-to-medium positive association with anxiety and depression in that same meta-analytic review, supporting the finding of our study that indicate that changing the subject away from confinement is a typical coping strategy of psychologically affected children. Feeling angry or seeking comfort from others are also usual coping strategies shown by children for coping with distress (e.g., Miers et al., 2007; Zimmer-Gembeck and Skinner, 2011).

This study has some limitations and some strengths. The main limitation of this study is that the information was collected online from parents, as contact with the children was not possible due to the confinement situation. Despite the importance of applying self-reports, some previous studies have examined coping using measures completed by parents, as in the present study (e.g., Connor-Smith et al., 2000). In this study, children's coping strategies were evaluated, and these can be easily identified by people who live with the child (e.g., asks very often about coronavirus or quarantine or seeks affection from others). Therefore, parents were considered better informants than the children. Also, data collection *via* the parents allowed us to obtain information about younger children. Although it would have been desirable to use a multi-informant method, it was not possible due to the limited access to children during home confinement. Although the sample is not representative, it includes a large number of cities in three European countries (94 cities in Portugal, 94 in Italy, and 84 in Spain) and can be illustrative of the behavior of children and adolescents in the first weeks of the COVID-19 crisis. More studies are required to examine how coping behaviors developed during the health crisis are related to the onset of future psychopathology, especially through a longitudinal approach.

To our knowledge, this is the first study examining the coping strategies used by children during the quarantine for COVID-19. The following conclusions of the study may be highlighted. First, a task-oriented strategy was the most common in the

sample, although some differences between countries were found in the strategies used by children to cope with the situation. Second, children who used a task-oriented or an avoidance-oriented coping strategy showed fewer emotional and behavioral symptoms. Third, children who coped with the situation using positive strategies, such as highlighting the advantages of being at home, were less emotionally and behaviorally affected. The present study has provided information about the specific coping behaviors in the COVID-19 confinement that can be protective factors against psychopathological symptoms. Therefore, coping behaviors related to less disturbance should be promoted by educators and professionals in early interventions.

## A Corrigendum on

### Coping Behaviors and Psychological Disturbances in Youth Affected by the COVID-19 Health Crisis

by Orgilés, M., Morales, A., Delvecchio, E., Francisco, R., Mazzeschi, C., Pedro, M., and Espada, J. P. (2021). *Front. Psychol.* 12:565657. doi: 10.3389/fpsyg.2021.565657

In the original article, there was an error. All results that were statistically significant were informed, rather than only those that were found to be significant after applying the Bonferroni adjustment.

A correction has been made to *Results, Coping Strategies, Paragraph 1*. The corrected paragraph is shown below.

**Table 2** shows the proportion of children using coping strategies during the home confinement due to COVID-19. The most frequently used coping strategy was acceptance, with more than half of the parents reporting that their children use it (58.9%). Other commonly used coping strategies (at least 30% of the children) were collaborating with social activities such as drawings on windows or collective applauses (35.9%), ignoring the problem and acting as if nothing was happening (35.5%), highlighting the advantages of being at home (35.1%), seeking comfort from others (31%), and not showing concern about what was happening (30.1%). According to age, the most used coping strategies (more than 30% of parents reported that their children used them) were similar among preschool children, school-age children, and adolescents, although their order could differ for each group. In preschool children (3–5 years), the most used coping strategies were: accepts what's going on (45.5%) (Task-oriented); acts as if nothing is happening (44.4%) (Avoidance-oriented); doesn't seem to care what is happening (40%) (Avoidance-oriented); and seeks affection from others (36.9%) (Emotional-oriented). In the school-age children (6–12 years), the most used coping strategies were: accepts what's going on (60.6%) (Task-oriented); highlights the advantages of being at home (41.3%) (Task-oriented); seeks affection from others (33.8%) (Emotion-oriented); and acts as if nothing is happening (32.3%) (Avoidance-oriented). In the adolescent group (13–18 years), the most used strategies were: accepts what's going on (69.9%) (Task-oriented); highlights the advantages of being at home (37.9%) (Task-oriented); and acts as if nothing is happening (32.2%) (Avoidance-oriented). When comparing the three countries, and after applying for Bonferroni correction, Spanish children were more likely to collaborate in social activities than children from the other countries. Compared to the Italian children, those from Portugal were also more likely

to collaborate in social activities. Spanish children were more likely to seek affection in others, compared to the rest of children. Italian children were more likely to act as if they were not worried about what was happening, compared to the rest. Compared to the Portuguese children, those from Spain were also more likely to seem worried about what is happening.

Additionally, a correction has been made to *Discussion, Paragraph 2*.

Results show that the most frequently used coping strategy was task-oriented (accepting what was happening), with 59% of parents reporting its use by their children. Also, at least 30% of the children collaborated in social activities, acted as if nothing was happening, highlighted the advantages of being at home, sought comfort from others, or did not seem worried about what was happening. Differences by countries show interesting results. Collaborating in social activities and seeking comfort from others were more likely in Spanish children than in children from the other countries. Compared to Portuguese and Spanish children, Italian children did not seem worried about what was happening. Although it is unclear, the different rules of confinement imposed by each country could explain these differences. Portugal followed voluntary confinement, so maybe children's routines did not change as much as in the other countries; the few cases of infections and deaths compared to Spain and Italy might have contributed to their not perceiving the situation as dangerous. Children from Spain used adaptive strategies to cope with the situation, such as collaborating in social activities, but they were also more likely to seek comfort from their parents. Spain had the most restrictive confinement rules, not allowing children to go outside until April 26th. Although more data are necessary to explain this finding, the interruption of all social contact and staying at home with the parents for such a long time could have encouraged Spanish children to seek more comfort than Portuguese and Italian

children, who followed a less restrictive confinement. Also, Spanish children collaborated more in social activities, such as collective applause from the balconies or windows, probably showing their need for social contact with others, which was limited indoors. Finally, Italian children seem less concerned about the situation than children from the other countries. Unlike Italy, Portugal used voluntary confinement, with habits and routines depending on each family's decision, so the children may have perceived inconsistent situations outdoors that might have worried them. Italian children were allowed to go outside before Spanish children, so Spanish children may have been more worried than Italian children because they had to follow the prohibition of going outside. Although further research is needed, allowing Italian children to go outside while maintaining consistent rules for all the children (a walk with one adult near their house) may have reduced their concerns.

There were also errors in **Tables 2** and **5** as published. The corrected **Tables 2** and **5** are shown below.

The authors apologize for these errors and state that they do not change the scientific conclusions of the article in any way. The original article has been updated.

The novel coronavirus disease COVID-19 that first emerged in Wuhan, China, in Nov-Dec 2019 has already impacted a significant proportion of the world population. Governments of many countries imposed quarantines and social distancing measures in 2020, many of which remain in place, to mitigate the spread of the SARS-Cov-2 virus causing the COVID-19 disease. The direct impact of COVID-19 on people infected with the virus, their families and the health care workers, as well as the impact of the mitigation measures such as quarantine, social distancing, and self-isolation on the rest of the population have contributed to a global mental health pandemic, including anxiety, depression, panic attacks, posttraumatic stress symptoms, psychosis, addiction, obsessive-compulsive disorder, and suicidality. These effects are present acutely (for example, due to fear of contamination or losing loved ones, effects of quarantine/isolation, withdrawal of community and social services, etc.) and may continue long after the pandemic is over (for example, due to bereavement, unemployment, financial losses, etc.). The COVID-19 pandemic has triggered mental health problems in people without previous history of mental illness, as well as worsened the symptoms in those with pre-existing psychiatric diagnosis. Therefore, the global effort is called for to deal with this mental health pandemic secondary to COVID-19 itself to address the emergence of new as well as the exacerbation of the existing mental health issues. Conversely, this global context provides an extraordinary opportunity for studying individual differences in response to and resilience in the face of physical and psychological threat, challenge to “normal” way of life, and long-term uncertainty. In this viewpoint article we outline the particular suitability of mindfulness, its skills and mechanisms, as an approach to the prevention and management of mental health issues, as well as to the promotion of well-being and building the foundations of adaptability and flexibility in dealing with the long-term uncertainty and profound changes to the social, economic, and possibly political systems as this pandemic continues to unfold.

**Keywords:** COVID-19, mental health, mindfulness, depression, anxiety, PTSD, psychosis, coping

## INTRODUCTION

The novel coronavirus disease COVID-19 that first emerged in Wuhan, China, in Nov-Dec 2019 is continuing to spread rapidly with over 94 million confirmed cases world-wide (1). To minimize its human-to-human transmission rates, governments of many countries imposed quarantines and social (physical) distancing measures in the first quarter of 2020 that lasted for months, and have been reinstated in the last quarter of 2020 in many countries, including the UK, that are witnessing a severe outbreak due to more transmissible variants of the SARS-Cov-2 virus. The direct impact of COVID-19 on people infected with the virus, their families and the health care workers, as well as the indirect impact of the mitigation measures such as quarantine, social distancing and self-isolation on the rest of the population has led to a global mental health crisis (2–5) that calls for a global effort in dealing with. This global context also provides an unprecedented opportunity for studying the factors and mechanisms underlying individual differences in response to, and resilience in the face of, an unprecedented challenge to one's "normal" way of life in the context of physical as well as psychological threat and uncertainty.

The international scientific community has risen to the challenge, first in the fields of virology and epidemiology, with the psychology and neuroscience of mental health gathering a strong momentum in appraising the evidence from previous pandemics as well as the data generation during the current pandemic to inform governmental policies for public health interventions and provision. A rapid evaluation of evidence by Brooks and colleagues (6) published in *Lancet* shortly before the start of quarantine period in the UK and many other countries reviewed the psychological impact of quarantine during previous pandemics and found most studies to report negative psychological effects including post-traumatic stress symptoms, confusion, and anger. The identified stressors for worse mental health outcomes included longer quarantine duration, infection fears, inadequate supplies, inadequate information, financial loss, frustration, boredom, and stigma, with suggestions of long-lasting effects for the mental health issues. It is becoming increasingly evident that the same stressors and psychological effects, as well as information transparency, supplies of necessities, and appeals to the altruistic behavior for the wider societal benefit as mitigators are indeed relevant to the current pandemic (7).

There is significant evidence that the COVID-19 pandemic has triggered mental health problems in people without any previous history of mental illness and worsened the symptoms in those with pre-existing psychiatric diagnosis (3–5). The common mental health problems reported during the Wuhan lockdown imposed between January and March of 2020 included fear, anxiety, depression, and sleep problems in patients with COVID-19 infections, close contacts, the public, and the health care professionals (8–10). The mental health situation in Wuhan was particularly challenging for the subpopulations with existing mental health difficulties, with patients having serious psychiatric needs being considered to be highly vulnerable population to contract COVID-19 (11). Hundreds of patients with psychiatric

disorders, as well as mental health professionals, were infected in China (12). Similar findings have since then emerged from other countries and cultures (4, 5). There are also reports of coronavirus infection-related delusions and hallucinations in vulnerable people from China (13) and elsewhere (14). A range of negative mental health consequences are likely during the pandemic (for example, due to fear of catching coronavirus infection, underlying health conditions, losing loved ones due to COVID-19, withdrawal of other healthcare and community services, or a consequence of quarantine measures) and for years to come after it is over (for example, trauma due to the experience of illness or bereavement, survival guilt, unemployment and financial losses) (6, 15).

Quarantine is a necessary preventive measure during major infectious outbreaks but its negative mental health impacts, especially if lasting for more than a few weeks, are also well-documented (6). According to the poll published by the Office of National Statistics (16) in the UK, 85.2% respondents are worried about the effect that coronavirus is having on their life, with 53.1% having stated the coronavirus pandemic has impacted their well-being, and 46.9% reporting high levels of anxiety. Importantly, the general population survey by Ipsos MORI (17) revealed that becoming unwell with COVID-19 disease was ranked lower than the concerns regarding psychological effects of social (physical) distancing on well-being, including increased anxiety, depression, stress, and other negative feelings. The survey by the mental health charity MQ highlighted concerns about the impact of social isolation and increased feelings of anxiety and depression in people with lived experience of a mental health issue. In addition to growing concerns about the impact of isolation on mental health in the general public, there is a clear recognition that the coronavirus pandemic will put the healthcare workers at risk of burn-out and post-traumatic stress disorder. Even after the quarantine/lockdown measures are eased in the UK and elsewhere, we will have to live most likely with a new "normal" for an extended period of time, facing social and economic uncertainty, with a high fear/probability of future waves of infection spread, followed by the periods of stricter restrictions on our way of life to contain and manage the pandemic. The short and long-term impacts on the global economy is likely to have a devastating effect on mental health, affecting ever increasing number of people worldwide.

In what follows we provide a theoretical perspective on why mindfulness-based approaches might be well-suited for responding to the current mental health challenges and managing the short- as well as long-term impact on mental health of the pandemic itself and measures to mitigate it. It should be noted that by "suitability" we do not imply "superiority" to other alternative or complimentary approaches that might also be suitable in the context of COVID-19 pandemic (18, 19). We use the term "approaches" (which is broader than "interventions") to discuss the suitability of mindfulness and its skills that could be trained by many different means, including in the context of mindfulness-based interventions, using online apps/mp3s, joining online drop-in sessions led by experienced mindfulness instructors/teachers, etc. The systematic reviews and meta-analysis of mindfulness-based interventions (MBIs) on a

range of conditions have been conducted (20, 21), including the effects on depression, anxiety and stress reduction in older adults (22) and post-traumatic stress (23). We acknowledge that more rigorous studies are needed to evaluate the efficacy of MBIs and further clarify their mechanisms of action [for the evaluation of the state of the field in terms of methodological rigor please see (24, 25)]. Here we aim to present an appraisal of mindfulness's suitability in terms of its theoretical underpinnings and known mechanisms of action in the context of the stressors, demands, and challenges of COVID-19 pandemic.

## MINDFULNESS SKILLS, TRANSDIAGNOSTIC MECHANISMS, AND RELEVANCE TO THE COVID-19 PANDEMIC

### What Is Mindfulness?

*Mindfulness*, one of the words used to translate the Pali term *sati*, in the secular context is defined as “the awareness that arises when paying attention on purpose, in the present moment, and non-judgmentally” (26). This definition has three elements to characterize mindfulness as: (i) our innate ability of attention to bring our experiences to the forefront of our awareness; (ii) a process of doing so with an intention of directing it toward the present-moment experiences, without judging them as likable or dislikeable, pleasant or unpleasant, “good” or “bad”; and (iii) awareness with certain qualities that arises as a “result” of applying the ability and the process, which include openness, receptivity, spaciousness, and “stillness” or steadiness that is able to hold any “movement” within it, such as thoughts, emotions, body sensations, or any external stimuli coming from our senses.

It is important to note that the scope of what is denoted by the term *mindfulness* in the secular context exceeds the use of mindfulness as a translation of *sati* in the context of Buddhist meditation praxis methods [for an extensive and comprehensive discussion of the differences, please see the special issue on Mindfulness in Contemporary Buddhism, 2011]. Briefly, this mainly stems from a different approach to meditation practice within different traditions of Buddhism, from which mindfulness as a concept made its way into the secular clinical and scientific context. We do not aim to solve this debate here, but merely point out that when we use the term *mindfulness* in this viewpoint article and the related secular approach to mindfulness practice, we mean it in the way in which Jon Kabat-Zinn has originally intended it (27). The term *mindfulness* in secular usage denotes a far broader range of concepts than used in Buddhist philosophy, psychology and praxis (27), including mindful awareness, which is “captured” by different concepts and referent terms depending on the school of Buddhism. Mindful awareness is referred to as *choiceless awareness* in the context of Mindfulness-Based Stress Reduction (MBSR) (28) and Mindfulness-Based Cognitive Therapy (MBCT) (29). Other terms used for it in the secular context is *open presence* (30) or *non-dual mindfulness* (31). These distinctions between traditional Buddhist and secular usage of the term *mindfulness* in terms of the breadth of the definition/conceptual capture are important to note in relation to identifying the mechanisms affording change, both psychological

and behavioral. That is, when researching the mechanisms and effects of mindfulness on cognition, emotional regulation and neural dynamics, it is important to be precise regarding the definition and specific aspect(s) of mindfulness (i.e., ability, process or “result”) being studied.

Mindfulness practice as incorporated in Mindfulness-Based Interventions (MBIs) is contrasted with more effortful concentration-based practices, such as taught in Theravada Buddhism (32). The traditions of Buddhism most closely aligned with mindfulness approach intrinsic to MBSR and MBCT are Dzogchen and Mahamudra of Tibetan Buddhism, which take more gentle and effortless approach to practice by letting go of any striving in achieving any particular mental state and simply resting in a present-centered awareness that is non-preferential to the experiential content, free of emotional reactivity to it and conceptual elaboration upon it, whilst being cognizant of experiences as they arise and dissolve in awareness (27, 31). Hence, the attitudes toward mindfulness practice encouraged by MBSR and MBCT include curiosity toward experience, acceptance of what is there to be experienced (which does not entail a passive resignation but rather openness and receptivity as an opposite of experiential avoidance and suppression), non-striving, non-judging one's practice and oneself, and adopting a beginner's mind (suspending preconceived ideas and beliefs about the experiential content and one's identity).

### Mindfulness Skills

The list of beneficial skills afforded by mindfulness practice is potentially long. Here, we will mention a few that we consider to be most relevant to the discussion of the relevance of mindfulness to the context of adopting to challenges presented by the COVID-19 pandemic.

Mindfulness skills captured by the self-report measure *Five Facet Mindfulness Questionnaire* (FFMQ) (33) include: *observing*, *non-judging*, *non-reacting*, *acting with awareness*, and *describing*. *Observing* involves deliberately turning toward and noticing present-moment experiences during daily activities, such as body sensations during walking, showering and eating, or sensory stimuli, such as sounds, smells, or sights. *Non-judging* taps into the tendency to judge one's experiences, emotions, feelings and thoughts, as irrational, inappropriate, or bad, as well as the tendency to be critical of oneself more generally. *Non-reactivity* refers to the ability to be aware of the distressing feelings, thoughts or images without getting caught up in them, noticing them in a decentred way, letting go of them, and returning to feeling calm soon after they have passed. *Acting with awareness* measures the propensity to get distracted from the present-moment experience by mind-wandering (day-dreaming, worrying), running on automatic pilot, and rushing through activities without giving them attention. *Describing* refers to the ability to put one's sensations, feelings, thoughts, beliefs, opinions into words and the tendency to do so. Although there is somewhat of a debate as to whether the ability to act with awareness could be captured by its “opposite”—the propensity for “mindlessness” or lapses of attention, or whether ability to describe is one of the core mindfulness skill [for an in-depth discussion see (34)], there is a consensus that the other three

facets, *observing*, *non-judging*, and *non-reacting*, constitute the core of mindfulness as a trait, both as a personality disposition as well as acquired through formal (e.g., meditation) and informal (daily life) mindfulness practice.

## Transdiagnostic Mechanisms of Action and Implications for the COVID-19 Pandemic

Detailed accounts of the mechanisms underpinning transdiagnostic efficacy of mindfulness practice have been elaborated in relation to depression relapse prevention (35) and more generally for managing psychopathology, as well as promotion of mental health and well-being (36). Wielgosz and colleagues (37) have provided the most recent review of the current understanding of how skills (or capacities) acquired through mindfulness practice translate into its efficaciousness across the psychopathologies, including depression, anxiety, post-traumatic stress, eating disorders and substance abuse by mapping them onto cognitive and affective constructs of the Research Domain Criteria matrix adopted by the NIH (38). Here we briefly outline the most established effects and mechanisms of transdiagnostic efficacy before discussing the relevance of mindfulness to COVID-19 context.

Neuroticism has an established link to psychopathology, both as an efficient marker of non-specified general risk for the common mental disorders (CMDs) (39) and through the association with the CMDs (40). Neuroticism is strongly inversely correlated with *non-reacting* and *non-judging* as dispositional mindfulness traits (41). The relationship between mindfulness and psychological well-being is mediated by the self-compassion (42), with self-compassion being the indirect gain (i.e., not explicitly taught) of the MBCT (43). Self-compassion attenuates anxiety after an ego-threat, and an increase of self-compassion over a one-month period has been shown to augment psychological well-being (42). The practice of mindfulness thus promotes psychological well-being directly via decreased neuroticism due to the acquisition of *non-judging* and *non-reacting* skills, with the benefits being further enhanced by the increases in self-compassion. Self-compassion in the face of negative thoughts has emerged as a key component of the mechanism of change afforded by MBCT (35). Neuroticism as a trait associated with increased stress vulnerability also links to the direct effect of mindfulness on psychological stress reactivity (43).

The relationship with experiences as transient events in the mind attained via *observing*, *non-judging*, and *non-reacting* skills is akin to the concept of *decentering* in Cognitive-Behavioral Therapy (CBT); learning to experientially decenter through CBT has been linked to the CBT's efficacy in depression relapse prevention (44). Other terms related to this skill are *cognitive diffusion* (45) and *dereification* (46). The experiential mode captured by these terms stands in contrast with self-referencing (identification or fusion with the thoughts and experiences as “me” or “mine” rather than perceiving them as passing events in the mind), and is distinct from the states of dissociation, depersonalization, or derealisation that are associated with psychopathology. This non-elaborative (i.e., simply noticing/observing without reappraisal), non-judgmental,

and non-reactive way of processing and relating to experiences, whether they are thoughts, feelings or body sensations, characterize mindfulness as an emotion regulation strategy (47).

Increased self-referencing has been linked to a number of common mental disorders; for example, in a form of rumination in depression or paranoid thoughts in psychosis and schizophrenia. Self-referencing has been linked to the function of the Default Mode Network (DMN) (48). The DMN hyperactivity and over-connectivity has been observed in schizophrenia and depression (49), predicted the post-traumatic stress disorder (50), and is altered in insomnia disorder (51), amongst other psychopathologies (we mention most relevant to the impact of COVID-19 on mental health). The ability to attenuate self-referential processing associated with the DMN activity is enhanced by mindfulness practice (52). This, in part, appears to underpin brain's increased efficiency of information processing (53), relapse prevention in depression (54), and general well-being associated with mindfulness (36).

As argued by Brewer et al. (55) and demonstrated using functional magnetic resonance imaging neurofeedback in conjunction with subjective reports, the DMN's sustained activity, and particularly that of the posterior cingulate region, when processing self-related content (e.g., sensations, memories, emotions, thoughts) may represent “getting caught up in” one's experiences rather than narrative self-referential processes *per se*. Hence, the effect of mindfulness practice on downregulating the DMN activity associated with “sticky” narrative self-referencing alone theoretically underpins its utility for the prevention and management of CMDs (56), as well as for the promotion of mental health and well-being (38).

Related to this is the development of the capacity to disengage from *attention capture* by future- or past-orienting thinking [self-projection, (57)]. Self-projection, also associated with the function of the DMN, is known to be biased toward negative affect (e.g., regret about the past or worry about the future) and maladaptive thinking patterns more generally (58). The inability to disengage from such patterns leads to repetitive negative thinking or proliferation of ruminative self-referential thought, contributing to depression, anxiety, addictive craving, and general stress reactivity (59–61). *Attention capture* is not limited to internal events (e.g., thoughts); for example, visual stimuli of negative valence create stronger fixation than neutral ones (62). In addition to attenuating the activity of DMN, mindfulness training is thought to reduce *attention capture* and enable more efficient disengagement when the fixation occurs via enhanced conscious executive control and entrainment of automatic regulatory circuits (46), as well as improved interoception (63, 64). Reductions in *attentional capture* is thus another important transdiagnostic mechanism by which mindfulness practice can ameliorate the formation of new, resurfacing of past, and exacerbation of the present mental health issues in the context of COVID-19.

Next, we consider the notion of the *beginner's mind* (*shoshin* in Japanese used in Zen Buddhism) that is not currently well-conceptualized in the cognitive approaches to mindfulness. It refers to having an attitude of openness and readiness to experience even the most mundane and repetitive mental events

as new, fresh, and free of preconceptions. We showed attenuated startle habituation, which we conceptualized as an index of openness toward repetitive aversive stimuli, in experienced mindfulness practitioners (65). Buddhist psychology posits that one of the reasons for the discontent or dis-ease that even people with no psychiatric diagnosis often experience is a rapid habituation to sensory stimulation, leading to wanting new or higher intensity experiences. In healthy meditation-naïve adults, faster startle habituation is associated with impulsivity, behavioral disinhibition, and sensation seeking (66). Mindfulness practice might thus allow for fresh and alert attention to each incoming stimulus, no matter its valence or familiarity. This might lead to experiential novelty and appreciation of even the most mundane (one of the functions of a “raisin exercise” that opens the MBSR programme is to do just that—to provide an experience of novelty and appreciation of the sensory experience of touching, smelling, and savoring a raisin by adopting mindful awareness). This effect of mindfulness practice in the context of COVID-19 might serve to reduce aggressive or violent behaviors driven by increased irritability and impulsivity that could be brought about by the strict social distancing measures, such as lockdown or quarantine.

Additional relevance of the *beginner's mind* is its possible link to creativity through the ability to see things in a new light and from “out-of-the box” perspectives. In the words of Shunryu Suzuki who popularized the notion of the *beginner's mind* in the book *Zen Mind, Beginner's Mind* (67): “In the beginner's mind there are many possibilities, in the expert's mind there are few.” [p. 21]. Long-term mindfulness meditators exhibit higher divergent thinking (an aspect of creativity assessed by the performance on Alternative Uses Task), which was found to correlate with their mindfulness practice expertise and to be accompanied by an inverse relationship with inter-hemispheric functional connectivity between the main nodes of the DMN (medial prefrontal and posterior cingulate areas) (68). Previous research has linked divergent thinking with greater ability for creative problem solving, over and above the effects of intelligence or expertise (69). Together, these findings present a possibility that the practice of mindfulness might facilitate creative problem solving when dealing with the social and economic aftermath of the pandemic, on both individual and governmental levels.

The final aspect of COVID-19 pandemic that we consider where mindfulness mechanisms might have an important beneficial implication and application is dealing with grief. Grief is a natural response to loss, which can take many forms in the context of COVID-19 pandemic: the death of a loved one; a loss of job, business or important relationship; deterioration of physical and/or cognitive functioning due to COVID-19 illness; a loss of mental equilibrium; or a loss of motivation, sense of purpose and meaning in the face of persistent uncertainty and existential threat.

The beneficial effects of mindfulness on dealing with loss and grief are commonly assumed, with many free resources having been made available for using mindfulness to deal with grief since the start of the pandemic. The very few empirical studies that have assessed the effect of mindfulness-based

interventions on grief have indicated promising effects, yet to be confirmed in more rigorously designed larger-scale studies. MBSR in chronic pain patients (70) was found to facilitate a quicker transition through the initial stages of grieving process as compared with the control group of patients seeking or receiving medical assistance. MBSR in breast cancer patients (71) showed significant improvements in existential well-being as well as the reduction in a number of self-identified losses and associated grief.

Theoretical models based on the known mechanisms of mindfulness have been proposed for the use of mindfulness practices for treatment of traumatic and complicated bereavement [e.g., (72)]. MBCT in bereaved individuals was found to significantly improve both executive function and emotion regulation by alleviating emotional interferences on cognitive functions (73), as well as to reduce self-reported anxiety concurrent with increases in self-reported mindfulness that were associated with inter-network reorganization within the brain during the resting state (74).

The Kübler-Ross grief model (75) postulates five stages that those who go through a grieving process may experience, each associated with a distinct emotion: denial, anger, bargaining, depression, and acceptance. Acceptance is inherent to mindfulness process as an attitude or orientation adopted during mindfulness practice toward the experiential content, supporting non-reactivity and experiential openness (32). Mindfulness practice when dealing with loss and grief can bring about an understanding and acceptance of transient and ever-changing nature of all our experiences, whether mental (thoughts, emotions, body sensations) or physical (events, things, relationships). This experiential understanding of all phenomena as being “impermanent” (76) might prove to be an important mechanism for promoting positive adaptation to a highly unpredictable and constantly changing landscape of COVID-19 pandemic. Mindfulness practice has also been shown to increase the sense of meaning, rather than search for meaning *per se*, in a longitudinal study (77), suggesting that grief due to the loss of purpose and meaning, which might be brought about by rapidly changing circumstances, could be regained through mindfulness practice.

## DISCUSSION

### Mindfulness Provision for COVID-19: Now and the Road Ahead

Given the outlined relevance of mindfulness practice and associated skills to dealing with the mental health crisis as secondary to the COVID-19 pandemic, we now discuss its current place within the mental health advice and provision offered through the National Health Service (NHS) in the UK (with implications for health care services elsewhere), as well as offer suggestions for increasing the benefit that could be afforded by a greater exposure and more coordinated implementation.

In recognition of the psychological effects of social distancing and isolation on the UK population, Public Health England's *Every Mind Matters* platform has launched new advice,

focused on looking after people's mental well-being during the coronavirus (COVID-19) pandemic. It includes a tailored COVID-19 Mind Plan with content for dealing with specific mental health and well-being issues such as anxiety, stress, low mood and sleep disturbances by signposting the individuals to activities such as mindful breathing exercises, help reframing unhelpful thoughts, and muscle relaxation. The *NHS in Mind* app, rolled out at the end of March 2020, provides a set of free resources designed to help NHS staff to deal with high anxiety, panic and fatigue whilst dealing with the unprecedented demands of their profession in the context of COVID-19. The resources offered include mindfulness-based approaches, such as a 3-min breathing space. *The Mindfulness Initiative* has compiled the list of online resources with the NHS staff in mind that could be accessed via their website.

Whilst we welcome such recommendations and signposting to freely available mindfulness-related resources for the general public and the NHS workers, our opportunistic survey of uptake by the target groups has revealed that the engagement with the free online resources particularly amongst the healthcare professionals is very low, with about 1–2% accessing the recommended materials and <1% doing so consistently. Experienced mindfulness instructors across the UK have been providing free Zoom sessions for the NHS staff during their shifts at different times of day across the weekdays and the weekend to enable flexible participation. However, participation has been limited to single digit numbers of NHS professionals per Zoom group/session. Given how supportive mindfulness practice can be for this target group, the reasons for the low uptake need to be understood. According to the mindfulness instructors we have surveyed, the engagement with the Zoom mindfulness sessions during staff break periods appears to be higher in the NHS trusts/hospitals where it is encouraged by the management.

Our online focus group ( $N = 11$ , all female, comprised of the general practitioners and nurses working for the National Health Service (NHS) in London, UK) that explored the reasons for the low uptake amongst the healthcare professionals suggest a number of possible reasons. First, these highly altruistic individuals have difficulty in “giving care to themselves” even though they recognize the benefits that mindfulness practice can offer them in general, and at this time in particular. Second, a popularized notion that mindfulness expertise development requires at least 10,000 h of practice creates the erroneous belief that extensive practice is required to start experiencing the benefits of mindfulness practice. Being close to burn-out due to the workload, plus having to balance long shifts with family responsibilities, the idea of starting something that will require many hours of practice before the tangible effects will be felt as off-putting. 10,000 h of practice might be a useful criterion to apply for research purposes to define mindfulness practice expertise in the absence of established and reliable objective markers, but it appears to be unhelpful for encouraging individuals to initiate mindfulness practice. Even a simple instruction for mindful emotion regulation of pain experience in meditation-naïve individuals produced the same phenomenological and neural effects as would be expected in experienced mindfulness practitioners (78). A clear distinction should be made when providing a rationale for

mindfulness-based approaches between the dose-related effects of mindfulness practice in terms of skills' transfer from state to trait vs. potential benefits gained from mindfulness as a state induced by a single practice session with expected 'spill over' effect, even if short-lived at the early stages of practice development, for dealing with daily pressures and stressors.

Related to this is a common belief that mindfulness practice requires effort. Again, in the context of exhaustion faced particularly by the health professionals, this belief is counter-productive in encouraging this population to test the benefits of mindfulness practice for themselves. Instead, the information on mindfulness resources should emphasize that secular mindfulness approach rests on the notion of non-striving; the only “effort” required is in remembering to come back to the present-moment experience whenever the mind becomes distracted by or caught up in the experiences. Mindfulness should be presented as an opportunity to create space, however brief, for diffusion of daily trauma that the mental health professionals in particular are exposed to.

We would also like to suggest providing more in-depth rationale for mindfulness practice in terms of its benefits when offering/recommending it to the target populations to fully harness its potential as a preventative cost-effective public intervention. The signposting materials we have surveyed thus far tend to present it as one of the alternatives to other methods of coping, such as distraction by a pleasurable activity, hobby or similar. However, distraction can be adaptive or maladaptive as an emotion regulation strategy depending on whether it is combined with acceptance or avoidance (79). Acceptance has been shown to be associated with positive psychological outcomes [e.g., (80, 81)]. Emotional avoidance, on the other hand, is associated with higher levels of anxiety and affective distress [e.g., (82)]. Nakamura and Orth (83) proposed the distinction between active acceptance, associated with positive psychological outcomes, and resigning acceptance, associated with negative psychological outcomes, and showed active acceptance to be an adaptive response to unchangeable situations. Active acceptance involves experiential openness (84), which is facilitated by mindfulness practice, and is one of the attitudes toward the experiential content adopted during mindfulness practice. Therefore, a combination of mindfulness practice followed by a pleasurable activity and hobby may have a more positive effect on well-being than distraction alone, which is likely to be used as avoidance-type coping with stress and anxiety in COVID-19 context.

We have also found in our own experience of signposting to the freely available online resources as well as offering virtual mindfulness courses and drop-in mindfulness sessions to the NHS staff, University students and University staff (both academic and professional) that there is a great appreciation for the group setting, in terms of support of the contact with a mindfulness instructor for the understanding of the rationale and the know-how of mindfulness practice *per se*, as well as the normalizing and supportive effects of shared group experience. Therefore, our recommendation for the provision of mindfulness-based support during the COVID-19 pandemic is to offer free virtual mindfulness sessions/courses with trained and experienced mindfulness instructors whenever possible, in

addition to signposting to free online resources that could be supportive for personal practice in between regular virtual group sessions.

One notable “success” story in terms of uptake from our survey of online resources is *Headspace*, a private company teaching meditation via a website or a phone app, which has seen a surge in the uptake of its products since mid-March 2020, most notably a doubling of the downloads of the app; 14-fold increase in users completing a free guided meditation for relieving stress; 110% increase in the usage of a “buddy” support; and 70% increase in free live group meditation starting-out sessions. The latter two figures highlight the need for inter-personal support and the value of shared practice experience sought by the users at this time. In recognition of the benefit that mindfulness practice can bring particularly to the health professionals, *Headspace* has been offering free access to its products for US healthcare professionals working in public health settings and all NHS staff to support them in dealing with the present crisis. Given that *Headspace* has a strong emphasis on establishing the evidence-base for their products through collaborative partnerships with academics and is highly popular at a workplace as well as amongst younger users, utilization of its products might be worth considering by the policy makers in the UK and in other English-speaking countries when developing strategies around coordination of mindfulness-based support for mitigating mental health pandemic secondary to COVID-19. Additionally, international collaborative effort is required to develop multilingual evidence-based free online resources to support populations in the face of deteriorating economic conditions globally, and particularly in low and middle income countries.

The intra- and inter-national collaborations on mental health management, provision, and research are essential in dealing with the challenges of the present pandemic and in preparing the best and timely response for the possible future ones. Xiang et al. (2) called for a joint international collaboration to combat mental health challenges during the global COVID-19 pandemic faced by the mental health professionals due to the lack of relevant guidelines and stretched mental health resources in particular. Holmes and colleagues (85) stressed the importance of high-quality data collection on the mental health effects of the COVID-19 pandemic across the whole population and vulnerable groups.

We would like to propose that in addition to understanding the effects of the pandemic on mental illness, the pandemic presents an unprecedented opportunity for studying the factors for resilience, and particularly the role of mindfulness practice, whether in the form of meditation, yoga, qigong, or other, across countries and cultures. Systematic research is urgently needed to examine if adopting these mindfulness-based approaches can not only offset many of the negative mental health consequences, but also help individuals channel the COVID-19-related stress toward positive growth and resilience (86).

The research should also consider the possibility of “negative effects” of mindfulness. As many other phenomena, mindfulness practice appears to follow a non-monotonic or inverted U-shaped trajectory where positive effects at lower to moderate “doses” might turn negative at higher “doses” (87). The research into the “negative effects” needs to make a clear differentiation, mostly

lacking in previous research, between what constitutes “negative effects” *resulting from* vs. difficult/challenging experiences which might arise *during* mindfulness practice. This research also needs to be better formulated conceptually, as currently it is heavily culturally relative/biased in terms of what constitutes a “positive” vs. “negative” effect.

Mindfulness developed through the formal practice extends to all aspects of one’s life, resulting in greater enjoyment of hobbies, enhancement of inter-personal interactions, and pro-social engagement. The latter will support social cohesion in the times when cooperation is essential, and potentially reduce engagement in conspiratorial and otherwise antagonizing approaches as a way of coping with the disruption posed by the pandemic to what once was the normal order. Hence, the research into the effects of mindfulness practice upon the individuals should extend to understanding its effects on groups and societies at the time of extreme challenge. Schlosser and Bond (88) have observed positive effects of an intervention incorporating elements of different mindfulness-based approaches on team cohesion, team values, and willingness to support each other in a crew of six astronauts during training in isolation over a two-week period.

## CONCLUSION

Mindfulness-based approaches appear well-suited to deal with the challenges presented by the time of unrepresented uncertainty, change, and loss, which can take many forms in the context of COVID-19 pandemic. Mindfulness practice facilitates acceptance of the uncomfortable, difficult, and painful experiences, allowing them to simply be, feeling them as they are without judgement, being present with them until we are ready to let go, and thereby opening ourselves to new experiential and behavioral possibilities. Mindfulness as a way of being exemplifies an approach to life captured by the American poet Robert Frost: “The best way out is always through.” And it is our thesis that it is.

## DATA AVAILABILITY STATEMENT

The original contributions generated for this study are included in the article/supplementary material, further inquiries can be directed to the corresponding author/s.

## AUTHOR CONTRIBUTIONS

EA, RP, and VK contributed to the conception of the manuscript and its overall structure. KS contributed to manuscript preparation. EA wrote the first draft of the manuscript and revised the manuscript for the final version. VK, RP, and KS provided feedback and contributed to the revision. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by the BIAL Foundation grants to EA (Grant Number 183/16), and VK and RP (Grant Number 92/18).

Northern Italy: From Isolation to  
Rehabilitation.  
*Front. Psychol.* 12:588193.  
doi: 10.3389/fpsyg.2021.588193

The objective of this paper is to describe the organization and modality of provision of clinical psychology services for those patients who had to be hospitalized due to COVID-19 during the pandemic in Northern Italy. The IRCCS Policlinico San Donato hospital in Milan was converted into a COVID-19 center in March 2020, and all the staff, including the Clinical Psychology Service Team, were diverted to assist these patients. A description is given of how the service was organized and the modalities which were utilized to assist the patients. Following the pertinent ministerial decrees, guidelines, and relevant literature, the patients were followed up through telehealth (via phone, smartphone, or tablet with audio or audio-visual calls). A COVID-19 rehabilitation unit was later opened in April 2020, where all patients were seen and followed up by the Clinical Psychology team, the last patient being discharged at the end of June. Details are given about the type of services provided during the hospitalization at the different points in time. At admittance and subsequent isolation, patients indicated by the medical and nursing staff, and those who specifically requested it, were given psychological support. Patients transferred to the COVID-19 rehabilitation unit were all evaluated for anxiety, depression, posttraumatic stress disorder, and sleep disorders both on admission and at discharge when possible.

**Keywords:** COVID-19, clinical psychology, telehealth, anxiety, depression, PTSD, sleep disorders, rehabilitation

## INTRODUCTION: THE OUTBREAK OF COVID-19 IN NORTHERN ITALY

The official date of the start of the outbreak of COVID-19 in Italy was the 31st of January 2020. This followed the arrival of two Chinese visitors on a flight from Wuhan to Milan Malpensa Airport on the 23rd of January, who tested positive in a central hotel in Rome. The first Italian patient confirmed with COVID-19 (patient 1) was a 38-year-old man admitted to the hospital in Codogno, Lombardy, on the 21st of February. After that, in <1 week there was a surprising increase in the number of cases in Italy, which put the Italian health service under considerable

strain, leading to the discovery of cases in various bordering regions and autonomous provinces of northern Italy (Carinci, 2020).

Following these events, many hospitals in northern Italy were converted into COVID-19 centers to deal with the emergency. On the 9th of March, it was communicated that also the IRCCS Policlinico San Donato would become a COVID-19 center and that all the staff, including the Clinical Psychology Service Team, would need to be diverted to assist this population. This caused considerable strain on the team, which had to quickly get organized to provide psychological assistance to a new population by utilizing new modalities. There was the additional stress of finding oneself in the same situation of the patients and the families themselves (The British Psychological Society, 2021), which was handled by holding daily remote meetings. During the peak of the pandemic, 283 hospital beds were made available for COVID-19 patients in our institute, and a total of 632 COVID-19 patients were admitted to our center, until the 30th of April. After that date, some patients were followed remotely after their discharge if required and but no further COVID-19 patients were admitted.

## PSYCHOLOGICAL FACTORS ASSOCIATED WITH HOSPITALIZATION OF COVID-19 PATIENTS

In the COVID-19 Prevention and Treatment Manual 2020a, it is reported that in isolation wards about 48% of confirmed COVID-19 patients experience psychological stress during initial admission.

The organization of health care for COVID-19 patients must necessarily include mental health care in a timely and urgent manner (Bao et al., 2020; Carvalho et al., 2020; Jiang et al., 2020; Onyeaka et al., 2020; Xiang et al., 2020).

Specific attention needs to be given to the older population, who are considered more vulnerable and more limited in regard to technological access and to remote care (Yang et al., 2020).

In fact, anxiety, and sleep disturbances have been shown to increase significantly following isolation hospital-based treatment. However, preliminary findings indicate that asymptotic muscle relaxation training, also conducted remotely, can be used to alleviate anxiety and improve sleep quality of patients with COVID-19 (Liu et al., 2020a).

In this study based in China, quality of life, anxiety, and depression were specifically assessed in the rehabilitation setting, and both quality of life and anxiety improved after a 6-week program (Liu et al., 2020b) in which the following interventions were carried out: respiratory muscle training, cough exercise, diaphragmatic training, stretching exercise, and home exercise.

Practitioners working in respiratory rehabilitation can also deal with reducing anxiety and depression in patients who experience symptoms of deliriousness, anger, fear, dysthymia, insomnia, panic attacks, or sense of abandonment during isolation and to monitor and improve the quality of life as much as possible. In addition, it is important to monitor the possibility of non-collaboration and non-adherence to

treatment (Vitacca et al., 2020; Zhou et al., 2020). From our clinical experience, non-adherence to treatment in hospital may occur because the patients are not aware of the effects of the treatment, because of extreme fatigue and because of severe psychological distress. Psychologists can help patients understand the importance of their treatment and provide support and indications for relaxation.

## NATIONAL AND INTERNATIONAL GUIDELINES AND RECOMMENDATIONS ABOUT PSYCHOLOGICAL SUPPORT DURING THE COVID-19 PANDEMIC

As a consequence of the pandemic, a series of decrees were issued by the President of the Council of Ministers in Italy (*Presidente del Consiglio dei Ministri - PDCM*) 2020b. In particular, on the 8th of March 2020 a decree was issued (PCDM, 2020) in which it was specified that in order to “counter and contain the spread of the COVID-19 virus,” “movements are authorized only if motivated by work needs or situations of need, that is displacement for health reasons.” It was highlighted that in all possible cases, “remote connection modalities with particular reference to public and community health and public utility services” must be adopted, to find alternative ways to proceed rather than physically moving people between locations.

Interim guidelines that addressed the use of personal protective equipment with coronavirus disease (COVID-19) and for operating during periods of severe shortages (World Health Organization, 2020), indicated that all bedside contact between health workers and COVID-19 patients should be restricted to only staff providing direct care, and that even this contact should be minimized and carefully planned. The advice to psychologists with respect to COVID-19 issued by the National Council of the Order of Psychologists (*Consiglio Nazionale Ordine Psicologi - CNOP*) (Consiglio Nazionale Ordine Psicologi, 2020) recommended that consultancies and therapies take place remotely when faced with clear epidemiological risk factors. The relevant regional order of psychologists recommended that the guidelines specified in the ministerial decree issued on the 8th of March should also be followed by psychologists in relation to organizing their work (Ordine Degli Psicologi Della Lombardia, 2020).

Further, international research and guidance papers recommended that psychological services should be delivered remotely, online, and/or over the telephone (Carvalho et al., 2020; Jiang et al., 2020; Liu et al., 2020c; Wind et al., 2020; Wright and Caudill, 2020; Xiang et al., 2020; Zhou et al., 2020). Nonessential staff, such as psychiatrists, psychologists, and social workers, were strongly discouraged from entering isolation wards for COVID-19 patients to observe the strict infection measures required by the pandemic (Duan and Zhu, 2020). It was suggested that patients should be guided to complete relevant questionnaires via their mobile phones 2020a.

In the recommendations relating to respiratory rehabilitation, it was indicated that psychological support is also important at the time of hospitalization (Brugliera et al., 2020; Xiao et al.,

2020). Further, rehabilitation programs for those patients who have been isolated should be conducted remotely with telehealth systems, in order to avoid the spread of infection (Vitacca et al., 2020; Zhou et al., 2020).

## ORGANIZATION AND MODALITY OF DELIVERY OF CLINICAL PSYCHOLOGY SERVICES

The rapid evolution of the situation in Northern Italy did not allow the possibility of structuring an intervention plan. In fact, before our institute was converted to a COVID-19 center in 2020, all of the Clinical Psychology Service staff were exposed to the virus without any personal protective equipment, having been in the presence of patients who were later diagnosed as having a positive diagnosis. All team members tested negative at the COVID-19 screening. However, in May, after a period of quarantine that followed this initial exposure, one psychologist's results indicated the presence of virus antibodies (but not the virus itself).

In order to establish how to proceed, a literature review was carried out. The pertinent ministerial decrees and indications from the regional order of psychologists were consulted, which will be described in detail in the following paragraphs. Operative instructions were drafted based on the decrees and guidelines and inserted in the official system of the hospital. These were automatically forwarded to all the staff of the hospital via e-mail, initially to provide guidance for the care of patients hospitalized for acute admissions. These were subsequently also applied for patients in rehabilitation following the opening of the COVID-19 Rehabilitation Unit on the 6th of April 2020.

In both cases, the operative instructions describe the expected psychological pathway for patients hospitalized in the various departments and therefore urgently requiring psychological crisis intervention (Jiang et al., 2020; Parolin et al., 2020).

## MODALITIES OF DELIVERY OF PSYCHOLOGICAL SUPPORT IN THE VARIOUS OPERATIVE UNITS AT THE IRCCS POLICLINICO SAN DONATO HOSPITAL

Taking into consideration all guidelines and recommendations, all clinical psychology services were organized online and/or via telephone. In those cases when patients did not own a smartphone or mobile phone, arrangements were made with staff to use the departmental telephone or tablet.

### Patients in Isolation and Intensive Care Unit

During the pandemic, more than 283 hospital beds (out of which 28 were intensive care beds) were dedicated to COVID-19 patients. For those patients who were in isolation and hospitalized in the intensive care unit. Although psychological support was provided for patients in the intensive care unit, no

psychometric evaluations were carried out, in order to avoid the risk of contributing further to their distress. Due to the large number of patients hospitalized, it was not possible to contact all of them to enquire whether or not they required psychological support.

The main route of referrals to the Clinical Psychology Service was through the medical and nursing staff, who alerted other colleagues via e-mail, phone, and word of mouth that the service was available remotely when required. A WhatsApp message was also circulated, instructing the medical staff on the procedure for referring patients.

The medical and nursing staff could refer the patients and their relatives by calling the service's fixed line from 8 a.m. to 8 p.m. (7 days a week), by writing an e-mail, or by messaging or calling the Clinical Psychology Service team mobile phone numbers.

The following information was requested when referrals were made: first and last name of the patient, their age, a brief description of their medical situation, the telephone number on which the patient could be contacted (possibly specifying if it is a smartphone or a normal phone), the operative unit in which the patient was hospitalized, and the phone contact of the referring physician and the head nurse of the operative unit.

During this phase, the type of psychological intervention was based upon the evaluation which was carried out during the first session, taking into consideration the presence of psychological distress (including anxiety, depression, and sleep disturbance), the patients' psychosocial situation, and the support they currently feel they had. All the questionnaires utilized have cutoffs which indicate the level of distress. When patients reported moderate or severe distress, this was explored and the patients were closely monitored, on a daily basis. If the distress was absent or mild, the patients were contacted once or twice a week.

A total of 21 patients were seen (9 females and 12 males, average age 67 years, ages ranging from 31 to 84 years) from the 9th of March to the 6th of June. The average duration of hospitalization was 25 days, and 189 sessions were provided, which lasted approximately 20 min each. 13 family members were also supported, and 2 patients were also provided psychological support after discharge. One patient who was referred to the Clinical Psychology Service refused the offer of support.

### Patients in COVID-19 Rehabilitation Unit

When it comes to performing assessments in COVID-19 rehabilitations, it has been recommended that questionnaires which can be compiled quickly by patients, and which can help to quickly identify the type of psychological dysfunction should be utilized (Zhao et al., 2020). In addition, patients should have access to psychological support also through a hotline (Zhao et al., 2020). Further, it is recommended to provide patients counseling sessions, psychological support, and cognitive training as required (Brugliera et al., 2020).

When the patients were transferred to the rehabilitation unit, they were in a more stable condition, and this allowed for a more thorough psychological screening with the utilization of psychometric tests and a psychosocial assessment. The average

length of hospitalization in this unit was of 18 days (with a minimum of 8 days and a maximum of 39 days).

The patients were identified upon hospitalization in the unit by the communication of the medical staff to the clinical psychology service staff and through the daily consultation of the GALILEO, a management system for coordinated activities to efficiently direct and govern patient-centered hospital processes. The same information was obtained for patients in isolation if this had not previously been gathered.

For each patient, a minimum of 3 sessions were programmed during their hospitalization of about 20 days; if the patient stayed for <10 days, at least 2 sessions were provided. At the end of each session, an activity report file which included the date, the starting time of the end time of the session, the duration in minutes, and the qualitative description of the type of intervention was compiled by the staff of the service on an online excel database.

During the first interview, a general assessment of the patients' psychological status was carried out as well as the appropriateness of administering psychometric tests.

In the second session, if the psychosocial questionnaire could be administered to the patient, the assessment was carried out remotely. If, for some reason, it was not possible to administer the psychosocial questionnaire to the patient, a psychological support session was provided. Some reasons which did not allow patients to be tested were the patients feeling too weak and tired, being completely deaf, severe cognitive impairment, and when patients refused to proceed.

When it comes to the third interview, if the hospitalization lasted <15 days, the psychometric tests were not re-administered (because most tests assess psychological functioning on a period of 2 weeks). If the patients' hospital admission lasted for 15 days or more, the psychometric tests were re-administered [anxiety (GAD-7), depression (PHQ-9), post-traumatic stress disorder (IES-R), and insomnia (ISI)], and the evolution of the psychological situation was discussed with patients.

For all patients entering the rehabilitation unit, two reports were drawn up: an initial psychological report, which included all the results from the psychometric tests, and the task report form, where all the sessions and the number of minutes were indicated. For patients who were hospitalized for 15 days or longer, a final psychological report was drafted, where the evolution of the psychological condition was described. When patients required and/or requested psychological support also after discharge, it was provided. All the documentation was sent via e-mail to the head of the COVID-19 Rehabilitation Unit via the hospital e-mail, to be included in the patients' medical records, and stored digitally in the area of the server dedicated to the service of Clinical Psychology.

A total of 37 patients were admitted to the COVID-19 Rehabilitation unit, and 35 were evaluated and provided support (18 females and 17 males, average age 75, age ranging from 52 to 92) from the 8th of April to the 30th of June. The remaining 2 patients could not be supported because one was completely deaf and the other one had severe Alzheimer's disease. Five of the patients who were supported during isolation were subsequently

moved to rehabilitation. A total of 108 sessions were provided which lasted on average 20 min.

## Psychosocial Assessments Utilized in COVID-19 Rehabilitation

The following questionnaires which have been validated and freely distributed in Italy are suggested in order to monitor anxiety and depression: the Patient Health Questionnaire-9 (PHQ-9) (Spitzer et al., 1999; Cannon et al., 2007; Stafford et al., 2007; Kroenke et al., 2009) and the GAD-7-General Anxiety Disorder-7 (Spitzer et al., 2006; Esser et al., 2018). As specified in the previous paragraphs, it is extremely important to monitor anxiety and depression in hospitalized patients with COVID-19. The following short questionnaires may be particularly useful for measuring a range of psychological symptoms in this population.

The Impact of Event Scale (IES) (Spitzer et al., 2006; Esser et al., 2018) has been previously utilized to assess levels of posttraumatic stress disorder in patients infected with severe coronaviruses and who were also hospitalized. The initial assessment was carried out through a psychosocial questionnaire that evaluated the general patient history including demographic and social variables: marital status, presence/absence of children, culture of origin, education level, occupation status, and religion.

In regard to assessment of social support and loneliness, patients were asked if they had any close relationships, the quality of those relationships, and if they were receiving adequate support.

## Psychometric Testing

The following validated tests were administered after the psychosocial assessment.

- The Fagerström test (Heatherton et al., 1991) is a self-administered test that evaluates the current dependence on nicotine.
- The Morisky, Green, and Levine Adherence Scale (MGL) (Morisky et al., 1986) is the most widely used on adherence to drug therapy.
- The Satisfaction with Life Scale (SWLS) (Broadbent et al., 2006) measures the overall cognitive assessment of life satisfaction experienced by the patient.
- The Patient Health Questionnaire - 9 (PHQ-9): (c Kroenke et al., 2001) is a short psychological screening tool designed to measure symptoms of depression in primary care facilities.
- The Generalized Anxiety Disorder (GAD-7): (Kroenke et al., 2007) is a screening tool for generalized anxiety disorder in clinical practice and research. In addition, it provides a measure of severity and is linked to the criteria of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV).
- The EuroQoL-Visual Analog Scale (VAS): (EuroQoL Group, 1990) is the second part of the EuroQoL-5D questionnaire, a standardized tool that measures the health of respondents and their quality of life and consists of a VAS of 20 cm, graphically represented as a graduated thermometer, on which the patient indicates the best (score=0) or worst (score=100) possible state of health.

- The QoL-VAS: (Moons et al., 2006) consists of a visual analog scale of 20 cm, graphically represented as a graduated thermometer, on which the patient indicates the best (score=100) or the worst (score=0) about the perception of own quality of life.
- The Impact of Event Scale (IES-R): (Weiss et al., 1997) is a self-report measure (for DSM-IV) that assesses subjective distress caused by traumatic events.
- The Insomnia Severity Index (ISI): (Bastien et al., 2001; Castronovo et al., 2016) is a self-report questionnaire assessing the nature, severity, and impact of insomnia.

If the cutoffs of the various tests indicated the presence of anxiety, depression, PTSD, and sleep disturbances and if there was a particular indication of social isolation and/or also a lack of awareness and adequate coping, the medical staff were alerted. These elements guided the psychologist to plan additional sessions as needed.

## DISCUSSION AND CONCLUSIONS

In this perspective paper, the organization of clinical psychology services for COVID-19 patients who were severe enough to necessitate hospitalization, in a red zone, was described. The progression of the pandemic was extremely rapid and unexpected in Northern Italy, and in that period, there was a lot of uncertainty about the characteristics of the virus. This caused a lot of difficulty when it came to the determination of the modality of the provision of the clinical psychology service and on the type of intervention which was required. Another peculiar characteristic, which varied from the routine situation, was that all the members of the staff were exposed to the same situation in which the patients were, even though none of them developed any severe symptoms.

The first cases which were referred to the service included young people who were affected with a Cytokine Storm. As the isolation departments were being organized, the medical staff requested our intervention. In the beginning, there was a lot of uncertainty about whether to proceed remotely or in person.

Following consultation of all the decrees, recommendations, and pertinent literature, there was no doubt that the interventions needed to be provided remotely, to minimize, as much as possible, the spread of the virus during the peak.

As indicated in the literature described in the previous paragraphs, in the absence of the option of in-person contact, that remote modalities remote psychological support is highly effective when it comes to the assessment and monitoring of the hospitalized patients and also the delivery of psychological support. Patients who had to wear breathing caskets because of a very low saturation confirmed that it was easier to communicate remotely, because they had the possibility to put earphones inside the casket. Face-to-face communication was extremely

difficult also because the healthcare providers who were present had to wear a considerable amount of protective gear, making communication even more difficult.

During the sessions, the patients were helped to become aware of their emotions and express their distress (also with the help of the patient reported outcomes) and they were taught to relax through very basic breathing exercises. Their psychological status was monitored, and if at discharge they still reported experiencing distress, they were supported also during the follow up period. In agreement with the literature we cited, we therefore recommend providing remote psychological support to the patients and their families.

In order to monitor the well-being of Clinical Psychology Staff, a remote “check-up” was organized twice a day, once in the morning and once in the evening. Temperature and symptoms were checked, and support was provided also within the team, as required, to increase resiliency during this highly stressful period marked by significant uncertainty. In conclusion, even though patients in rehabilitation were all screened and supported, and all referred patients were contacted, it could be possible due to the highly demanding and unexpected circumstances that not all isolated patients who required psychological support were referred to and contacted by the Clinical Psychology Service.

We recommend that in future, it would be useful to identify medical and psychosocial characteristics that could help the clinical psychology service to recognize suitable patients independently, without the need for direct referrals by medical staff. Ensuring that patient mobile phone numbers are reliably recorded on their medical chart would facilitate this. Based on our experience, we suggest that indicators could be based on certain medical and psychosocial indicators (such as preexisting psychiatric or psychological conditions, possibility of a bad prognosis, etc.). Such measures as these may increase the efficiency and expediency of the provision of clinical psychology services in the midst of pandemic conditions.

**Background:** The COVID-19 pandemic is a worldwide public health emergency that forced the Italian Government to deliberate unprecedented actions, including quarantine, with a relevant impact on the population. The present study is one of the first Italian nationwide survey within the first period of the COVID-19 outbreak aimed to understand the social and psychological impact of the COVID-19 outbreak.

**Methods:** An online survey collected information on sociodemographic data, history of direct or indirect contact with COVID-19, and other information concerning the COVID-19 emergency. The General Psychological Well-Being Index and a modified version of the PTSD Checklist for DSM-5, focused on the COVID-19 experience, assessed the respondents' general psychological condition.

**Results:** Of 1,639 respondents equally distributed in the Italian territory, 5.1% reported PTSD symptomatology, and 48.2% evidenced lower psychological well-being linked to COVID-19 diffusion. Lower psychological well-being was significantly higher in women, younger than 50 years, and with health risk factors. Lower psychological well-being was also detected in individuals who did not know if they were infected, who have had direct exposure or were uncertain about their exposure to COVID-19, or who knew infected people. Regarding the social and behavioral consequences, respondents perceived worsening in demographic, economic, social, and relational conditions. Moreover, they reported increased film viewing, cookhouse time, social media use, and decreased physical activity.

**Conclusion:** The COVID-19 pandemic appears to be a risk factor for psychological diseases in the Italian population, as previously reported in the Chinese people. About half of the respondents reported a significant psychological impact. Moreover, we confirmed the role of restraining measures that led to modify lifestyles, social perception, and confidence in the institutions. These results underline the need for further studies aimed to develop psychological interventions to minimize the consequences of the COVID-19 pandemic.

## INTRODUCTION

Since December 2019, several world places have gradually experienced an outbreak of pneumonia epidemic caused by the 2019 novel coronavirus (2019-nCoV, later named SARS-CoV-2, and then COVID-19) (1). The COVID-19 outbreak was defined as a pandemic by the World Health Organization (WHO) (1). The governments of many states immediately focused attention on the best strategies to reduce the virus diffusion and the number of victims.

In Italy, since the first case of COVID-19 (February 20, 2020), a rapid spread of the contagions was reported in the first weeks of March. This condition resulted in the Italian Government's deliberation of unprecedented actions aimed to reduce the diffusion of the virus, in line with the measures already adopted in China. Since March 10, a lockdown was requested for the Italian population. This measure included avoiding gathering and requiring to maintain the social distance of at least 1 m, limiting the number of people in public places, going out to work only if the physical presence was essential, and going out of one's own home if it was strictly necessary. Moreover, the blocking of all unnecessary economic activities (e.g., gyms, restaurants, and beauty centers) was imposed. For the first time since the end of the Second World War, the Italian population is facing a reduction in freedom of movement and a severe economic and job crisis that adds to the uncertainty linked to the increase in COVID-19 cases and victims. As of March 30, 2020, the pandemic had caused 12,428 deaths out of 105,792 confirmed cases in Italy (2). Despite the obvious benefits of the extreme social distancing measures adopted in countries such as Italy, the spread of COVID-19 is still unstoppable worldwide.

One of the main features that impact psychological well-being is the restriction of freedom of movement connected to social isolation. Previous studies on several epidemics, such as HIV/AIDS diffusion, the SARS and H1N1 pandemic, the Ebola virus, and the Zika virus, have underlined psychological consequences not only on individuals affected by these diseases but also on the non-infected community because they involve different levels of social life (3–6). Hence, both the sudden outbreak of a new and unknown virus and the measures adopted to decrease its spread have had a strong impact on the quality of life and the population's psychological well-being. Accordingly, a recent review suggested that the psychological impact of quarantine and social distancing is wide ranging, substantial, and can be long lasting. It includes anxiety and mood disorders, psychological distress and post-traumatic symptomatology, sleep disturbance, and other psychopathological conditions that negatively impact general psychological well-being and quality of life (7). However, although there are similarities with previous epidemic outbreaks and other diseases, the COVID-19 pandemic has some peculiarities, such as its rapid global spread, its high social and mass-media impact, the high uncertainty due to its origin and its consequences on global health, and the extreme measures taken on a large scale, which make it different from previous cases and underline its scientific relevance in understanding the impact of such kind of event, also on a psychological level.

Starting from the first weeks and over time, some studies have proposed investigating the psychological impact of the COVID-19 pandemic in the first phases of its spread [e.g., 5, 6, 8]. However, most of the first research focused on identifying the epidemiology and clinical characteristics of patients infected by the virus (8, 9) and the challenges for the health systems and the national and international institutions (10). More recent studies analyzed the psychological effects of this emergency in more detail in Italian samples (11–13).

The present study is part of a first nationwide, large-scale survey conducted in the Italian population within the first and more tumultuous weeks of the COVID-19 outbreak (March 2020), focused on assessing the general psychological well-being of the Italian population and the perceptions about the impact of this experience on the Italians' life. Our goal is to provide a photograph of the Italian condition in the first weeks of the restrictive measures related to the period immediately following the promulgation of the "I stay home" decree determined by the broad and severe diffusion of the COVID-19 in Italy.

## METHODS

### Setting and Participants

A cross-sectional design to assess the public response during the epidemic of COVID-19 was adopted. We used an anonymous online survey disseminated to platforms and social media. Due to the current research aim, being at least 18 years old was the only inclusion criterion. The 97.03% of the total respondents (1,689) that started the questionnaires completed the whole survey (1,639) and were considered for the statistical analysis. The main demographic characteristics of the sample are shown in **Table 1**.

### Procedure and Survey Development

As the Italian Government recommended to minimize face-to-face interactions, participants completed the questionnaires through an online survey platform (KoboToolbox). Expedited ethics approval was obtained from the Ethics Committee of the Department of Dynamic and Clinical Psychology of "Sapienza" University of Rome (protocol number: 0000266). The study conformed to the principles of the Declaration of Helsinki. All respondents provided electronic informed consent before starting the investigation. Data refers to the period from March 18 to 25, 2020. The structured survey consisted of questions that covered several areas and took ~30 min to complete. After a demographic questionnaire, participants responded to items assessing the knowledge and perceptions of COVID-19 diffusion and the government measures adopted to contain it; then, questionnaires to evaluate psychological aspects were administered. Participants could withdraw from the survey without providing any justification, and no data were saved. Only data with a complete set of responses were considered.

### Outcomes

Sociodemographic data were collected on gender, age, education, current location, employment status, and the number of usual day interactions. The social impact of COVID-19 was measured,

The analyses refer to the comparison between people with high and low general psychological well-being.

\*Risk factors for the COVID-19 include hypertension, diabetes, cardiovascular and pulmonary diseases, immunodepression, oncological pathologies, kidney disorders, or other medical conditions also in comorbidities.

including quarantine experience, level of confidence in State Institution, information about COVID-19, the trend of new cases and deaths, and previsions on the potential end of the infection. Respondents were required to indicate their source of information and their confidence with it. Concerns about COVID-19 variables included self and other family members that had or could contract the COVID-19 virus. The psychological impact of COVID-19 was measured using the *Psychological General Well-Being questionnaire (PGWB)* (14) and the *Post-Traumatic Stress Disorder Related to COVID-19*.

The *Psychological General Well-Being questionnaire (PGWB)* (14) was adopted to measure subjective general psychological well-being. The PGWB consists of 22 items on six-point Likert scales, divided into six dimensions: Anxiety, Depressed mood, Positive well-being, Self-control, General health, and Vitality. A global score and measures for each dimension are calculated, with higher scores indicating greater well-being in subscales and global scores. In our study, scores higher than 60 indicate adequate psychological general well-being (15).

**TABLE 2** | Confidence of the responders on specific sources of information during the COVID-19 emergency.

<i>n</i> (%)	Extremely	Quite a bit	Indifferent	A little bit	Not at all
Italian government	485 (29.6)	810 (49.5)	125 (7.6)	176 (10.7)	43 (2.6)
Civil protection	666 (40.6)	739 (45.1)	111 (6.7)	105 (6.4)	18 (1.2)

Demographic condition	14 (0.9)	46 (2.8)	289 (17.6)	395 (24.1)	508 (31.0)	387 (23.6)
Economic condition	21 (1.3)	13 (0.8)	34 (2.1)	127 (7.7)	1,345 (82.6)	99 (6.0)
Political condition	31 (1.9)	218 (13.4)	466 (28.4)	307 (18.7)	294 (17.9)	323 (19.7)
Social condition	34 (2.1)	191 (11.6)	199 (12.1)	418 (25.5)	683 (41.7)	114 (7.0)
Relationship status	52 (3.2)	222 (13.5)	244 (14.9)	377 (23.0)	641 (39.1)	103 (6.3)
Sense of identity	67 (4.1)	239 (14.6)	376 (22.9)	257 (15.7)	306 (18.7)	394 (24.0)

The *Post-Traumatic Stress Disorder Related to COVID-19* (COVID-19-PTSD; Modified version of PTSD Checklist for DSM-5; PCL-5) (16, 17) is a self-report measure designed *ad hoc* to assess specific symptoms consequent to the COVID-19, similar to PTSD symptoms, according to the DSM-5 criteria. The questionnaire includes 19 items structured in five-point Likert scales, from 0 (not at all) to 4 (extremely). To test the psychometric quality of this questionnaire, data were collected in an independent subsample ( $n = 300$ , 150 women; mean age:  $26.22 \pm 1.27$ ). The principal component analysis indicated one factorial structure, including 19 items that explain 49% of the variance. Then, confirmatory factor analysis confirmed a mono-factorial structure with 19 items with good model fits and adequate reliability (CFI = 0.80, SRMR = 0.06,  $\chi^2/df = 871.45$  with  $p < 0.001$ ; Cronbach's  $\alpha$ : 0.94). In this study, scores higher than the mean of the sample plus 1.5 standard deviations were indicative of higher PTSD symptomatology.

## Statistical Analysis

Descriptive statistics were calculated for sociodemographic characteristics, and social and psychological variables were collected. Prevalence data (number and percentage) for each dimension assessed were reported. The scores of the PWBI subscales and COVID-19-PTSD test were expressed as means and standard deviations. T-Student was used to compare our sample data with normative data. Chi-square test ( $\chi^2$ ) was used to compare the differences in prevalence between groups with high general psychological well-being and low general psychological well-being. Logistic regression and correlation models were performed to explore potential influence factors for psychological well-being and PTSD symptomatology during the COVID-19 epidemic. Odds ratio (OR) and 95% confidence

interval (95% CI) were obtained from logistic regression models.  $P$ -values of  $<0.05$  were considered statistically significant (two-tailed test). All data were analyzed using the Statistical Package for Social Sciences (SPSS) version 24.0 (IBM SPSS Statistics, New York, United States) and Statistica 10.0.

## RESULTS

### Demographic Characteristics

Sociodemographic characteristics are presented in **Table 1**.

One thousand six hundred and thirty-nine respondents completed the questionnaires (completion rate: 97.04%). The mean age of the respondents was 30.37 (SD: 12.14) years. The majority of the respondents were women (75.8%), aged from 19 to 30 years (66.4%), students (46.6%), or employees (30.9%). Respondents were equally distributed in Italian territorial areas, 30.3% in the North, 32.6% in the Center, and 37.1% in the South of Italy. Most respondents lived in a city with over 10,000 inhabitants (74.5%) and declared to generally have from 10 to 50 daily interactions with others (48.9%). In most cases, the quarantine experience was shared with members of the family (70.4%). The majority of the respondents reported that they had perceived the emergency state before the restrictive actions taken by the government with the "I stay at home" decree (81.3%).

Considering the history of contacts with confirmed and suspected cases of COVID-19, overall, 2.0% of the respondents have been in direct contact with an individual with suspected COVID-19; 8.3 and 5.2% reported, respectively, to know a person who was currently an inpatient in an intensive care unit or died because of the COVID-19 infection.

**TABLE 4** | Activity changes of the responders during the COVID-19 emergency.

<i>n</i> (%)	Significantly increased	Moderately increased	Unchanged	Moderately decreased	Significantly decreased
Book reading	267 (16.3)	387 (23.4)	823 (50.2)	49 (3.0)	116 (7.1)
Film viewing	624 (38.1)	536 (32.7)	386 (23.6)	48 (2.9)	45 (2.7)
Physical activity	186 (11.3)	280 (17.1)	448 (27.3)	253 (15.4)	472 (28.8)
Cookhouse time	429 (26.2)	547 (33.4)	33 (32.5)	66 (4.0)	64 (3.9)
Use of social media	652 (39.8)	514 (31.4)	402 (24.5)	31 (1.9)	40 (2.4)

## Social Aspects

The measures taken by the government were perceived by more than half of the respondents as adequate (58.7%) (see **Table 1**). Considering the confidence in the source of information about COVID-19, the respondents reported being fairly confident of health information available by Civil Protection (49.4%), government (49.4%), general practitioner (33.7%), and scientific journal (36.1%). Confidence in social media information (35.8%) was relatively low (see **Table 2**).

Regarding the social consequences of COVID-19 (see **Table 3**), the respondents perceived high improvement in the environmental condition (37.8%) and high worsening in demographic (31.0%), economic (82.6%), social (41.7%), and relationship (39.1%) conditions. Moreover, no relevant changes were perceived on identification (22.9%), politic (28.4%), and cultural (28.9%) conditions.

Considering changes in activity during the COVID-19 emergency, respondents reported an increase in film viewing (38.1%), cookhouse time (33.4%), use of social media (39.8%), and a decrease in physical activity (28.8%) (see **Table 4**).

## Psychological Aspects

The sample showed a lower mean than normative data in the PGWB questionnaire, considering all the subscales and total well-being, confirming low psychological well-being (see **Table 5**).

Overall, the prevalence of COVID-19-PTSD was 5.1%, with a mean total score of 19.88 (SD: 15.81), and the prevalence of lower psychological well-being was 48.2%, with a mean total well-being score of 62.77 (15.13). The prevalence of lower psychological well-being was significantly influenced by gender ( $X^2 = 73.96$ ;  $p < 0.0001$ ), age ( $X^2 = 8.23$ ;  $p < 0.01$ ), education ( $X^2 = 13.72$ ;  $p < 0.003$ ), health risk factors ( $X^2 = 25.03$ ;  $p < 0.0001$ ), number of usual daily interactions ( $X^2 = 7.63$ ;  $p = 0.04$ ), history of infection by COVID-19 ( $X^2 = 7.57$ ;  $p = 0.02$ ), direct contact with people infected by COVID-19 ( $X^2 = 11.93$ ;  $p = 0.002$ ), occupational status during the COVID-19 emergency ( $X^2 = 13.40$ ;  $p = 0.009$ ), knowledge of people infected by COVID-19 ( $X^2 = 12.99$ ;  $p = 0.01$ ), and confidence in the measures adopted by the government ( $X^2 = 15.18$ ;  $p = 0.0005$ ). All Chi-squared values are reported in **Table 1**.

Positive linear correlations were found between age and dimension of psychological well-being, except considering general health ( $p = 0.01$ ) and PTSD symptomatology related to COVID-19 ( $p = 0.02$ ) that reported negative correlations. Conversely, considering the number of days spent in quarantine, negative linear correlations were observed with psychological

**TABLE 5** | Comparisons between responders' results and normative data on PGWB.

	Survey responders	Normative data	<i>t</i>	<i>P</i>
<b>Psychological well-being, mean (SD)</b>				
Anxiety	62.35 (20.97)	72.80 (19.18)	14.46	0.0001
Depressed mood	79.06 (15.77)	83.35 (16.43)	7.43	0.0001
Positive well-being	44.55 (17.23)	62.67 (18.65)	28.18	0.0001
Self-control	69.83 (18.70)	80.27 (18.80)	15.52	0.0001
General health	70.37 (15.84)	75.87 (18.47)	8.94	0.0001
Vitality	58.29 (18.80)	68.48 (18.32)	15.29	0.0001
Total well-being	62.77 (15.13)	72.86 (15.56)	18.34	0.0001

well-being and a positive one with PTSD symptomatology related to the COVID-19. The correlational matrix is shown in **Table 6**.

Logistic regression models showed statistical differences (**Table 7**). Being a woman (OR = 3.00; 95% CI = 2.31–3.88), belonging to the age groups of 18–29 (OR = 1.56; 95% CI = 1.13–2.15) and 30–49 years (OR = 1.62; 95% CI = 1.12–2.33), with a high school degree (OR = 1.63; 95% CI = 1.19–2.23) or a bachelor degree in disciplines other than healthcare (OR = 1.6; 95% CI = 1.2–2.3), and with the presence of health risk factors (OR = 1.76; 95% CI = 1.41–2.20) represent higher risk conditions for experiencing low psychological well-being. Regarding the COVID-19 outcome role on psychological well-being, respondents who were uncertain about the COVID-19 infection (OR = 1.31; 95% CI = 1.05–1.64) or who had some contacts with individuals affected by the virus (OR = 2.6; 95% CI = 1.2–0.3) were more likely to report low psychological well-being, as well as people who knew someone infected by COVID-19 (OR = 1.32; 95% CI = 1.05–1.66) or who knew people who were hospitalized in intensive care units (OR = 1.38; 95% CI = 0.97–1.96) or dead people consequent of COVID-19 infection (OR = 1.61; 95% CI = 1.04–2.49). Finally, no confidence (OR = 1.45; 95% CI = 1.15–1.81) or uncertainty (OR = 1.54; 95% CI = 1.15–2.06) about the suitability of the measures adopted by the Italian Government impacted negatively on psychological well-being (see **Table 7**).

Concerning PTSD symptomatology, the previous results on PGWB on women (OR = 6.6; 95% CI = 2.4–18.1), health status (OR = 2.5; 95% CI = 1.6–3.9), uncertainty about the presence of COVID-19 infection (OR = 1.7; 95% CI = 1.1–2.7), having had direct contacts with people infected by COVID-19 (OR = 3.3; 95% CI = 1.1–1.9), knowing someone infected by COVID-19 (OR = 2.2; 95% CI = 1.4–3.4), or hospitalized in intensive care

units (OR = 2.6; 95% CI = 1.4–4.7), or dead people consequent to the COVID-19 infection (OR = 2.3; 95% CI = 1.1–4.8), represent high risk factors to develop PTSD symptomatology (see **Table 7**).

## DISCUSSION

According to the results of this study, just a few weeks after the outbreak of the COVID-19 in Italy and a few days after the declaration of the restrictive measures, 5.1% of the respondents reported PTSD symptomatology linked to the COVID-19 diffusion, and 48.2% evidenced lower psychological well-being, characterized by anxiety and depressive symptoms, negative well-being, perception of loss control, less vitality, and lower general perceived health. These data are in line with those found by Sun and colleagues (18). The authors reported a percentage of 4.6 of PTSD symptoms in a large sample of the Chinese population (*n* = 2,091) with ages ranging from 30 to 60 years, and with some Italian studies that focused on COVID-19-related psychological distress in the Italian population (12, 13, 19, 20). In further studies, it could be interesting to compare the results obtained by Italian samples with samples from other countries (e.g., China) to check the similarities and differences on both psychological status and social and cultural changes that are COVID-19 related.

As expected, the comparison between our data with normative ones (15) on an Italian sample of healthy people suggested lower levels of general psychological well-being in Italians living this extraordinary emergency condition. These results would confirm that the stressful impact of the COVID-19 condition on psychological well-being is similar to the psychological burden caused by SARS and other virus outbreaks reported by studies in different countries (18, 21–23). These studies reported high levels of distress, anxiety, and mood disorders.

Considering sociodemographic and lifestyle information, the photograph of Italians in the coronavirus' time reported that most respondents spent social isolation at home, not quite alone but generally with other family members. The number of direct or indirect contacts with people affected by COVID-19 seems to be relatively low in the sample, especially considering the high reproductive number of the COVID-19 (24, 25). However, this result could be affected by the data collection in the early COVID-19 spread in the Italian population.

The results on the number of days spent in quarantine underlined a relationship with different aspects associated with psychological distress, such as anxiety, depression, decreasing of vitality, global well-being, and a general PTSD symptomatology.

These results would confirm the effect of the restrictive measures on psychological aspects, highlighting how the higher number of days spent in quarantine can play a cumulative role in developing distress, in line with previous studies on the effect of social isolation and quarantine (26). However, further studies are needed in order to report other risk factors and hopefully implement remote delivery of psychological interventions, to control psychological distress during the first stages of the present emergency.

Generally, we evidenced interesting results on the risk factors for well-being and psychological distress in emergencies due to the COVID-19 pandemic. Women, individuals younger than 50 years, those with high school degree or a bachelor's degree in disciplines other than health care, and those who present health risk factors seem to be more likely to have low psychological well-being. Moreover, people who are sure that they have had no contact with people affected by the infection reported higher psychological well-being levels. Also, those who have had close relationships with individuals (i.e., family members and friends), who were affected more or less severely by the virus, reported low psychological general well-being, confirming a role of fear and uncertainty about the epidemic progression on the levels of psychological distress (6). Finally, no confidence or uncertainty about the suitability of the Italian Government's measures negatively impacted psychological well-being, probably also as a consequence of the changes in the lifestyles, as suggested by our results.

These findings agree with previous studies (5, 6, 18, 26). The risk of infection generates fear in people, and above all, the COVID-19-related stressors, which include economic, daily life, social, and relational stressors, appear to be associated with worse psychological well-being. It would be useful to consider these aspects in order to implement specific interventions to prevent worsening of the psychological symptoms, leading to real psychological diseases, such as posttraumatic stress disorder. Both general demographic conditions and risk factors more closely related to the COVID-19 spread seem to influence the individuals, generating high levels of distress, and in some cases, they represent a warning sign for PTSD symptomatology, as confirmed by our results.

Another aim of this study was to consider the social impact of the COVID-19 outbreak. Our findings suggest that despite the optimism that referred to an improvement of the environmental condition, respondents had a negative perception about the influence of the COVID-19 on life and social aspects.

People largely perceived a moderate to drastic worsening of the economic and social conditions, although most of the respondents appeared highly confident about the information on the COVID-19 derived from state institutions as the Italian Government and the Civil Protection and even if they considered the restrictive measures taken by the government to be appropriate to the epidemic emergency. These findings agree with those reported during the H1N1 epidemic in Hong Kong (27), which showed a similar ambivalence between the general support toward the government and a sense of low confidence in its success to control the epidemic diffusion. The drastic changes due to the Italian Government measures to contain the COVID-19 were perceived as adequate for a large majority of the population during the survey, but they inevitably impacted daily life and recreational activities. The need for further risk analysis to identify what aspects of the pandemic emergency impact people, reduce the risk of psychopathological conditions that arise or persist even over the acute emergency, and represent an additional burden for the public health system is highlighted (28). This should be done in the light of the extension overtime of the state of emergency in several countries around the world (e.g., Spain, United States, and Brazil), the risk of second waves of the contagion, and the long-term consequences of the pandemic state of emergency.

The findings of this study provide the first evidence about the necessity to develop a psychological support strategy in the Italian population during and after the state of emergency, according to the suggestions of previous studies on epidemics (21, 29–33). It is crucial to prepare healthcare systems for the long-term medical and psychological consequences of this pandemic. Although further studies are needed, our results could help identify more high-risk populations for clinical diseases.

This study has some limitations. First, our design did not allow making a causal relationship, and prospective studies are needed to make causal inferences. Second, the possibility of selection bias due to the online survey should be considered, as evidenced by the oversampling of a particular population (e.g., students and women). This limit is particularly important to take into account considering the risk factor analyses, which the characteristics of the sample could influence. Another limitation is the use of self-report measures in the online survey. These instruments, especially if administered remotely, may be subjected to data collection biases. However, as reported in other studies on the COVID-19 pandemic, the adoption of an online survey represented the best solution because the social distancing measures limited data collection.

Therefore, the number of respondents with contact history with the COVID-19 was low, probably due to the data collection times. In the first days of the pandemic, the COVID-19 was not yet widespread in the Italian population, making our findings not generalizable to confirmed cases of COVID-19. Finally, it is more difficult to differentiate the influences due to the medical impact of the infection from the impact of quarantine measures, and further studies should consider it.

Our findings indicate that the COVID-19 pandemic appears to be an influential risk factor for the development of psychological diseases in the Italian population, as reported by other studies (5, 6, 18, 26) also on Italian samples (12, 19, 20), and accordingly with other studies on epidemic and quarantine conditions (7, 21, 34). The COVID-19 outbreak has substantially changed lifestyles, social perception, and institutions' confidence in the Italian and worldwide population, and it appears to have significant psychological consequences. Despite some limitations, this study provides information on the initial psychological, social, and lifestyle responses during

the outbreak of COVID-19 in Italy. Moreover, it provides an interesting point of view suggesting how future studies should distinguish between the effects directly resulting from the spread of the virus, and therefore closely related to the fears of contagion, and those caused by changes in people's lifestyle, due to more or less severe containment measures taken by governments. Our main goal was to demonstrate that the psychological and social impact of this outbreak cannot be minimized. According to our results, we propose considering the psychological, social, relational, and behavioral consequences of these exceptional events in interventions aimed at improving or preventing psychological distress and their impact on the general population's quality of life.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Ethics Committee of the Department of Dynamic

and Clinical Psychology, "Sapienza" University of Rome. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

MC, FF, and GF had the idea for and designed the study and had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis, and drafted the paper. FF and GF did the analysis. MC, FF, GF, and RT collected the data. All authors agreed to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved. All authors critically revised the manuscript for important intellectual content and gave final approval for the version to be published.

## ACKNOWLEDGMENTS

We would like to thank all the people who helped in the data collection by sharing our survey on the various socials, in particular, Gianluca Pistore, for his help.

**Introduction:** Parkinson's Disease (PD) is characterized by motor and non-motor symptoms, among which deficits in social cognition might affect ~20% of patients. This study aims to evaluate the role of social cognitive abilities in the perceived impact of COVID-19 emergency, and the effects of lockdown measures on patients' social network and caregivers' burden.

**Methods:** Fourteen PD patients performed a neuropsychological battery including sociocognitive tasks before the introduction of COVID-19 restrictive measures (i.e., social distancing and isolation). A structured interview through an online platform was performed in the last 2 weeks of the first lockdown phase to assess patients' health status, perception of COVID-19 emergency, changes in caregivers' burden, and patients' social isolation. Non-parametric analyses were performed to evaluate the association between social skills and patients' COVID-19 perception, as well as the effects of restrictive measures.

**Results:** At baseline evaluation, half of the PD patients showed sociocognitive dysfunctions, mainly on mentalizing abilities. Patients with impaired social cognition skills showed a significantly lower concern on the possible effects of COVID-19 on their health. Caregiver burden and patients' social network remained stable during the lockdown.

**Conclusion:** These preliminary results underline that PD sociocognitive dysfunctions might affect patients' abilities to estimate the effects of COVID-19 infection. However, the lack of a significant increase in caregivers' burden and social isolation suggests, in our sample, a good coping to COVID-19 emergency. Since COVID-19 pandemic can have direct and indirect severe consequences in patients with PD, the development of educational and preventive programs is recommended.

## INTRODUCTION

Since the end of 2019, the world has been overwhelmed by the spread of a new coronavirus (SARS-CoV-2), which forced the World Health Organization to declare the state of pandemic in March 2020. This action has been paralleled by the introduction in many countries of restrictive measures, such as social distancing, quarantine, and massive closure of commercial and productive activities, with a substantial effect on people habits and routines. To prevent the spreading of the virus and the high risk of the health-care system overwhelming, the Italian government introduced emergency security measures on March 9, 2020, including closed borders, social distancing, and isolation. With the progressive control of the emergency in terms of reduced rate of positive cases, hospital admissions, and patients requiring intensive care, less stringent measures were introduced. Overall, the Italian lockdown included restrictive measures that lasted from March 9, 2020 to May 3, 2020. However, the long-lasting period of quarantine may have led to important consequences in healthy subjects (Cerami et al., 2020) as well as in patients living with a chronic disease such as Parkinson's Disease (PD).

The restricted access to health care, physical inactivity, and psychosocial effects (Prasad et al., 2020) could potentially worsen motor and non-motor symptoms characterizing the disease and resulting from nigrostriatal dopamine depletion. Among these, cognitive symptoms might include executive, visuospatial, and social cognitive dysfunctions (Robbins and Cools, 2014). Notably, extensive literature on PD reports significant deficits in different facets of the social cognition such as emotion recognition (e.g., Baggio et al., 2012; Mattavelli et al., 2020), theory of mind (e.g., Bodden et al., 2010), and empathy (Martinez et al., 2018). Overall, social skills play a crucial role in detecting and predicting actions, intentions, and emotions on the basis of individual knowledge (Barnes-Holmes et al., 2004), and they have been previously related to the individual engagement in recommended precautions during a health crisis (Puterman et al., 2009). An impairment in these abilities in the context of COVID-19 quarantine may thus lead to severe consequences, such as situational misinterpretations and increased conflicts in social and familial relationships.

Social cognition deficits contribute to characterize PD clinical picture together with other motor and non-motor symptoms. With the progression of the disease, PD patients might tend to move from a public into a private world to mask these symptoms, with a significant and progressive reduction in their social engagement due to stigmatization (Maffoni et al., 2017). Social isolation represents one of the major risk factors for the development of cognitive decline and dementia (Livingston et al., 2017), and specifically in PD social support has been found as one of the major variables in positively affecting daily living (Ambrosio et al., 2019). In this sense, informal caregivers have a key role in practical and psychological support for PD patients. However, this role exposes them to changes in emotional and physical health, social life, and financial status (Martinez-Martin et al., 2012). Despite an emerging body of literature on PD care during the COVID-19 emergency (Papa et al., 2020;

Prasad et al., 2020; Salari et al., 2020; Shalash et al., 2020), very little is known about caregivers' experiences. Quarantine and lockdown measures significantly forced them to deal with changes in their daily routines, including personal, family, and patients' management. While recent evidence showed in PD carers higher anxiety levels related to COVID-19 emergency compared to controls (Salari et al., 2020), it is still unclear whether the restrictive measures affected caregivers' well-being.

The aim of this preliminary study is thus to explore the effects of social cognition deficits in the perception of COVID-19 emergency in PD patients as well as their relationship with caregivers' burden. Besides, we investigated possible changes in patients' perceptions of social support and in caregiver well-being through an online interview performed in the last 2 weeks of the first lockdown phase in Italy. We hypothesized that social cognition deficits in PD might affect patients' perceptions of the COVID-19 emergency and that COVID-19 containment could possibly increase PD patients' perceived social isolation and caregivers' burden.

## MATERIALS AND METHODS

### Subjects

Fourteen PD patients were included in the context of the longitudinal project "Study of the neural bases underlying the beneficial effects of physical activity in Parkinson's disease." Patients were recruited from the Centre for Neurocognitive Rehabilitation (CeRiN) in Rovereto, Italy. Inclusion criteria were diagnosis of idiopathic PD based on the criteria of the International Movement Disorder Society (Postuma et al., 2015), Hoehn and Yahr scale  $\leq 3$  (Hoehn and Yahr, 1967); absence of dementia or other significant psychiatric or neurological disorders; basic computer knowledge and Internet access. All subjects underwent a baseline clinical evaluation by experienced neurologists and neuropsychologists between January and February 2020, and a follow-up assessment through an online platform between April 20 and May 3, 2020. Patients were assessed during the "ON" state, and data on the motor symptoms through the Unified Parkinson's Disease Rating Scale (MDS-UPDRS) part III (Goetz et al., 2008) were collected. Caregivers were interviewed at both baseline and follow-up. Demographics and clinical data for the 14 PD patients are shown in **Table 1**. Eleven patients were characterized by a tremor-dominant phenotype and three patients by a postural instability and gait disturbances phenotype. Mean UPDRS-part III score was  $15.5 \pm 5.8$ . All patients were treated at the time through antiparkinsonian drugs, that is (levodopa, dopamine-agonists, MAO-, and COMT-inhibitors). Patients' caregivers included first-degree relatives (caregiver-patient relationship: consort  $n = 12$ , offspring  $n = 2$ ; caregiver civil status: married  $n = 13$ , single  $n = 1$ ; male/female: 6/8; average age in years =  $60.2 \pm 13.4$ , average years of education =  $13.5 \pm 4.6$ ).

All subjects gave informed consent to clinical evaluation according to the local Ethical Committee. The original study protocol, as well as the telemedicine extension, was approved by the Institutional Review Board (Protocol Number 2019-033).

SD, standard deviation; UPDRS, Unified Parkinson's Disease Rating Scale; MoCA, Montreal Cognitive Assessment; SET, Story-based Empathy Task; IRI, Interpersonal Reactivity Index.

\*Based on (Yesavage et al., 1982).

\*\*Due to the lack of Italian normative values, mean, and standard deviation values previously reported (Rankin et al., 2005) were used to derive explorative cut-off scores (mean ± 2 SD for impaired performance; mean ± 1.5 SD for borderline performance).

## Baseline Neuropsychological Assessment

Social cognition abilities have been assessed through different tests evaluating emotion recognition abilities (Ekman 60 Faces Test-Ek-60F) (Dodich et al., 2014) and theory of mind (Story-based empathy task-SET) (Dodich et al., 2015). The SET is a non-verbal task assessing the ability to attribute mental states based on intention (SET-IA) and emotion (SET-EA), as well as the ability to infer causal relationship (i.e., SET-CI).

Empathic attitude has been assessed through the Interpersonal Reactivity Index (IRI) (Davis, 1980; Rankin et al., 2005), a 28-item questionnaire administered to caregivers and including both cognitive (perspective-taking IRI-PT, fantasy IRI-F) and affective aspects of empathy (empathic concern IRI-EC, and personal distress IRI-PD). The revised version of the Lubben social network scale (LSNS-R) (Lubben et al., 2006) has been used to assess patients' social network.

Besides, all subjects underwent a standard neuropsychological assessment, including tests evaluating the global cognitive status (Conti et al., 2015), short-term memory [Digit Span forward (Monaco et al., 2013), Corsi block-tapping test (Monaco et al., 2013)], long-term memory [Rey Auditory Verbal List test (Carlesimo et al., 1996), Rey-Osterrieth complex figure recall (Caffarra et al., 2002a)], attention/executive functions [i.e., attentional matrices (Spinnler and Tognoni, 1987), digit span backward (Monaco et al., 2013)], verbal fluency (Carlesimo et al., 1996; Zarino et al., 2014), Stroop task (Caffarra et al., 2002b), trial making test (Giovagnoli et al., 1996), language [i.e., naming (Caticala et al., 2013; Papagno et al., 2020)], visuospatial line orientation judgment test (Benton, 1983), the unknown face recognition test (Benton et al., 1983), and visuo-constructional abilities [Rey-Osterrieth complex figure copy (Caffarra et al., 2002a)].

Caregivers' burden were assessed through the Caregiver Burden Inventory (CBI) (Novak and Guest, 1989). This questionnaire includes 24 items investigating five different dimensions: time-dependence (CBI-TD), developmental (CBI-D), physical (CBI-P), social (CBI-S), and emotional (CBI-E) burden. Higher scores implicate greater burden.

## Telemedicine Assessment

The follow-up assessment was performed through an online platform. The structured interview included questions about patients' health statuses ("Have you received medical assistance in the last 2 months?" "Have you modified your pharmacological treatment?" "Have you noticed a disease progression?") and perceived changes in motor and non-motor symptoms ("Do you think that your cognitive/motor symptoms are worsened during the lock-down?" "Have you noticed mood changes during the lockdown?"). In case of positive answers, subjects were asked to specify. Patients were then asked if they were aware of the COVID-19 emergency, and patients' perceptions were assessed through two questions ("Are you concerned about the effect that COVID-19 may have on your health?" and "How severe do you think the COVID-19 emergency is for the society?") using a 5-point Likert scale (1: not at all, 5: very much). Together with the structured interview, LSNS-R and CBI scales were also readministered to assess changes in patients' social network and in caregivers' burden.

## Statistical Analyses

We evaluated the percentage of patients with social cognition deficits based on the Italian normative data. Then, in order to assess the effects of social cognition abilities on patients' responses to lockdown measures and to caregivers' well-being, we correlated through Spearman's rank correlation analysis the adjusted performance at social tasks with patients' perceptions of COVID-19 emergency and CBI subscales. Besides, a Mann-Whitney U test has been performed to compare patients' perceptions of the COVID-19 emergency, dividing PD patients according to social cognition impairments, based on literature-defined cut-off scores (Table 1). Finally, CBI and LSNS-R scores were compared through Wilcoxon Signed Ranks Test in order to assess the effect of lockdown measures on caregivers' well-being

and patients' social network. Non-parametric statistics were performed due to the small sample size and to non-normal data distribution, evaluated through the Shapiro-Wilk test. Analyses were conducted using IBM SPSS Statistics for Windows v23.0 (Armonk, NY IBM Corp.).

## RESULTS

At the baseline neuropsychological evaluation, 10 patients were classified as cognitively unimpaired, while four patients presented a non-amnesic mild cognitive impairment (Table 1). No patients showed defective performance at the EK-60F test according to the normative data. Emotion attribution, evaluated through SET-EA, was impaired in 3 patients out of 14, with the other two patients obtaining a borderline score. Only two subjects poorly performed in the SET subtask of intention attribution. Notably, in the IRI, five patients showed reduced perspective-taking, while half of the sample was characterized by poor empathic concern. Finally, four patients showed high levels of IRI personal distress, while fantasy was above the cut-off score in all patients. At the follow-up structured interview, three patients felt the disease went faster in the 2 months of lockdown. Four patients reported increased memory difficulties, while increased anxiety was reported in three patients out of 14. A worsening in motor functioning was reported in eight patients out of 14. Three patients received medical assistance related to PD symptoms with subsequent PD-therapy modifications (two therapy reductions secondary to increased levodopa-induced dyskinesia and one increased therapy due to worsening of tremor and bradykinesia). Concerning COVID-19 emergency, all patients were aware of the situation and perceived a high severity for the society (median = 5, IQ range [4.75–5]), despite a low concern for their own health (median = 2, interquartile range [1–3]).

The correlation analysis between COVID-19 perception and social cognition abilities showed a correlation of patients' concerns related to health with patients' perspective-taking abilities (IRI-PT  $r_s = 0.71$ ,  $p = 0.005$ ) and personal distress (IRI-PD  $r_s = -0.72$ ,  $p = 0.004$ ). No significant relationship was found with other social skills. However, IRI-PT was significantly correlated with emotion attribution abilities (SET-EA subscore  $r_s = 0.60$ ,  $p = 0.02$ ) and overall mentalizing abilities (SET-GS  $r_s = 0.55$ ,  $p = 0.04$ ). PD patients with social cognition deficits showed a reduced concern (mdn = 2, interquartile range [1–2]) compared to patients with unimpaired social skills (mdn = 3 interquartile range [2.5–4]) (Mann-Whitney  $U = 40$ ,  $p = 0.04$ ). No significant results were found in the association between judgement of the COVID-19 emergency at the societal level and social skills. MCI and cognitively unimpaired PD patients showed no significant differences in COVID-19 perception (COVID-19 emergency at societal level Mann-Whitney  $U = 19$ ,  $p = 0.9$ , COVID-19 health-related concern Mann-Whitney  $U = 12$ ,  $p = 0.3$ ), and no significant correlation emerged with the global cognitive status, evaluated through the MoCA score (COVID-19 emergency at societal level  $r_s = -0.17$ ,  $p = 0.5$ , COVID-19 health-related concern  $r_s = 0.40$ ,  $p = 0.15$ ).

Concerning caregivers' burden, lower perspective-taking abilities were found to be associated at baseline with higher caregivers' burden in the CBI subscales time-dependence (CBI-TD  $r_s = -0.57, p = 0.03$ ), Developmental (CBI-D  $r_s = -0.6, p = 0.02$ ), and emotional (CBI-E  $r_s = -0.60, p = 0.02$ ) burden, as well as in CBI global score ( $r_s = -0.62, p = 0.02$ ). Lower mentalizing performance was associated with higher physical (SET-GS:  $r_s = -0.60, p = 0.02$ ) and emotional (SET-GS:  $r_s = -0.60, p = 0.02$ ) CBI scores. Finally, higher CBI global scores were associated to higher personal distress (IRI-PD  $r_s = 0.56, p = 0.04$ ). No other significant correlations emerged. Non-parametric analyses, performed to evaluate significant changes in CBI and LSNS-R, found no significant differences, except for CBI social burden scores, in which caregivers showed a burden reduction compared to the baseline assessment ( $T = 5, z = -2.1, p = 0.04$ ) (Table 2).

## DISCUSSION

In this preliminary study, we report our experience at ascertaining the implications of COVID-19 in 14 PD patients from our center, and we explored the relationship between social cognition deficits and patients' perceptions of the COVID-19 emergency, as well as the effect of COVID-19 restrictive measures (i.e., lockdown and self-isolation) on caregivers' burden and patients' social isolation.

Overall, the results of the present study possibly suggest that social cognition deficits in PD patients might influence the correct interpretation of the risks related to COVID-19 infection, confirming the first hypothesis of the present study. Despite these results being explorative, we provided evidence of a possible association between lower abilities of perspective-taking and lower concern on the possible effects of COVID-19 on patients' health. Furthermore, a lower concern for COVID-19 was associated with a higher personal distress, which is considered as the negative side of affective empathy (i.e., tendency to feel pain when exposed to the suffering of others). Representing the most primitive precursor of empathy from a developmental point of view, personal distress seems to have

an adverse effect in thwarting empathic response rather than enhancing it (Kim et al., 2018). Future studies on larger samples with a comparison group are thus recommended to investigate the effect of social cognition deficits on the perception of the COVID-19 emergency and on the adherence to preventive measures. Recent evidence suggests in fact a higher risk in PD patients for worse respiratory complications after the COVID-19 infection (Fasano et al., 2020; Helmich and Bloem, 2020) and a possible higher mortality rate for older patients with a longer disease duration (Antonini et al., 2020). Thus, it is highly desirable for PD patients to strictly apply to all the required preventive measures to minimize the risk of infection. In our sample, lower empathy and mentalizing ability were also associated with higher caregiver burden. This result is in agreement with previous studies showing that social cognition impairments in PD can significantly affect caregivers' well-being, possibly due to caregivers' lack of awareness of these deficits (Martinez et al., 2018).

On the other hand, despite the risk of negative effects on patients' social isolation and caregivers' burden due to COVID-19 restrictive measures, the lack of significant changes in our sample does not confirm the second hypothesis of the present study (i.e., increase of PD patients perceived social isolation and caregivers burden due to COVID-19 containment). Unexpectedly, caregivers showed a reduction in social burden, possibly suggesting a supporting role of patients' families, also in agreement with the lack of significant changes in patients' social network. This could be partially explained by the Italian sociocultural framework, in which family has a central role in patients' caring (Glaser et al., 2004), or by a reduced burden of daily activities due to the forced lockdown. Overall, the small sample size and the lack of a control group represent the main limitations of the current work, hampering the generalization of the results. Despite finding a good coping to the COVID-19 emergency, studies on larger samples are needed, including patients with different disease severities and with limited access to new technologies. As a matter of fact, while elderly people from rural areas and with low education are those who have the most limited access to new technologies (Marcellini et al., 2007; Poushter, 2016), they are also those

who may have been most affected by the social distancing measures. Finally, another limitation of this work is represented by the inability to carefully assess the effects of individual sociodemographic and psychological factors in coping with the COVID-19 emergency. Studies including larger patient samples are required to evaluate the possible effects of behavioral variables (Santangelo et al., 2016; Preis et al., 2017), as well as the role of individual features (e.g., Park et al., 2021), in the interpretation of the COVID-19 emergency. Besides, a more in-depth assessment of patients' perceptions of the risks related to the COVID-19 pandemic is recommended. While no specific questionnaires were available at the time of this preliminary study, the progressive introduction of validated scales and questionnaires (e.g., Cortez et al., 2020) will allow a more detailed evaluation of the cognitive and psychological factors related to the interpretation of the COVID-19 emergency. In conclusion, in this study we provided preliminary evidence in PD of a possible effect of social cognition dysfunctions in interpreting the COVID-19 emergency. Since PD patients represent a vulnerable population for the COVID-19 infection, the development of educational initiatives for both patients and caregivers, possibly converted into telemedicine programs, might help in managing the possible consequences of this new health challenge.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Comitato Etico per la sperimentazione con l'essere umano, Università di Trento. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

LT, CP, MF, AD, and FZ: conception and organization of the project. CM, MF, PN, AG, and EP: acquisition, analysis of data. AD, MF, and CP: data interpretation. AD and CM: first drafting the work. All authors revised the manuscript and provided the approval of the work.

## FUNDING

This study was supported by Comune di Rovereto, with the project: Study of the neural bases underlying the beneficial effects of physical activity Parkinson's disease and by Caritro Foundation, project: Strategie per migliorare la cognizione negli anziani.

## ACKNOWLEDGMENTS

We thank all the patients and the CeRiN staff for the support in patient recruitment and management, as well as in data acquisition. We thank the Parkinson Association in Trento, and Trento and Rovereto Neurology Departments for their support in patient recruitment.

The COVID-19 outbreak has simultaneously increased the need for mental health services and decreased their availability. Brief online self-help interventions that can be completed in a single session could be especially helpful in improving access to care during the crisis. However, little is known about the uptake, acceptability, and perceived utility of these interventions outside of clinical trials in which participants are compensated. Here, we describe the development, deployment, acceptability ratings, and pre-post effects of a single-session intervention, the Common Elements Toolbox (COMET), adapted for the COVID-19 crisis to support graduate and professional students. Participants ( $n = 263$ ), who were not compensated, were randomly assigned to two of three modules: behavioral activation, cognitive restructuring, and gratitude. Over 1 week, 263 individuals began and 189 individuals (72%) completed the intervention. Participants reported that the intervention modules were acceptable (93% endorsing), helpful (88%), engaging (86%), applicable to their lives (87%), and could help them manage COVID-related challenges (88%). Participants reported pre- to post-program improvements in secondary control (i.e., the belief that one can control their reactions to objective events;  $d_{av} = 0.36$ ,  $d_z = 0.50$ ,  $p < 0.001$ ) and in the perceived negative impact of the COVID-19 crisis on their quality of life ( $d_{av} = 0.22$ ,  $d_z = 0.25$ ,  $p < 0.001$ ). On average, differences in their perceived ability to handle lifestyle changes resulting from the pandemic were positive, but small and at the level of a non-significant trend ( $d_{av} = 0.13$ ,  $d_z = 0.14$ ,  $p = 0.066$ ). Our results highlight the acceptability and utility of an online intervention for supporting individuals through the COVID-19 crisis.

## INTRODUCTION

In addition to the serious physical health consequences of COVID-19, the resulting societal changes have had major impacts on population-wide mental health (Liu et al., 2020). COVID-19 has introduced a variety of stressors into modern life, including fears about contracting the virus, concern for loved ones, economic instability, social distancing, and other major lifestyle disruptions

(Pfefferbaum and North, 2020). Many of these concerns have affected graduate and professional students (i.e., students earning advanced degrees, as well as non-traditional and non-degree seeking students). Even before the crisis, students were vulnerable to depression, anxiety, loneliness, and suicidal ideation (Evans et al., 2018). The COVID-19 crisis has exacerbated these concerns: many universities have ceased non-essential operations, mandated that students leave campus, and shut down university counseling centers (Zhai and Du, 2020). These measures, while appropriate to avoid the spread of COVID-19, have led to considerable uncertainty, stress, and disruption for graduate and professional students (Chirikov et al., 2020; Sahu, 2020). In open-ended surveys, graduate and professional students report a variety of concerns relating to their health, productivity, and well-being (Wasil et al., 2021a). Furthermore, in a recent survey of over 15,000 graduate students, about 32% of students reported elevated depressive symptoms and 39% reported elevated anxiety symptoms (Chirikov et al., 2020). The estimated rates of depression and anxiety in 2020 were 1.5–2 times higher in 2020 than in 2019 (Chirikov et al., 2020). To support graduate and professional students, evidence-based mental health and wellness promotion efforts are needed.

Traditional mental health services, while essential, will not be sufficient to meet the growing need for mental health care during this crisis. As a result of social distancing requirements, many clinicians and mental health care organizations have moved counseling activities to telehealth platforms (Torous et al., 2020). However, even before the COVID-19 crisis, the demand for mental health services greatly exceeded the availability of professionals, with only a small fraction of individuals in need of mental health services receiving care (Kazdin and Blase, 2011). Due to the pre-existing lack of mental health care providers, the growing demand for services, and the strain on the health care system, telehealth platforms cannot serve as the only option during the pandemic. As such, scalable methods of delivering mental health interventions could be especially impactful during the COVID-19 crisis.

One promising approach involves the development and dissemination of evidence-based digital self-help interventions. Digital self-help interventions have several features that make them appealing in times of crisis. First, these interventions do not require in-person support and thus do not place additional burden on the health care system. Second, these interventions can be disseminated cheaply (or for free) to wide audiences. Third, digital interventions can be updated and adapted in short periods of time. This could be especially useful during the pandemic, as evidence-based content could be adapted specifically to address concerns relating to COVID-19. Finally, digital interventions are effective for a variety of mental health conditions, including depression and anxiety (Josephine et al., 2017; Karyotaki et al., 2017), and some have been shown to be effective in just a single session (Schleider and Weisz, 2018; Osborn et al., 2020). Thus, digital interventions could provide low-intensity evidence-based care to individuals who need support during the crisis but lack access to other services.

However, the uptake of digital interventions in real-world settings has been poor. Although evidence from clinical trials

supports the acceptability of digital mental health interventions, findings from controlled clinical trials may not generalize to use in naturalistic settings. Recent evidence shows that uptake and engagement rates for digital interventions are lower in open field studies than in formal clinical trials (Fleming et al., 2018). Because participants in clinical trials are often financially compensated for consistent participation and clinical trials attract highly motivated participants, formal trials yield unrealistically high estimates of engagement. In order to improve the dissemination of digital interventions, studies focused on the acceptability and uptake of digital interventions in real-world contexts are needed (Mohr et al., 2017). Although there are some digital interventions with relatively high uptake (as measured by number of downloads), these interventions have not been rigorously evaluated, contain a limited amount of evidence-based content (Wasil et al., 2019), and generally fail to retain users (Baumel et al., 2019; Wasil et al., 2020a, 2021b). Indeed, most mental health apps have only 4% of users continue to engage with the apps after 15 days, and many have no active monthly users (Baumel et al., 2019; Wasil et al., 2020b, 2021c). Some barriers that limit engagement for digital interventions include lack of perceived utility, limits on accessibility (e.g., fees or geographic restrictions), poor user experiences, and high demands on users' time (Torous et al., 2018). As a result, there is a need for digital mental health interventions that (a) include evidence-based content, (b) demonstrate acceptability and feasibility outside of formal clinical trials, (c) minimize demands on users' time, and (d) are available at no cost.

Single-session interventions, which can be completed in one sitting, may be particularly useful. Meta-analytic evidence suggests that single-session interventions have effects similar in magnitude to those of psychotherapies that last several months (see Schleider and Weisz, 2017), and some online single-session interventions have shown effects on depression even at 4–9 months follow-ups (e.g., Schleider and Weisz, 2018). In addition to their effectiveness, single-session interventions are highly scalable, can be disseminated at very low costs, and can be adapted readily for new populations (see Osborn et al., 2020; Wasil et al., 2020c). Online single-session interventions also circumvent concerns about user retention, as users only need to engage with the intervention once to receive the full dose of content. However, there are several gaps in research on online single-session interventions. For instance, limited research has examined the acceptability of online single-session interventions outside the context of controlled clinical trials. Additionally, while online single-session interventions often include content that has been shown to be effective for individuals across age groups, most research on online single-session interventions has been conducted with youth and adolescents (Schleider and Weisz, 2017). Finally, few online single-session interventions have been adapted to respond to a public health emergency, such as the COVID-19 crisis. As such, a digital single-session intervention adapted specifically to meet the needs of the current crisis would provide a considerable contribution to the field.

Such an intervention would be especially valuable if it included modules that are commonly included in empirically

supported interventions. Whereas mental health interventions have traditionally been tested in multicomponent packages, often in the form of published treatment manuals, scholars have recently pushed for a focus on specific procedures within interventions (Hofmann and Hayes, 2019). Relatedly, some scholars have identified treatment procedures that are commonly included in treatment manuals of empirically supported interventions (Chorpita and Daleiden, 2009). These procedures, known as “common elements,” have formed the basis of recently-developed modular interventions. Such interventions include the *Modular Approach to Therapy for Children with Anxiety, Depression, Trauma, or Conduct Problems* (MATCH; Weisz et al., 2012) and the *Common Elements Treatment Approach* (CETA; Murray et al., 2014). Advantages of modular interventions include their flexibility, scalability, and adaptability (see Weisz et al., 2012). Modular interventions could be especially useful in the context of the COVID-19 crisis, as modules can be adapted or replaced to meet the needs of specific populations (e.g., patients, healthcare workers, individuals under stay-at-home orders). While previous research has shown that modular interventions are effective when delivered by clinicians (Weisz et al., 2012) and trained lay counselors (Murray et al., 2014), relatively little is known about modular interventions as self-administered digital interventions.

To fill these gaps, and to provide timely support to students dealing with the COVID-19 crisis, our team adapted and deployed an online single-session intervention for graduate and professional students.

We believed that a self-administered intervention focused on common elements could be valuable. In this paper, we describe the *Common Elements Toolbox* (COMET), a self-administered digital single-session intervention. Here, we describe (a) the development and design of COMET, (b) adaptations we made to COMET to respond to the COVID-19 crisis, (c) an evaluation of the acceptability and perceived utility of COMET, and (d) changes in secondary control and COVID-19 related concerns from pre-intervention to post-intervention. In addition to filling important gaps in the literature, our goal is to provide information that can directly inform other digital mental health promotion efforts in response to the COVID-19 pandemic.

## MATERIALS AND METHODS

### Selection of COMET Intervention Modules

In September of 2019, our team began to develop an online single-session intervention to promote college student mental health. To begin this process, we reviewed literatures on common elements in empirically supported treatments (Chorpita and Daleiden, 2009; Higa-McMillan et al., 2016), treatment elements in existing digital interventions (Wasil et al., 2019), psychologically “wise” single-component interventions (Walton and Wilson, 2018), positive psychology interventions (Seligman et al., 2005), and single-session interventions (Schleider and Weisz, 2017). As much of this literature focused on youth and adolescent populations, we supplemented our review by

examining treatment manuals for adults (Nathan and Gorman, 2015). Our aim in this review was to identify intervention techniques to include in the single-session intervention that were shown to be effective, ideally when administered on their own, and could be taught easily in a self-guided format.

With these criteria in mind, we chose three modules to include in COMET: behavioral activation, cognitive restructuring, and gratitude. Behavioral activation and cognitive restructuring are both considered core components of cognitive-behavioral therapies. Numerous studies have demonstrated the effectiveness of web-based cognitive behavioral therapy in treating depression and anxiety (see Karyotaki et al., 2017 for a meta-analysis). Gratitude is a common element in several empirically supported positive psychology interventions (see **Supplementary Materials** for details). Additionally, meta-analytic evidence suggests that gratitude interventions reduce symptoms of depression and anxiety (Cregg and Cheavens, 2020) and improve subjective well-being (Davis et al., 2016; Dickens, 2017).

From September 2019 to February 2020, we prepared an intervention with these three modules for a pre-registered randomized controlled trial with undergraduate students (NCT04287374; see **Supplementary Materials** for details). The undergraduate version of COMET was based on previous CBT and gratitude interventions, and the design of the intervention was informed by that of previous web-based single-session interventions (Seligman et al., 2005; Nathan and Gorman, 2015; Schleider and Weisz, 2017, 2018; Osborn et al., 2020; Schleider et al., 2020; Wasil et al., 2020d). As we finished developing the undergraduate version of COMET in March 2020, COVID-19 began to rapidly spread throughout the United States, including the greater Philadelphia area. In light of the mental health crisis due to COVID-19 disruptions, we decided to adapt the existing intervention into a separate intervention for graduate and professional students.

Over the course of 2 weeks, adaptations were made to COMET to increase its relevance to the COVID-19 crisis. For example, the initial intervention included a vignette about a student struggling with rejection from summer internships. For the adapted version, we replaced this vignette with one about a student who is struggling to adjust to lifestyle changes resulting from the COVID-19 crisis. We also consulted relevant stakeholders: we received feedback from undergraduate students, graduate students, and faculty in order to refine the intervention. In response to input from university deans about the length of the intervention, we decided to provide only two of the three modules to each participant. This was done to maximize the likelihood that students would choose to participate, thus increasing the reach of our intervention. The specific modules provided to a given student were determined randomly (see **Supplementary Materials** for details).

### Adapted Version of COMET for COVID-19

At the beginning of the adapted intervention, participants read a short introduction message describing the purpose of the intervention. Participants were then randomly assigned to receive two of the three intervention modules: behavioral activation, cognitive restructuring, and gratitude.

## Behavioral Activation

The purpose of the behavioral activation module (labeled “positive activities” to sound less technical and to improve comprehension) was to help participants identify and perform activities that bring them happiness or provide a sense of mastery. Participants received psychoeducation about pleasurable activities (i.e., enjoyable activities) and mastery activities (i.e., activities that provide a sense of accomplishment). Next, they were prompted to brainstorm and list positive activities, with at least one being a pleasurable activity and at least one being a mastery activity. Participants were then instructed to select an activity to perform more frequently in the upcoming weeks. Then, they reflected on why this activity is important to them and how this activity influences their mood. Finally, participants completed a plan describing when they will perform the activity, where they will be, who they could tell about their plan to help them stay accountable, and how they will overcome obstacles that might get in the way of their plan (see **Supplementary Figure 1**).

## Cognitive Restructuring

The purpose of the cognitive restructuring module (labeled “flexible thinking” to sound less technical and to improve comprehension) was to help participants notice and reframe unrealistic negative thoughts. Participants first received brief psychoeducation about negative thoughts and thinking traps. They were then presented with a short vignette about “Gwen,” a hypothetical graduate student whose routine has been affected by coronavirus. In the vignette, participants read that Gwen feels like she has lost control over her routine and feels frustrated with herself for not keeping up with her work and health goals while under quarantine. Gwen also expresses worries that her friendships may suffer while she’s in isolation (see **Supplementary Figure 2**).

After reading the vignette, participants learned a cognitive restructuring technique called the “ABCD Technique” and applied it to Gwen’s situation. They were prompted to identify details about the Activating Event (i.e., list objective facts about Gwen’s situation), list Beliefs (i.e., initial worries or concerns that Gwen might have), generate ways to Challenge the negative or unrealistic beliefs (i.e., ways Gwen could reframe her initial concerns), and Debrief (i.e., indicate how Gwen might be feeling as a result of challenging her beliefs). After each step, participants viewed an example of a completed response (e.g., after they listed ways Gwen could challenge her beliefs, they were provided with examples of ways that Gwen could challenge her beliefs). These examples were presented to participants to provide them with real-time feedback and a model response (see **Supplementary Figure 3**). After applying the ABCD Technique to Gwen’s vignette, participants were prompted to use the ABCD Technique to restructure their thoughts about a distressing situation in their own lives.

## Gratitude

The purpose of the gratitude module was to encourage participants to notice and appreciate positive things in their lives. Participants started the module by briefly reading about

benefits of gratitude and past research on gratitude interventions. Then, participants completed the Three Good Things exercise (see Seligman et al., 2005). They received instructions to identify three good things that happened to them in the past 2 days. For each good thing, they also wrote a brief reflection explaining why it was meaningful to them and how to increase the odds of it happening again. Before writing their good things, participants viewed an example written by a hypothetical student (see **Supplementary Figure 4**). Finally, participants completed a novel *present-focused gratitude* exercise. In this exercise, participants were prompted to take a few moments to notice and appreciate things around them (e.g., “I love the color of that chair,” “I’m very warm and comfortable right now”). Because the present-focused gratitude exercise involves noticing things in one’s immediate environment, we believed that it would be especially relevant during the COVID-19 crisis, in which many individuals are staying in the same environment (e.g., at home).

## Recruitment

We partnered with the Behavior Change for Good Initiative and administrators at the University of Pennsylvania to email students in the Graduate School of Arts and Sciences and the College of Liberal and Professional Studies. The email, sent via official student listservs at the end of March 2020, invited students to take advantage of “an online tool grounded in behavioral science” and mentioned that “this is an option, not an obligation.” The email also included a link to the intervention, hosted on Qualtrics. Based on estimates provided by the university, we expect that approximately 3,000 students received the invitation. To maximize the reach of the intervention, all graduate and professional students were eligible to participate; there were no exclusion criteria. In the present study, we analyze responses from the first week of recruitment (i.e., March 30 to April 6).

## Procedure

Upon opening the Qualtrics link, participants were directed to a brief introductory screen with information about the study’s purpose and a general description of the activities. Participants then filled out a brief baseline questionnaire with measures of depressive symptoms, anxiety symptoms, secondary control, and perceived ability to handle the COVID-19 crisis (described in further detail below). Once the baseline questionnaire was completed, participants were randomized to receive two of the three intervention modules described above. Module order was also randomized, resulting in six possible combinations of the three modules (i.e., 1/6 of participants received cognitive restructuring followed by gratitude while 1/6 received gratitude followed by cognitive restructuring, etc.). After each intervention module, participants were asked to rate the module on acceptability, perceived helpfulness, engagement, and applicability. After completing both modules, participants filled out a brief post-intervention questionnaire, including some of the pre-intervention measures, feedback questions about the intervention, and demographic information (described in detail below). Upon finishing the intervention, participants received an automated email encouraging them to continue practicing

the activities they performed; the email included worksheets to help them practice. Because our primary intention was to provide support to students in light of the pandemic, we chose not to include a control group or require participants to complete follow-up assessments. With this in mind, we applied for Quality Assurance/Quality Improvement approval from the Institutional Review Board (see **Supplementary Materials** for details). Study procedures were reviewed and deemed quality improvement by the University of Pennsylvania Institutional Review Board.

## Measures

### Baseline Measures

#### *Depressive symptoms (patient health questionnaire-2)*

The Patient Health Questionnaire-2 (PHQ-2; Kroenke et al., 2003), a commonly used measure of depression, was administered to participants at baseline. The PHQ-2 asks participants to report the frequency of depressed mood and anhedonia over the past 2 weeks. Each item is scored from 0 (“not at all”) to 3 (“nearly every day”). The PHQ-2 has demonstrated strong psychometric properties, including construct validity. PHQ-2 scores are associated with functional impairment, symptom-related difficulties, and clinician ratings of depression (Kroenke et al., 2003). Cronbach’s alpha in our sample was 0.8.

#### *Anxiety symptoms (generalized anxiety disorder-2)*

The Generalized Anxiety Disorder 2-item scale (GAD-2; Kroenke et al., 2007), a commonly used measure of anxiety, was administered to participants at baseline. The GAD-2 asks participants to report the frequency of anxiety and inability to stop worrying over the past 2 weeks. Each item is scored from 0 (“not at all”) to 3 (“nearly every day”). The GAD-2 has demonstrated strong psychometric properties, including construct validity. GAD-2 scores are associated with functional impairment, and clinician ratings of anxiety (Plummer et al., 2016). Cronbach’s alpha in our sample was 0.87.

### Post-module Measures

#### *Acceptability and perceived utility*

After each module, participants were asked to complete the Acceptability of Intervention Measure (AIM; Weiner et al., 2017). The items of the AIM prompt participants to rate the degree to which they approved of, welcomed, liked, and found a module appealing. Participants respond to the four items on a 5-point Likert scale, ranging from 1 (completely disagree) to 5 (completely agree). The four ratings are averaged to yield an acceptability score (Weiner et al., 2017).

We also administered three items to assess the perceived helpfulness, engagement, and applicability of each intervention module. Item wording was adjusted depending on the modules that participants received. For instance, participants who received the behavioral activation module were asked to rate the following statements: “I found the positive activities exercise helpful,” (perceived helpfulness), “I found the positive activities exercise engaging,” (engagement), and “I think I will continue applying content from the positive activities exercise in the weeks ahead”

(applicability). Each item was rated on a 7-point Likert scale ranging from 1 (“strongly disagree”) to 7 (“strongly agree.”).

### Pre- and Post-intervention Measures

#### *Secondary control (secondary control scale)*

Secondary control refers to individuals’ perceived ability to manage the personal or psychological impact from objective conditions or events (Weisz et al., 2010). Secondary control has been contrasted with primary control, the ability of individuals to influence objective conditions or events in their lives (Rothbaum et al., 1982). Secondary control may be especially important during times of crisis, when individuals have relatively less primary control over their objective situations. For example, individuals during the COVID-19 crisis do not have much control over where they can travel or whom they can visit (primary control). However, they are able to control how they respond to the pandemic and the lifestyle changes caused by social distancing (secondary control).

To assess secondary control, we adapted three items from the Secondary Control Scale for Children (SCSC; Weisz et al., 2010), which we administered at baseline and post-intervention. The SCSC asks participants to rate the extent to which various statements are true about how they react to negative events. Each item is scored on a 4-point Likert scale from 0 (“very false”) to 3 (“very true”). Although the scale was initially designed for youth and adolescents, it contains items that are relevant across age groups. To reduce participant burden and to ensure that the questions were relevant to our sample of graduate and professional students, we selected three items from the SCSC (see **Supplementary Materials**). The SCSC has demonstrated strong psychometric properties in samples of youth and adolescents (Weisz et al., 2010; Schleider and Weisz, 2018). Cronbach’s alpha for the three items in our sample was 0.74.

#### *Ability to handle COVID-19 and perceived impact*

We developed and administered three questions relating to the COVID-19 pandemic. The first two questions were administered at baseline and post-intervention. The first question asked participants about their perceived ability to handle lifestyle changes that result from the COVID-19 crisis (“Over the next 2 weeks, I think I will be able to handle lifestyle changes that have resulted from the coronavirus pandemic”). The second asked participants to predict the impact of the coronavirus on their overall quality of life (“Over the next 2 weeks, I think the pandemic will have an extremely negative impact on my quality of life”). Both statements were rated on a 7-point Likert scale ranging from 1 (“strongly disagree”) to 7 (“strongly agree”).

### Post-intervention Measures

#### *Ability to handle challenges relating to COVID-19*

A third question about COVID-19, administered post-intervention only, asked participants if they believed that the content in the program could help them handle challenges relating to coronavirus (“I think the content covered in this program could help me handle challenges related to the coronavirus over the next few weeks.”). This statement was also

rated on a 7-point Likert scale ranging from “strongly disagree” to “strongly agree.”

### Demographic information

Participants were asked to report their biological sex, sexual orientation, race, economic class, and mental health history. To avoid biasing participants' responses to other questionnaires, we included the demographic questions at the end of the survey. When developing our items and response options, we followed guidelines on best practices for assessing demographic characteristics (see Hughes et al., 2016).

## Analytic Plan

Below, we describe our analyses. All analyses were planned prior to beginning data analysis. Because our primary goal was to examine the potential of the online single-session intervention delivery format (as opposed to specific content modules), we pooled the data from each intervention condition (behavioral activation/cognitive restructuring, behavioral activation/gratitude, and cognitive restructuring/gratitude). Potential differences between conditions will be examined in a future report.

### Sample Characterization and Usage Patterns

To assess usage patterns with the single-session intervention, we report the number of students who encountered the first screen of their first module (“starters”). Starters are divided into “completers” (people who finished both of the modules assigned to them) and “non-completers” (people who completed only one module or zero modules). Completion rate is the proportion of completers to starters. We also report the number of times the Qualtrics link was clicked. However, because an individual could have clicked the link multiple times, this number does not represent the number of individuals who clicked the link.

We report the symptom levels for completers ( $n = 189$ ) and non-completers ( $n = 74$ ). As demographic information was obtained from participants after they completed both modules, we only have demographic information for completers. Fifteen completers chose not to provide demographic information.

To assess whether completion of intervention was related to reported levels of depressive symptoms, anxiety symptoms, or secondary control, we conducted independent samples  $t$ -tests comparing completers and non-completers.

### Acceptability and Perceived Utility

Acceptability was measured after each module. Thus, completers filled out two sets of acceptability ratings (one for each of the two modules they received), while some non-completers (those who completed one module) filled out one set of acceptability ratings. For completers, we averaged the acceptability scores across the two modules that they rated. For non-completers who completed one module, we used the score from the one module they rated. Drawing from previous research on single-session interventions (Schleider et al., 2020), we operationalized mean scores  $>3$  as overall perceived single-session intervention acceptability.

To evaluate potential group-level differences in acceptability ratings, we examined the association between acceptability and

sex, race, sexual orientation, age, economic class, depressive symptoms, anxiety symptoms, and secondary control. We also compared acceptability ratings between completers and non-completers.

Helpfulness, engagement, and applicability were also assessed after each module. We treated the ratings by completers and non-completers in the manner described above for acceptability. We report the mean score and standard deviation for each of the three items relating to helpfulness, engagement, and applicability. Because scores were highly correlated (all  $r_s > 0.70$ ), we combined these items into a single variable, which we refer to as “perceived utility.” To evaluate potential group-level differences in perceived utility, we conducted the same analyses described above for acceptability.

### Secondary Control

We computed paired sample  $t$ -tests and estimated within-group effect sizes (Cohen's  $d$  with 95% confidence intervals) to assess reported changes on secondary control from pre-intervention to post-intervention. Following guidelines by Lakens (2013), we calculated the pre–post effect sizes using two methods. We report both  $d_{av}$  (which does not take into account correlations between pre- and post- program measures) and  $d_z$  (which accounts for correlations between pre- and post- program measures).

### Questions About COVID-19

For the two questions about COVID-19 administered pre- and post-intervention, we used the same process described above for secondary control. Because the two COVID-19 questions were conceptually distinct (one asked about ability to handle COVID-related problems and one asked about the perceived impact of COVID-19), we computed separate effect sizes for the two COVID-19 questions.

For the question about the perceived impact of the intervention on participants' ability to handle coronavirus-related challenges, which was administered post-intervention only, we report the mean, standard deviation, and % endorsement (scores  $> 4$ ).

### Missing Data

We used all available data for each analysis described above. Because one of our aims involved examining attrition, missing data are reported but not imputed. Missing data for analyses were handled via pairwise deletion.

## RESULTS

### Sample Characteristics and Usage Patterns

From 3/30/20 to 4/6/20, our survey link received 561 clicks. 263 individuals completed pre-test questions and were assigned to an intervention. Of these, 189 individuals completed both modules of the single-session intervention, yielding an overall completion rate of 72% among those who were assigned to an intervention. Demographic characteristics for completers are presented in **Table 1**.

**TABLE 1** | Sample demographics.

	<i>M (SD) or N (%)</i>
<i>N</i> (completers)	189 (100%)
PHQ-2	1.98 (1.65)
GAD-2	2.61 (1.86)
Age	31.04 (8.91)
<b>Race/ethnicity</b>	
White	114 (66.67%)
Asian	41 (23.98%)
Hispanic/Latinx/Spanish Origin	12 (7.02%)
Black	11 (6.43%)
Middle Eastern or North African	3 (1.75%)
Other	2 (1.17%)
Missing	18
<b>Sex</b>	
Female	127 (72.99%)
Male	42 (24.14%)
Other	2 (1.15%)
Prefer not to answer	3 (1.72%)
Missing	15
<b>Sexual orientation</b>	
Heterosexual or straight	140 (81.40%)
Bisexual	16 (9.30%)
Queer	10 (5.81%)
Fluid	6 (3.49%)
Gay or Lesbian	5 (2.91%)
Pansexual	5 (2.91%)
Demisexual	3 (1.74%)
Questioning	3 (1.74%)
Prefer not to answer	5 (2.91%)
Missing	17
<b>Social class (self-reported)</b>	
Poor	5 (2.89%)
Working class	27 (15.61%)
Middle class	111 (64.16%)
Affluent	30 (17.34%)
Missing	16
<b>Experienced a mental illness (self-reported)</b>	
Yes	72 (41.62%)
Unsure	22 (12.72%)
No	79 (45.67%)
Missing	16

Participants could select multiple options for race and sexual orientation.

Qualtrics records the amount of time that individuals spend on the survey. Among completers, the median time spent on the program, inclusive of all questionnaires, was 39.2 min (1st quartile = 26.7 min). However, participants were not prevented from multitasking or taking a break while completing the survey, and they had to complete the questionnaires in addition to the modules. Thus, the Qualtrics figures represent an overestimate of the time required to complete the intervention.

To describe our sample, we provide completers' and non-completers' reports of depressive symptoms [completers:

$M = 1.98$ ,  $SD = 1.65$ ; non-completers:  $M = 2.07$ ,  $SD = 1.87$ ;  $t(115.55) = -0.34$ ,  $p = 0.73$ ,  $d = -0.05$ ] and anxiety symptoms [completers:  $M = 2.61$ ,  $SD = 1.86$ ; non-completers:  $M = 2.92$ ,  $SD = 2.03$ ;  $t(119.12) = -1.12$ ,  $p = 0.27$ ,  $d = -0.16$ ]; differences between completers and non-completers were not statistically significant. Applying scoring guidelines for the PHQ-2 (using a cutoff score of 3), 30% of the completers and 36% of non-completers would screen positive for likely clinical depression. Applying scoring guidelines for the GAD-2 (using a cutoff score of 3), 42% of the completers and 47% of non-completers would screen positive for likely clinical anxiety.

## Acceptability and Perceived Utility

**Table 2** shows participants' ratings of acceptability, perceived helpfulness, engagement, and applicability.

We compared ratings on the acceptability metric (the AIM) between completers and non-completers. Because non-completers only had AIM ratings available for one module (the first module they were assigned), we used completers' scores on their first module for the comparison.

Acceptability ratings are provided for the first module participants received (completers:  $M = 4.14$ ,  $SD = 0.76$ ; non-completers:  $M = 3.96$ ,  $SD = 0.79$ ); differences between completers and non-completers were not statistically significant [ $t(28.86) = 1.09$ ,  $p = 0.29$ ,  $d = 0.24$ ]. For completers, ratings on the first module they completed were not statistically significantly different than ratings on the second module they completed;  $M = 4.19$ ,  $SD = 0.77$ ;  $t(179) = -0.83$ ,  $p = 0.41$ ,  $d = -0.06$ . 95% of completers and 83% of non-completers provided acceptability ratings that averaged greater than 3.0, with completers more likely to have scores above a 3;  $X^2(1, N = 209) = 4.31$ ,  $p = 0.04$ .

Differences in acceptability were not statistically significant by sex, race, sexuality, age, economic class, depressive symptoms, or anxiety symptoms (all  $ps > 0.17$ ). There was a weak association between secondary control at baseline and acceptability ratings. Individuals with greater secondary control at baseline reported slightly higher acceptability scores;  $r(207) = 0.21$ ,  $p = 0.002$ . To investigate this further, we applied a linear regression; we

**TABLE 2** | Acceptability and feedback ratings on single-session intervention.

	<b>Completers (<i>n</i> = 185) <i>M</i> (<i>SD</i>)</b>	<b>Non-completers with available data (<i>n</i> = 24) <i>M</i> (<i>SD</i>)</b>
<b>Acceptability items (range: 1–5)</b>		
Approve	4.18 (0.68)	4.00 (0.82)
Like	4.14 (0.69)	3.88 (0.90)
Welcome	4.23 (0.69)	3.88 (0.90)
Appeals	4.12 (0.70)	4.00 (0.76)
Average acceptability score	4.17 (0.65)	3.96 (0.79)
<b>Perceived utility items (range: 1–7)</b>		
Helpful	5.73 (1.01)	5.52 (1.19)
Engaging	5.57 (1.07)	5.48 (1.08)
Applicable	5.67 (0.97)	5.48 (1.08)
Average perceived utility score	5.66 (0.93)	5.49 (1.06)

**TABLE 3** | Changes from pre-intervention to post-intervention in secondary control and COVID-related questions.

Construct	Baseline		Post-intervention		Paired sample t-test results				
	M	SD	M	SD	p-value	Mean difference	CI	$d_{av}$	$d_z$
Secondary control (range: 0–9)	6.01	1.82	6.64	1.64	<0.001	0.63	[0.44, 0.82]	0.36	0.50
Negative impact of COVID-19 crisis (range: 1–7)	3.94	1.61	3.60	1.53	<0.001	0.35	[0.15, 0.55]	0.22	0.25
Ability to handle COVID-related lifestyle changes (range: 1–7)	5.50	1.25	5.64	1.05	0.066	0.14	[-0.01, 0.29]	0.13	0.14

found that a one-point increase on the secondary control scale was associated with an increase on the AIM of 0.08 points. The intercept was 3.69, suggesting that an individual with a score of 0 on the secondary control scale would still be predicted to rate COMET as acceptable. Additionally, at each level of secondary control (ranging from 1 to 9 in our sample), the majority of participants reported an acceptability score greater than three. Thus, while there was a significant association between secondary control and acceptability, even participants reporting lower levels of secondary control tended to view the COMET modules as acceptable.

Participants generally reported favorable ratings (i.e., >4) on the perceived utility items: perceived helpfulness (completers:  $M = 5.73$ ,  $SD = 1.01$ ; non-completers:  $M = 5.52$ ,  $SD = 1.19$ ), engagement (completers:  $M = 5.57$ ,  $SD = 1.07$ ; non-completers:  $M = 5.48$ ,  $SD = 1.08$ ), and applicability (completers:  $M = 5.67$ ,  $SD = 0.97$ ; non-completers:  $M = 5.48$ ,  $SD = 1.08$ ). We also calculated the percentage of participants who endorsed the modules (i.e., mean score > 4) as helpful (90% of completers and 76% of non-completers), engaging (86% of completers and 84% of non-completers), and applicable (89% of completers and 76% of non-completers).

As mentioned, due to the high correlation between these items, we combined these items into one variable (the perceived utility score) to reduce the number of tests we performed. We calculated perceived utility ratings for the first module participants received (completers:  $M = 5.61$ ,  $SD = 1.00$ ; non-completers:  $M = 5.49$ ,  $SD = 1.06$ ); differences between completers and non-completers were not statistically significant [ $t(30.07) = 0.53$ ,  $p = 0.60$ ,  $d = 0.12$ ]. For completers, ratings on the first module they completed were not statistically significantly different than ratings on the second module they completed;  $M = 5.71$ ,  $SD = 1.15$ ;  $t(180) = -1.13$ ,  $p = 0.26$ ,  $d = -0.09$ . Differences in perceived utility were not statistically significantly different by sex, race, sexuality, age, economic class, depressive symptoms, anxiety symptoms, or completion status (all  $ps > 0.37$ ). Individuals with greater secondary control at baseline reported slightly higher perceived utility scores;  $r(208) = 0.21$ ,  $p = 0.002$ . The trend described above for acceptability was also found for perceived utility; at each level of secondary control (ranging from 1 to 9 in our sample), the majority of participants reported an acceptability score greater than four. 92% of completers and 84% of non-completers provided perceived utility ratings that averaged greater than 4.0, and there were no statistically significant differences between completers and non-completers;  $X^2(1, N = 210) = 1.67$ ,  $p = 0.20$ .

## Changes in Secondary Control

Table 3 shows the results of our paired sample t-tests and effect sizes for the measures delivered at both baseline and post-intervention. Completers reported a statistically significant improvement in secondary control from pre-intervention to post-intervention;  $t(173) = -6.53$ ,  $p < 0.001$ . Secondary control scores were greater post-intervention ( $M = 6.64$ ,  $SD = 1.64$ ) than pre-intervention ( $M = 6.01$ ,  $SD = 1.82$ ), with moderate standardized effect sizes ( $d_{av} = 0.36$ ,  $d_z = 0.50$ ).

## Changes in COVID-19 Questions

Completers reported improvements in the perceived impact of the COVID-19 crisis on their quality of life from pre-intervention to post-intervention. Participants were less likely to endorse the statement that the COVID-19 crisis would have an extremely negative impact on their quality of life post-intervention ( $M = 3.60$ ,  $SD = 1.53$ ) than pre-intervention ( $M = 3.94$ ,  $SD = 1.61$ ), with small standardized effect sizes ( $d_{av} = 0.22$ ,  $d_z = 0.25$ ). This difference was statistically significant;  $t(178) = 3.51$ ,  $p < 0.001$ . Completers also reported improvements in their perceived ability to handle COVID-related changes from pre-intervention to post-intervention. Participants were slightly more likely to endorse the statement that they would be able to handle COVID-related changes post-intervention ( $M = 5.64$ ,  $SD = 1.05$ ) than pre-intervention ( $M = 5.50$ ,  $SD = 1.25$ ), with small standardized effect sizes ( $d_{av} = 0.13$ ,  $d_z = 0.14$ ). However, this difference did not meet the threshold for statistical significance;  $t(178) = 1.85$ ,  $p = 0.066$ .

Finally, 88% of completers believed that the content covered in the program could help them manage challenges relating to the COVID-19 crisis ( $M = 5.67$ ,  $SD = 1.17$ ).

## DISCUSSION

Overall, our findings demonstrate that brief online interventions, such as COMET, can be a feasible and useful way to provide support to individuals during the COVID-19 crisis. One major benefit of such interventions is that they are flexible; they can be modified and updated regularly. This is possible even under time constraints; responding to the COVID-19 crisis, our small team was able to adapt an existing online intervention over the course of just 2 weeks. The flexibility of single-session interventions allows them to be rapidly deployed in times of crisis. Once deployed, these interventions can quickly reach large numbers of people. In just 1 week, 263 individuals began and 189 individuals completed COMET. We not only found that

many graduate and professional students were interested in the single-session intervention and willing to complete it, but also that they rated COMET highly on acceptability and perceived utility. Furthermore, acceptability ratings and perceived utility ratings did not differ by reported depressive symptoms or anxiety symptoms; COMET appears to be welcomed by individuals with elevated mental health symptoms as well as those without. Acceptability ratings differed slightly by secondary control. Individuals with higher secondary control—the sense that they can control their reactions to objective circumstances—tended to provide slightly higher ratings of acceptability. This finding might be explained by the fact that individuals who believe they can handle their own responses may be more likely to like programs that promote agency in responding to objective circumstances.

Our findings also provide preliminary data suggesting that these interventions can be helpful during times of crisis. Participants reported greater levels of secondary control post-intervention, which may be especially important during the COVID-19 crisis. Perceived primary control (the belief individuals can influence objective events and circumstances in their life) and secondary control are protective factors for the development of mental health problems (Rothbaum et al., 1982; Weisz et al., 2010). However, while individuals have some control over the protective measures they take against COVID-19 (such as staying in their homes and avoiding gatherings), the crisis has limited the ability of people to influence their objective social, emotional, academic, and economic circumstances. COVID-19 has made it difficult or impossible for individuals to safely visit their loved ones, protect those who are exposed to the virus, keep their jobs, and maintain their daily routines. More broadly, individuals have little control over how long the pandemic will last, how the economy will change, or how the virus will affect the health and lives of their loved ones. In this context, we believe that secondary control, the tendency to believe that one can cope with stressful situations even when one has little control over the outcomes, will be especially important during the crisis. Interventions that improve perceived secondary control will be essential public health tools in the months ahead.

As we have emphasized, it is also important to evaluate the acceptability, implementation, and uptake of such interventions. Unfortunately, as mentioned previously, few digital interventions have demonstrated acceptability and uptake in real-world settings (Fleming et al., 2018; Buss et al., 2020). Drop-out rates in open trials of digital interventions are high (Fleming et al., 2018), users rarely spend more than a few minutes on digital mental health interventions (Baumel et al., 2019), and most publicly available mental health apps generally fail to retain users (Wasil et al., 2020e). With this in mind, some of our findings are especially promising. Individuals enrolled in our intervention over a short timeframe, considered our intervention acceptable, and believed our intervention was helpful, engaging, and applicable to their lives. Identifying specific strategies that led to high acceptability, especially strategies that could be replicated in future mental health promotion efforts, could be highly valuable.

There are a few unique aspects of our process that may have led to favorable acceptability ratings and uptake. First, we intentionally advertised COMET as a program that all students could benefit from. Drawing from work in low- and middle-income countries (e.g., Osborn et al., 2019), we reasoned that branding our intervention as a program that anyone could benefit from could circumvent some of the stigma associated with help-seeking for psychiatric disorders. Consequently, rather than mentioning depression or anxiety, we branded the intervention as one that could help individuals “adjust to changing life circumstances, manage emotions, and achieve goals”. Furthermore, rather than referring to two of the modules as “behavioral activation” and “cognitive restructuring”—technical terms that may be associated with formal psychotherapy—we relabeled these sections as “positive activities” and “flexible thinking.” Future research could examine different ways to present and advertise these or other evidence-based intervention modules. Such research could draw from work on the direct-to-consumer marketing of mental health interventions (Becker, 2015; Rith-Najarian et al., 2019b).

Our partnership with university deans was also essential. As a result of this partnership, information about our intervention was distributed to a wide array of students across the university. Additionally, since the recruitment messages were sent out using the official student listservs (which are often used for important communications), students may have been more likely to notice and open the message. In these ways, our findings showcase the potential utility of partnerships between researchers and university administrators. Finally, it is important to note that the COVID-19 crisis may have impacted our recruitment efforts. Students may be especially interested in developing skills that can help them cope with lifestyle changes as a result of the crisis. Additionally, due to social distancing and online learning, some students may have more free time than they normally do during the semester, which may have made them more responsive to our web-based intervention.

Our findings also have implications for public health officials, higher education leaders, and intervention developers interested in supporting people during the COVID-19 crisis. For example, our promising findings regarding students' experiences with COMET could encourage future collaborations between psychologists and higher education leaders. While such partnerships can be time-consuming and effortful, they are worthwhile to pursue when there is reason to believe that they will be impactful. This is especially true for collaborations around topics that could be considered sensitive, like programs relating to mental health. When we launched our collaboration, our team and our collaborators did not know if or how students would engage with our program. Our experience offers some room for optimism, showing that such collaborations can be fruitful, and students appear highly receptive to university-endorsed online mental health initiatives. With this in mind, we hope our findings encourage psychologists and higher education leaders at other universities to engage in student mental health promotion initiatives during the COVID-19 crisis. Individuals considering such

collaborations or interested in developing interventions may benefit from adapting content from pre-existing interventions or common elements from empirically supported interventions (see Chorpita and Daleiden, 2009; Weisz et al., 2012). In our experience, the decision to adapt existing modules (rather than to create a new intervention from scratch) allowed us to act quickly while ensuring that individuals received content with strong empirical support. From a public health perspective, repurposing existing interventions may provide a quick and efficient way to expand access to support. Additionally, modular interventions may be especially valuable given their flexibility and adaptability (Weisz et al., 2012). As an example, COMET was adapted for graduate and professional students over the course of a few weeks. COMET, or other modular interventions, could also be readily adapted for additional populations. New modules (e.g., mindfulness and problem solving) could be added, existing modules could be removed, or different combinations of modules could be deployed depending on the needs of specific populations. Finally, our findings highlight that students of a variety of age groups and backgrounds are interested in online self-help interventions. With this in mind, higher education leaders could consider launching low-intensity interventions to support students across the country.

Our findings should be interpreted in light of some limitations. First, our pre-post design is not sufficient to make causal claims, and our study does not remove the need for randomized control trials. It remains unknown if our intervention can produce lasting changes in participants' thoughts, behaviors, or feelings. In order to gauge those effects, there is a need for adequately-powered pre-registered randomized controlled trials which measure mental health outcomes (e.g., depressive and anxiety symptoms) longitudinally. Second, the rates of depressive symptoms and anxiety symptoms identified in our study should be interpreted within the context of COVID-19. Participants' reports of depression and anxiety may be higher than normal due to the stressors and lifestyle changes introduced by the crisis. For some individuals, these symptoms may be temporary, but for others, they may last beyond the crisis; future longitudinal and observational research would be useful to examine these trends. Third, while our sample was diverse along several dimensions, participants in our study were predominantly female. This is consistent with previous research; a recent review documented that most studies of prevention programs for college students and graduate students had samples that were two-thirds or more female (Rith-Najarian et al., 2019a). Such findings call for the development of recruitment techniques that may make digital interventions more appealing to male students (e.g., Rith-Najarian et al., 2019b). Fourth, in order to minimize participant burden and maximize the reach of our survey, our demographic questionnaire was brief. As a result, we did not comprehensively assess contextual factors that may be highly relevant during the COVID-19 crisis, such as participants' living situations, income, marital status, social support, or parental status. Future research is needed to understand contextual risk factors and protective factors

that may influence how students are affected by COVID-19. Additionally, future research could evaluate if psychosocial interventions can support students who are especially vulnerable during the crisis. Finally, participants in our study received pre-program and post-program questionnaires before being assigned to an intervention condition, making it difficult to estimate the exact amount of time that participants spent completing intervention content. Furthermore, it is possible that our baseline questionnaires deterred some individuals from engaging. If our intervention had not included baseline questionnaires, it is possible that it would have reached more students.

Overall, our findings suggest that brief digital interventions could be a useful way to expand access to care in times of public health emergencies such as the COVID-19 crisis. Students appear interested in these interventions, complete them at high rates, and find them helpful. Participants also reported improvements in their perceived sense of control and ability to handle the pandemic from pre- to post-intervention. Future research is needed to understand which content is best suited for brief interventions, which content is best suited for specific circumstances (e.g., public health emergencies), how such interventions should be ideally presented and disseminated, and for whom these interventions are most effective. Such research could ensure that the important findings and interventions from psychological science are successfully disseminated to the broader public, especially during public health emergencies like the COVID-19 pandemic.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study are not readily available because the authors did not receive clearance to share the data collected for this project. The R code associated with this project has been made available as a **Supplementary Material**. Requests to access the datasets should be directed to AW, [wasil@sas.upenn.edu](mailto:wasil@sas.upenn.edu).

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by University of Pennsylvania Institutional Review Board. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

## AUTHOR CONTRIBUTIONS

AW conceptualized the idea for the study with RD. AW and MT designed the initial versions of the interventions with guidance from RD. RF and JS participated in the adaptation of the interventions. AW performed data analysis with oversight from RD and support from MT, RF, and JS. AW wrote the initial R script. RF, MT, and JS reviewed and revised

the script. AW wrote the initial draft of the manuscript. MT, RF, JS, and RD revised the manuscript. All authors contributed to the article and approved the submitted version.

## ACKNOWLEDGMENTS

The authors acknowledge Angela Duckworth, Katherine Milkman, Joseph Kay, the Behavior Change for Good Initiative,

and the deans of the Graduate School of Arts and Sciences for their support.

## SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fpsyg.2021.569785/full#supplementary-material>

The spread of COVID-19 in Italy resulted in the implementation of a lockdown that obligated the first time the general populace to remain at home for approximately two months. This lockdown interrupted citizens' professional and educational activities, in addition to closing shops, offices and educational institutions. The resulting changes in people's daily routines and activities induced unexpected changes in their thoughts, feelings and attitudes, in addition to altering their life perceptions. Consequently, the present study explores how young adults perceived their lives under lockdown during the final week of March 2020, when the reported number of daily coronavirus infections reached its peak in Italy. The research was carried out among 293 university students (234 women and 59 men) with an average age of 20.85 years old (SD = 3.23). The researchers asked participants to describe the emotions, thoughts and experiences that characterized their time under lockdown. The study analyzed specific narratives related to time and space using grounded theory methodology, which was applied using Atlas 8 software, leading to the creation of 68 codes. The study organized these codes into three specific categories: confined in the present, confined in the past, and striving toward one's goals. Finally, the researchers also created a core-category labeled "continuity of being." The results showed that the closure of open spaces caused a division in participants' perceptions of time continuity, with many viewing themselves as feeling fragmented and as living the present in a static and fixed way. Additionally, participants also saw the present as being discontinuous from the past, while, simultaneously, projecting toward the future and the changes it might bring. Finally, this study examined further implications surrounding individual projecting among young people in greater depth.

**Keywords:** time, lockdown, storytelling, well-being, young adults, confined in the present, confined in the past, striving toward one's goals

## INTRODUCTION

The first COVID-19 emergency lockdown in Italy was in place from March 9 to May 4, 2020. During this period, the daily lives of Italians were turned completely upside down, as various government decrees restricted routine educational, professional and social activities. Recent studies on the COVID-19 emergency have highlighted that forced isolation has had a great impact on people's psychological condition (Brooks et al., 2020; Duan and Zhu, 2020; Pancani et al., 2020).

In particular, many studies have focused on the lockdown's impacts on children and adolescents (Orgilés et al., 2020), women vulnerable to domestic violence (Troisi, 2020) and students distress (Cao et al., 2020; Zurlo et al., 2020). Particularly, Di Napoli et al. (2021) and Migliorini et al. (2021) described that students' individual feelings were characterized by fear, distress, sadness, rage, and loneliness, which are detailed in conjunction with coping strategies and resilience, as well as interpersonal relations at the familial and institutional levels (Marzana et al., 2021).

Further variables associated with higher levels of depression, anxiety and stress were female gender, negative affect and detachment (Mazza et al., 2020) but people with more resilient coping strategies were more likely to experience fewer depressive symptoms (Roma et al., 2020a).

Moreover, psychological factors, such as self-efficacy, risk perception and civic engagement, had a central role in the adherence to the measures adopted by the institution to contain the spread of the virus (Roma et al., 2020b).

New individual and social insights about "we-ness" awareness arise (Walker et al., 2020), strengthening solidarity, connectedness and shared experiences of "we-ness," and improving individual and community well-being (Procentese et al., 2020; Di Napoli et al., 2021).

However, no known studies have investigated how the pandemic has affected people's subjective perceptions of time.

As observed in the biographies of those who have lived through experiences such as spending time in prison, forced confinement influence one's perceptions of time. For example, in his biography, Nelson Mandela (1994) sheds light on his many years in prison, describing how, even in the worst detention, he never gave up on his dreams and hopes for freedom, while constantly developing plans for future action. Indeed, many psychological researchers have investigated individuals' attitudes toward temporal perspectives. For example, Stolarski et al. (2018) examined the long history of time and its deep roots in philosophy and physics. Additionally, Zimbardo and Boyd (2015) defined time perspectives as individual subjective experiences through which each person refers to the psychological concepts of the past, present and future. Zimbardo and Boyd (2015) specifically elaborated five individual attitudes toward time, encompassing future, past-negative, past-positive, present-hedonistic, and present-fatalistic, which are correlated with differing levels of well-being. In particular, individuals possessing past-positive and present-hedonistic time perspectives are thought to have higher levels of well-being, while future time perspectives are associated with optimism, hope and an internal locus of control.

More recently, Prilleltensky et al. (2015) proposed a concept of well-being specifically measured using a temporal perspective, assuming that individual perceptions of well-being cannot ignore experiences from the past, those perceived in the present and those imagined in the future (Di Martino et al., 2018; Di Napoli et al., forthcoming). Moreover, the seminal contribution of Pichon-Rivière on time and space in everyday life pointed out that everything that happens in daily life takes place in a given space and at a given time. Furthermore, as expressed by

Quiroga and Racedo, these routine events possess a "rhythm" that is shaped by "the complex social relationships that govern the life of human beings in a certain historical era" (2012, p.18). In addition, external events alter how time and space frame individuals' daily lives and undermine our concrete conditions of existence. However, "only when everyday life hurts us, when there is no more pleasure or when we experience a crisis, [do] we start to think about it" (Quiroga and Racedo, 2012, p.18).

In principle, from an ecological perspective, individual dimensions and social events influence behaviors, as every external change modifies people's reference frameworks, and, in turn, these changes alter one's internal world and their world perceptions (Lewin, 1943). Earlier research has considered how particular sudden and unexpected events, such as serious illnesses, natural disasters, terrorist attacks, wars, geographical relocation or temporary time constraints influence time perspectives (e.g., Fung et al., 1999; Fung and Carstensen, 2004). Indeed, some studies have found that well-being is also strictly related to subjective experiences of these events (Petrillo et al., 2014). From a phenomenological point of view, illness, as with any other critical event, causes a break in one's sense of continuity, in addition to dramatic experiences of discontinuity. This perspective underlines a crisis of the subject's sense-making systems and the necessity to pursue meaning, in order to interpret ongoing experiences. Moreover, critical events and illness represent elements of discontinuity that saturate the present and the entirety of sense-making processes. During the perturbation phase, time is organized through extremely subjective modalities, appearing to be confusing and inconsistent at first glance. However, a deeper analysis regarding the effects of illness on time perceptions, such as the dyscrasia of the temporal order, indicates that time perceptions are the result of the ongoing sense-making processes concerning what is happening at that moment. In this regard, how illness affects time perceptions involves not only meaning construction in response to the rupture of canonical states, but also a separate process of crisis subjectification. In other words, illness-influenced time perceptions result in significant sense-making processes aimed at the construction of these perceptions (Freda et al., 2015, p. 209). As an example, people with chronic diseases when they suffer the unpredictable vulnerability of their illness are considering their selves under the Damocles Syndrome, in allusion to the Greek mythological tale about an imminent and ever-present peril (Gonzalez Leone et al., 2019). Consequently, i.e., oncology patients are worried and anxious about eventual cancer recurrence comprising a second pathology related to impending distress or possible danger that may materialize at an unknown time in the future.

Concerning natural disaster-related emergencies, such as floods, earthquakes and pandemics, common sense reflections emphasize their catastrophic aspects. However, these circumstances take also on unexpected dimensions, such as changes in relational and time perspectives. Consequently, significant external events cause time and space new perceptions, reconstructing individuals' inner worlds and their connections with their environmental frameworks.

In addition, according to the community psychology perspective utilized by the present study, space and time are both framed also by environmental, social and relational circumstances (Orford, 2008).

## Future Time Perceptions

Through-out life, people must adapt to circumstances that require the integration of new life events and changes (Kralik et al., 2006). Subjectively perceiving future time is essential because it is associated with one's choice of goals, objectives and preferences (Carstensen et al., 1999) at different ages (Donizzetti, 2019).

Life transition events lead to changes in time perceptions (Wittmann and Lehnhoff, 2005), especially those regarding the future (Carstensen et al., 1999).

In particular, life transitions are moments where time continuity is broken because of changes in temporal perspectives that result in a division between past experiences and future plans.

This implies that young adults seek information and knowledge regarding social goals, in order to maximize their future opportunities. Young adulthood is in fact characterized by new identity exploration and development and is often coupled with significant life changes, such as entering the labor market, achieving financial independence and establishing long-term intimate relationships (Arnett, 2000; Crocetti et al., 2012). This transition to adulthood is also imbued with optimism, given young adults' enhanced capacity to explore the world and envisage new life trajectories (Larson et al., 2002; Arnett, 2007). On the contrary, time perceptions among the elderly are more limited. Elderly individuals have limited time perceptions and are more motivated to pursue emotion-focused goals (Carstensen et al., 2006; Charles and Carstensen, 2010).

However, in the words of Rosa (2003), Italian youth's existence has also become de-temporalized, as "Life is no longer planned along a line that stretches from the past into the future; instead, decisions are taken from 'time to time' according to situational and contextual needs and desires" (p.19).

Therefore, listening to the voices of Italian youth during the peak of the unexpected COVID-19 pandemic let researchers deepen their understanding of how time perceptions could affect young people confined at home, who generally already perceived the future in uncertain, accelerated and fragmented terms (Leccardi, 2005).

To better understand time perceptions and representations during the lockdown, we conducted a research with Italian university students to document their personal experiences of this unexpected and unforeseen event.

From this perspective, understanding young adults' time perceptions while being confined at home due to the COVID-19 pandemic would provide valuable contributions to the existing literature.

In this light, the present article seeks to expand upon the existing research, by elaborating upon the effects of the COVID-19 lockdown on young Italian students' psychological perceptions of time.

This study analyses students' reports regarding their personal lives during home confinement. Generally, time is "taken into account in terms of life events and life experiences and, therefore, refers to a life-course perspective that is often processed in retrospect" (Kieslinger et al., 2020, p.1). In this case, however, our participants presented their present perceptions of their lives during forced confinement at home. Therefore, their perspectives represented a view of life in confinement and their texts described the meanings they attributed to time perceptions while confined at home.

This study sought to explore the effects of the sudden life changes resulting from the COVID-19 lockdown, in addition to examining their implications and impacts on participants' daily lives, emotions and thoughts. Specifically, this study further investigated the thoughts and emotions related to time perceptions in a confined space, seeking to expand upon the existing knowledge regarding any related impacts on well-being or distress. The researchers collected data in Italy during the last week of March 2020, when the Italian government decreed a total lockdown as measure to contain the spread of COVID-19.

## MATERIALS AND METHODS

### Participants

The research participants were composed of psychology students from the University of Naples Federico II. Recruitment occurred during online lessons, via invitations from teachers inviting students to share their thoughts about the lockdown through the digital platform, SurveyMonkey. The study involved a total of 293 students, including 234 females and 59 males, between 19 and 29 years old, with an average of 20.85 years ( $SD = 3.22$ ). The strong gender disparity is representative of the general population of psychology students in Italy, in which women comprise 77.6% of students (Centro Studio Investimenti Sociali, 2019). **Table 1** displays participants' sociodemographic characteristics.

### Methods and Procedures

This study used a storytelling approach, collecting individual and relational experiences with the aim of creating shared

**TABLE 1** | Participant characteristics.

Age	<i>M</i> = 20.85	<i>SD</i> = 3.22
	%	<i>N</i>
<b>Sex</b>		
Male	20.1	59
Female	79.9	234
<b>Housing Situation</b>		
Living with one or both parents	90.8	266
Living alone	0.7	2
Living with a partner	1.0	3
Living with one or more roommates	3.1	9
Living with other family members	4.4	13
<b>Total</b>	100	293

awareness. Therefore, storytelling was much more than a device to deepen individual biographical paths, as it also served as a tool for shared support, common identification and social change. The researchers collected students' texts using the online platform SurveyMonkey as a teaching tool to support an online undergraduate community psychology course. The study asked participants to report their thoughts and emotions related to their lockdown experiences, as well as any other actions or events that they wished to share, limiting their written contributions to 10,000 characters or less. In the context of this study, it is pertinent to highlight the importance of using qualitative methods to detect shared meaning in individual stories using specific, defined procedures (Rappaport, 1995), which allow for meanings attributed to events to be detected, deepening the general knowledge regarding the subject and uncovering new perspectives and ideas (Salvatore et al., 2018).

## Data Analysis

We conducted the textual analysis using grounded theory methodology (GTM), which develops theoretical frameworks through the close examination of participants' narratives. It is a bottom up, qualitative approach, in which findings emerge from the data, in accordance with Glaser's (1992) principles. The use of GTM found receptive audiences among psychology and community-based researchers (Stewart, 2000; Rasmussen et al., 2016). The research team developed its coding activities using a bottom-up approach that was not based on *a priori* categories. This entails an "iterative process proceeding from substantive to theoretical coding. Grounded theorists proceed from the relationships between indicators in the data to the relation of these indicators to larger categories... The distinction between substantive and theoretical codes is the difference between the content observed in the data and what researchers theorize about that content" (Rasmussen et al., 2016, p. 25).

Grounded Theory is a methodology applied to qualitative research that involves the construction of hypotheses and theories through the collecting and analysis of data and for this reason it is used in all those researches in which there is no well-defined starting hypothesis.

Indeed, it was already used in other research that have deepened the psychological impact of the COVID-19 emergency (Di Napoli et al., 2021; Marzana et al., 2021; Migliorini et al., 2021).

The researchers began by open coding the texts and then grouping codes into larger categories in order to more fully understand the texts' proposed meanings. Namely, this study structured data analysis in 5 phases: (a) familiarization with the data, (b) initial code generation, (c) grouping the codes and their subsequent review, (d) defining and labeling the codes, and (e) creating code macro-categories and describing any relationships among them. Throughout all five steps, the research team interacted and discussed meanings using their reflective competences, agreeing up content definitions through these reciprocal and collective thought interactions.

For the data analysis Atlas 8 software (Muhr, 2017) was used.

## RESULTS

The analysis of the textual material resulted in 68 codes. The researchers subsequently organized these codes into 10 groups, which they later divided in three macro-categories (see **Table 2**). The results section elaborates on these macro-categories, code groups and some particularly explanatory quotations in greater detail.

### Confined in the Present

This macro-category is comprised of code groups that refer to participants' perceptions of the present time. It is indicative of how young people involved in the study dealt with the passage of time during the lockdown at home in a confined space. In fact, the study revealed four distinct code groups that were "*confined in the present*," and which reported different ways of relating to daily life during the COVID-19 state of emergency.

One identified code group encompassed participants whose time perceptions could be characterized as "*frozen time*," in the sense that they perceived the lockdown as impeding their routine professional, educational and leisure activities. Codes that characterized this category highlighted a condition of immobility, as well as one of estrangement and detachment from people and daily life routines and habits, as illustrated by the excerpt below (*normality on hold, a suspension of daily life activities, every day is the same*), as illustrated by one participant's thoughts "*We were forced to stop, to change our habits, to deal with a reality that no one had ever imagined possible.*"

These participants perceived time as frozen (*a sense of immobility*) and lacking direction in the present, as if they were lost in a desert without anything around, bereft of life, movement and relationships. Moreover, participants experiencing "*frozen time*" indicated that they lacked any interest in partaking in potentially different experiences, as they possessed little notion of time and also viewed outdoor spaces as empty and devoid of life (*deserted cities*), as illustrated by one participant's thoughts "*Life slowed down and then stopped. My village became silent in an instant. We were so rowdy, sentimental, 'physical,' passionate and friendly with everyone. This all stopped. Now, we no longer meet. We no longer touch each other.*"

A second identified code group regarding how participants experienced everyday life during the lockdown comprised those who were "*trapped in the present*." This code group refers to the difficulties that some young people experienced during the state of emergency, characterized by social isolation and forced confinement. In this context, many young adults who were "*trapped in the present*" perceived themselves as being locked up and unable to move. In fact, participants often reported a perception of being trapped, which they frequently characterized as unescapable or lacking a defined exit (*feeling caged in, the absence of an escape route*), as illustrated by one participant's thoughts "*But, at the same time, unfortunately, it has become a 'cage' that keeps me locked in these walls and does not allow me to breathe.*"

In addition, many participants who were "*trapped in the present*" emphasized a sense of unease due to their inability to leave their respective homes and/or countries (*quarantined*

**TABLE 2 |** Coding process.

Code	Codes group	Macro-categories
<i>A feeling of emptiness; a sense of immobility; a sense of strangeness due to absence of contact; a suspension of daily life; deserted cities; endless days; every day is the same; frozen time; normality on hold.</i>	<b>Frozen time</b>	<b>CONFINED IN THE PRESENT</b>
<i>Absence of an end; concern about not returning home; feeling caged in; impossibility of returning to one's home country; quarantined country; the absence of an escape route; travel interruptions.</i>	<b>Trapped in the present</b>	
<i>A surreal situation; chaos; feeling destabilized; feeling overwhelmed by the situation; loss of a life balance; sense of bewilderment.</i>	<b>Lost in time and space</b>	
<i>Birthday in quarantine; change of attitude toward others; importance of the present; new form of social relations; new interests; new situation; sudden lifestyle changes.</i>	<b>New life routines</b>	
<i>Inadequacy of past behaviors; past-present comparison; regret the past; reevaluation of social relationships; reevaluation of what you have.</i>	<b>Revalue the past</b>	<b>CONFINED IN THE PAST</b>
<i>A lack of freedom; a loss of privacy; a need for multiple spaces; a need to return to one's daily life; a sense of invasion; forced cohabitation; forced to stay at home; I can't wait to relive normalcy; importance of normality; imposed free time.</i>	<b>Return to normality</b>	
<i>Carpe diem; life is unpredictable; live life to the fullest; live now and not tomorrow; reevaluation of life; reevaluation of time; time is precious.</i>	<b>There is no time to waste</b>	<b>STRIVING TOWARD ONE'S GOALS</b>
<i>Distancing oneself from today and embracing tomorrow; future prospects; interest in future implications; tolerating uncertainty; uncertainty about the future.</i>	<b>Living in the present, but in anticipation of the future</b>	
<i>A unique experience; being alone with yourself; opportunity for change; opportunity to reflect; situation that marks you; stop and think.</i>	<b>Turning point</b>	
<i>Achieving a new life balance; evolution of oneself; greater awareness; personal growth; rediscover oneself; reevaluation of oneself.</i>	<b>Self-evolution</b>	

country, travel interruptions), or, conversely, to return to their home countries (impossibility of returning to one's home country), as illustrated by one participant's thoughts "The day the red zone was established in all of Italy, I was with my boyfriend in Holland. We were supposed to have stayed there for a week on vacation. As a result, we were constantly worrying about not being able to go home in the following days."

The third code group was comprised of participants whose perceptions could be described as "lost in time and space," alluding to the negative experiences generated by the expansion of the pandemic. Many participants reported having undergone moments where they felt lost and thought they would not be able to cope with the emotional burdens resulting from the pandemic (a surreal situation, a sense of bewilderment, feeling overwhelmed by the situation), as illustrated by one participant's thoughts "We are living in a moment that could be defined as a cyclone of emotions. We feel completely overwhelmed."

In fact, this dramatic, unprecedented situation has led many participants to experience confusion and to lose sight of their past reference points (chaos, feeling destabilized) "This situation shocked me because it forced me to reorganize my daily life. It pushed me away from the university life routines that I had previously created."

Finally, the fourth code group consisted of texts who viewed the lockdown as a chance to adopt "new life routines," highlighting a way of dealing with the present by emphasizing the positive aspects of confinement at home. These codes refer to participants who demonstrated proactive attitudes and an ability to dedicate themselves to exploring new interests in their free time, in addition to those who embraced this new lifestyle (new interests, sudden lifestyle changes) "Then, I rediscovered my interests, which

I had not cultivated for a long time. I started reading, writing, cooking, playing and drawing. And this is another thing that I will carry with me, and that I hope to continue doing, even when this situation is over."

In addition, participants whose time perceptions were shaped by their "new life routines" emphasized their ability to maintain and manage interpersonal relationships and active ties with family and friends, despite spatial distances, thanks to the use of social networks. Among this code group, the inability to see others in-person both enhanced and deepened their social ties in certain ways (new forms of social relations) "We try to stay close, thanks to video calls, even if we are physically far apart."

Finally, participants who embraced "new life routines" under lockdown underlined both their ability and desire to celebrate life events, albeit in alternative ways. They celebrated parties with relatives and friends all the same, through group calls on social networks (birthdays in quarantine) "We still celebrated my friends' birthdays, despite the fact that they occurred during the weeks under lockdown. It was strange, but still beautiful!"

## Confined in the Past

This macro-category contains all code groups that refer to participants who indicated tendencies to escape from the present by taking refuge in the past. Many young people reported a desire to return to the past, prior to the pandemic and the lockdown. This macro-category is comprised of two specific code groups, whose participants both evoked memories of their earlier lives and/or desired past actions that they did not take.

The first code group consisted of participants who sought to "revalue the past," referring to their desire to change certain aspects of their past, resume suspended activities or start

new activities that were made impractical by the lockdown. For example, many participants reported revaluing their past, with a particular focus on their interpersonal relationships (*reevaluation of social relationships*) and on aspects of their lives that they considered to be valuable, but not normally not appreciated and often taken for granted (*reevaluation of what you have*) “*In this dark moment, I learned how important is to appreciate what we have, without taking things for granted, how fundamental it is to love normality every day, to dedicate more time to the people we love and to stop every now and again and reflect. It allowed me to understand the irreplaceability of physical contact and embracing one another, as well as the need for reciprocity.*”

In some cases, participants also expressed awareness in conjunction with certain feelings of guilt related to their failures to put prevention and common sense behaviors into practice earlier in the pandemic, which could have minimized the spread of COVID-19 (*inadequacies of past behaviors*) “*The situation we are experiencing now is a reflection of the initial attitudes that everyone had toward this virus. We have been too irresponsible.*”

The second code group consisted of participants whose time perceptions focused on a “*return to normality*,” in reference to their desires to restore pre-pandemic norms as soon as possible and to resume their pre-pandemic daily lives, composed of actions, spaces and consolidated times. In fact, students often referred to the desire to regain their freedom, understood as the need to regain control of their daily time management. In particular, they strove to restore the division between moments dedicated to productive activities (work or study) and leisure time, which often lacked a clear partition during the lockdown (*a lack of freedom, a need to return to one's daily life; imposed free time*) “*It is not free time that is at my disposal now, since it is not time that I voluntarily chose to dedicate to myself. It is time that has imposed itself on me.*”

Participants' references to their living spaces comprise another important aspect of this code group. Some participants described their homes, which typically embodied feelings of safety and protection, as places of confinement similar to a prison, given the limits they imposed upon participants' freedoms. The lockdown also forced family members to share domestic spaces for much longer than in the pre-pandemic past, leading many young people to feel that their physical and mental spaces were being invaded (*a need for multiple spaces, forced cohabitation, a sense of invasion*) “*I have to adapt slowly, even if it is very difficult at 20 years old to live with 6 people in a 4-room house and to share a room with two younger sisters.*”

## Striving Toward One's Goals

The final macro-category includes four code groups that focus on a sort of “*time travel*” on the part of the study participants. This journey led participants to explore new time perceptions that they had never experienced before, in addition to well-known domestic spaces that were viewed in a different light. This journey also led participants to reassess their lives and enhanced their desire to live without wasting a moment, leading them to

evolve, to seek new experiences and to imagine a new future. The first code group can be characterized by a philosophy based upon the belief that, “*there is no time to waste.*” In fact, this idea encapsulates the reflections of many participants regarding life's value and the fact that unpredictable events, such as the COVID-19 pandemic, can occur and lead to limitations and suffering. The thought of the possibility that unpredictable events may occur led many participants to reconsider the importance of living life to the fullest, to avoid postponing important decisions and actions and to experience the present by appreciating small moments of happiness in life (*carpe diem, time is precious, life is unpredictable, live life to the fullest*) “*This experience is teaching me that life must always be enjoyed, every day*”; “*I have never realized the importance of time in my life. We young people lose sight of time's importance every day. We do not realize how much it really matters, and the fact that it would be beneficial to stop for a moment to reflect upon this.*”

The second code group consisted of participants who were “*living in the present, but in anticipation of the future.*” These participants' time perceptions were focused on the ways in which they lived through the lockdown, possessing an evasive attitude toward the present, which was viewed as a period that they must get through in order to have a brighter future. In fact, the responses of participants “*living in the present, but in anticipation of the future*” often referred to a time in the future when it will be possible to resume physical contact with others and when the pandemic will be just a bad memory (*tolerating uncertainty, distancing oneself from today and embracing tomorrow, future prospects*) “*We must endure this moment. It is difficult, but we know it will pass. It must pass! We have to think about the future, which will surely be better. Everything will be fine!*”

The third future-focused code group viewed the pandemic as a sort of “*turning point.*” Their reflections characterized this tragic event as an evolutionary crisis that marked a turning point in the lives of individuals and the community. These participants saw the obligation to stay at home as an opportunity to stop and think about their own lives and the directions that they had taken thus far, as well as the course of their future lives following their lockdown experiences (*stop and think, an opportunity to reflect*) “*This is a time that allows for introspection, allows you to talk to yourself and to listen to your ego. It is a time that allows us to discover, to rest, to recharge, to show our creativity and to escape the fast-paced society to which we have become accustomed. It is a time to understand that everything is fine and beautiful and that we have to listen to the silence, a silence that submerges us and which almost seems unnatural and stunning in its intensity.*”

The uniqueness of the lockdown experience has led participants to believe that their future attitudes and behaviors will change, in addition to accepting the idea that there will be talk of a before and after COVID-19, which they considered to be an epochal event (*opportunities for change, a unique experience, being alone with yourself*) “*It is clear that an experience of this type will be remembered for life. I am 20 years old today, and what I often think about is how I will tell my children and grandchildren about this experience in the future, just like my grandparents told me about the war, its dangers and the fear that prevailed at that time.*”

The fourth and final code group, entitled “*self-evolution*,” focused on the positive aspects of temporal immobility, viewing everyday life from new perspectives and with new meanings. The suspension of everyday life activities allowed participants to find time to compare themselves with others, facilitating a process of self-reflection among some interviewees (*rediscovering oneself, achieving a new life balance*): “*I seek to... make this period a moment to become stronger and a chance to rediscover myself, as it is occurring in a completely new and undoubtedly singular context and situation.*”

This dramatic experience has caused many participants to develop a greater awareness of themselves and their own lives and to experience personal growth (*greater awareness, personal growth*) “*In the future we will overcome this crisis and return to normal, but in a more conscious way, knowing that we have acquired that freedom through our sacrifices.*”

### Continuity of Being

Finally, the researchers created a core category labeled, “continuity of being” (see **Figure 1**).

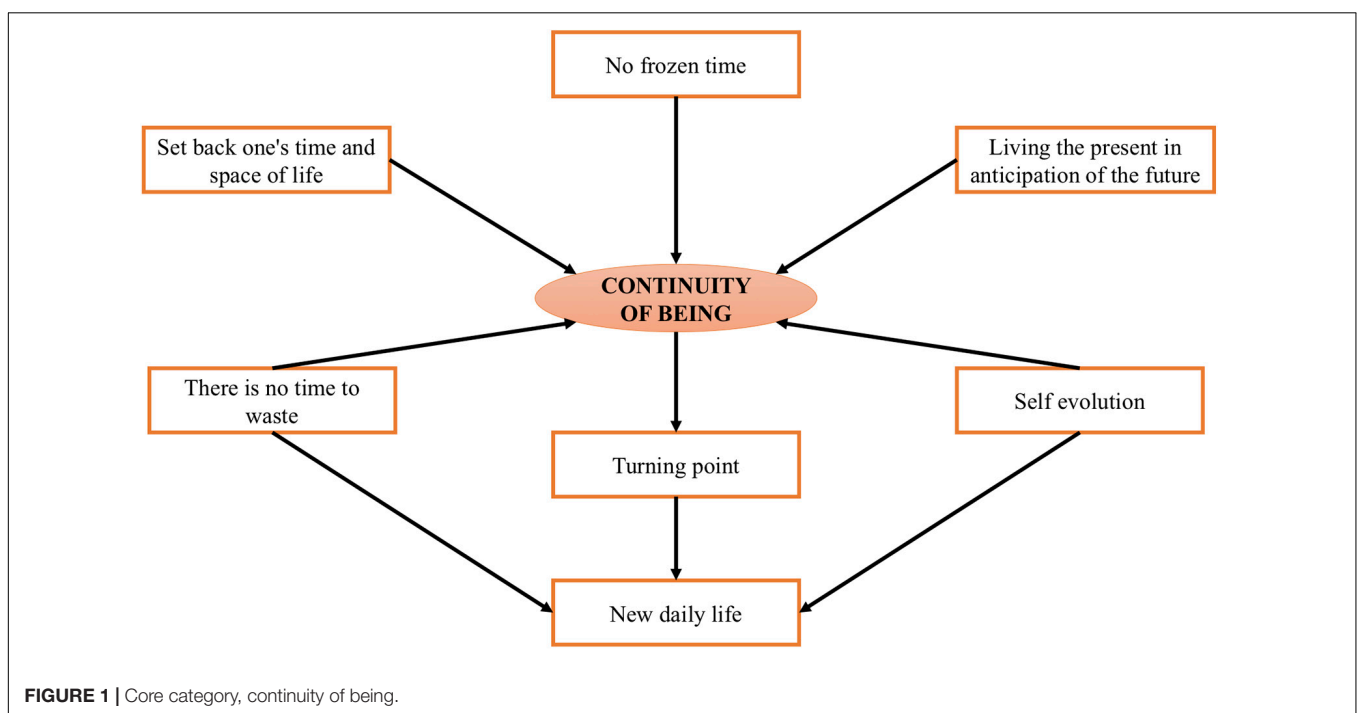

In light of the proactive and empowering approaches to the lockdown adopted by many participants, we named the core category, “*continuity of being*.” This core category was characterized by maintaining or creating connections with past experiences, the present and striving toward one’s goals. In this regard, we considered the importance of beneficial past and future time perceptions during the lockdown as resilience strategies to cope with pandemic-related distress. The interviewees consistently highlighted the importance of maintaining time continuity and defining time and space during the lockdown as methods of turning this period of downtime into an opportunity for personal growth.

## DISCUSSION

During the process of reading and interpreting the codes from this study and choosing participant quotations, the research team focused on the importance of the time-space divide that affected the interviewees’ emotions and thoughts. In fact, many interviewees reported changes in their daily time management in a confined space, in comparison with their usual activities. In the context of the COVID-19 pandemic, it would be interesting to understand any associations among people’s attitudes toward time and their levels of well-being, distress and anxiety. The experience of being spatially confined also confined many participants’ time perceptions to the present or in the past. However, for some participants, the lockdown has represented an unexpected opportunity to better understand themselves and to envision their futures.

Being confined in the present implied different meanings among the research participants. For multiple participants, being confined in the present has represented an opportunity to reorganize their time management and spaces, as well as to try new activities. However, for others, a present shaped by the lockdown represented a genuine obstacle that impeded their ability to envision new organizations of time and space, constructing their time perceptions of the present based upon their expectations to resume their pre-pandemic lives.

Conversely, other participants reported that home confinement entailed an excess of downtime that generated a state of stunned confusion, as well as perceptions of time characterized by feelings of suspension and immobility. Among these students, their lockdown experiences were framed by anguish, fear, uncertainty and sadness in relation to the recent events linked to the COVID-19 pandemic, in addition to an

unrelenting focus on the current situation and an inability to shift their focus to past events or hope for the future “*There are many conflicting thoughts and feelings that crowd our minds these days, during which we find ourselves experiencing an uneasy and worrying situation. Sadness was definitely the emotion that primarily characterized the first days of the lockdown.*”

Furthermore, among participants, a common sense of loss emerged. Home confinement became a distressing experience in a context of heightened anxiety surrounding death. This suspended, uncertain time confronted the study participants with their most primitive fears, such as their fear of death as pandemic dreaming also highlighted (Iorio et al., 2020), while limiting ties and changes to their family structures.

Conversely, several interviewees reported feelings of confinement in the past, shaped by positive nostalgic memories of their past everyday lives prior to the COVID-19 lockdown (Zimbardo and Boyd, 2015). Additionally, among some young adults, the changes in their daily routines under lockdown served as an opportunity to open or deepen a dialogue with themselves, connecting with their pasts and envisioning a new future. A break from the unrelenting perceptions of time imposed by society fostered acceptance of the situation, in addition to the development of proactive attitudes. Envisioning the future implied opportunities for greater self-awareness and for participants to deeply reflect upon their lives and lifestyles.

Moreover, the lockdown experience resulted in freedom from pre-pandemic routines, as well as the need to cope with this new reality. Being trapped in the present while looking toward the future induced many young interviewees to rediscover the potentiality of space and to create new plans for their own futures. Therefore, confinement at home and spatial distance could be viewed as a sort of transitional experience or a potential turning point.

It is important to mention that, although many young respondents experienced negative feelings regarding the lockdown, some of them were able to view the resulting spatial and time restrictions in a positive light, transforming their time under lockdown into something productive and finding ‘*serenity in disorder.*’ As a result, interviewees’ experiences in a confined space led them to develop different time perceptions of the past, present and future, characterized by time subjectivations that seem to exclude the possibility for dialog among the three temporal perspectives.

Moreover, the core category, “*continuity of being,*” described a proactive experience, especially for young people, to overcome what Rosa (2003) defines as a type of de-temporalization that pushes people to think moment by moment. In addition, the storytelling design of the study facilitated the development of awareness surrounding subjective oppression and vulnerability, as well as common experiences of suffering, giving voice to people’s shared feelings, in line with community psychology perspectives.

Individual narratives encompass the expression of individual and collective experience-making processes. Narration involves biographical, reconstruction, reinsertion, recreation, realignment and relocation perspectives. Additionally, for some authors, narration also serves as a semiotic device mediating the

connection between continuity and discontinuity, aimed not only at carrying out the previously mentioned functions, but also at creating new dynamic relations among them (Freda et al., 2015). Therefore, for participants, documenting their COVID-19 lockdown stories was an opportunity to reflect upon their lives that also acted as a resilience tool. In fact, opportunities mediated by creative expression, group discussions and shared actions aimed at individual and social awareness are a significant goal in community building, training and education (Carnevale et al., forthcoming; Arcidiacono et al., 2016; Di Napoli et al., 2019a). As a result, creating spaces in which people share their personal stories and ask questions about their common experiences is a preliminary goal of community psychology-based intervention strategies, while subsequently detecting meaning and symbolization in their interactions is the next step in promoting social awareness and community building (Arcidiacono, 2016; Procentese and Gatti, 2019; Procentese et al., 2019). Feeling part of a community where you share projects and consider the response of institutional members and referents reliable favors collective self-efficacy and the management of stress generated by this unforeseen emergency (Procentese et al., 2020).

## Limitations

Despite the contributions to the deepening of the existing literature, this study’s limitations included first of all its convenience sampling (non-probabilistic), so the generalization of results should be taken with caution. The unbalanced number of male and female respondents, although the sex composition of participants was representative of the general population of Italian psychology students (Arcidiacono and Tuozzi, 2017; Centro Studio Investimenti Sociali, 2019). Additionally, it is important to highlight the possibility that psychology students likely possess deeper reflective attitudes in comparison with students from other majors. Furthermore, the ethnic and geographical makeup of the sample was limited and was comprised solely of White university students living in a specific region of Italy. Therefore, any interpretation of the study results should be considered in conjunction with differing national and international contexts. Moreover, the researchers recommend that future studies also consider connections among young adults’ feelings regarding their physical and psychological well-being and their time perceptions. This study collected participants’ stories during the week with the highest number of reported COVID-19 cases in Italy; thus, it would be interesting to compare young peoples’ feelings and perceptions of their time under lockdown with their experiences during its de-escalation. The researchers further recommend that future studies explore any associations among time perceptions and well-being or negative emotions, in addition to comparing time perceptions across different phases of life.

## CONCLUSION

The space-time divide resulting from participants’ lockdown experiences was unexpected among the research team. Our

students' voices emphasized this aspect of the lockdown; thus, we sought to more profoundly explore this part of their experiences. Under lockdown, participants had to establish new time perceptions and new ways of "social sharing" to overcome physical confinement and distancing and to avoid further psychological distress in their daily lives.

According to Pichon-Rivière, in order to survive, hope must be planned through collective projects that help people face difficulties and changes. Planning hope emerges from people's abilities to create alternatives to collectively share spaces, such as singing from balconies in the context of the lockdown, as described by Di Napoli et al. (2021). The implications and impacts of the research findings could help in preparing plans and providing services in the context of a generalized pandemic. In this regard, the study findings help us recognize the impact of limits on one's actions and/or mobility on individuals' psyches. The young adult study participants described their lockdown experiences through varying perceptions of time, with some of them reliving their pasts, while others focused on rethinking and shaping their futures. The COVID-19 pandemic altered participants' lives in a spatial sense, relegating them to spend the days under lockdown reliving past connections, renewing contact with old friends and lovers and redefining their future expectations.

Moroccan anthropologist Zakaria Rhani (2019) documented experiences of severe confinement in Morocco during the Years of Lead (1956–1999). His interview with a political prisoner who spent most of his life confined in Tazmamart, a cold and secluded prison in the Atlas Mountains, best characterizes some of the effects of extreme confinement. In order to survive confinement in such a desolate space, the prisoner, Kawni, described how his body lived confined in prison, suffering from cold and hunger, while allowing his soul the opportunity to continue life far away from these deplorable conditions. Therefore, this body-soul divide allows individuals' spirits to survive in the face of repression and limits to individual freedoms. Reflecting upon this extreme situation aids in understanding how individual experiences of forced confinement may result in different time and space perceptions. In this regard, it is important to reflect upon how the effects of confinement on people's everyday lives results in the development of a wide array of individual resilience strategies.

The lockdown period has deprived people of their health, families and careers, but also of small everyday things, like grabbing a coffee in the morning or with friends, a kiss or a hug, affection, feelings, nature and the power of sharing. Furthermore, home confinement under lockdown implied an absence of close physical contact and the presence of other people in our lives. Therefore, maintaining continuity with past experiences and

future goals, without becoming trapped in the present, is a crucial need and a psychological resilience strategy to maintain life continuity. Tools and spaces for sharing during emergencies, became a goal. It will help to lower distress and favor a recovery path of continuity with the past and with new future perspectives. The continuity of time and space to meet and interact is a basic need that characterizes young people's life contributing to their well-being (Di Napoli et al., 2019b). Therefore, the core category of this research "continuity of being" emphasizes the role of time and moreover of shared time allowing the individual and relational experience of connectedness.

The soundness of these findings suggests the importance to take into account the perception of time, especially among young people that particularly suffer for their space limitation and lack of social interactions. Moreover, it would be interesting to devote some studies to the effect of lockdown space limitation on children with dyslexia already affected by time processing difficulties (Casini et al., 2017). In such cases tailor specific supportive interventions for their families may help in managing time/space limits of forced home confinement.

In the words of Ernest Pichon-Rivière (1985), from our youth we learned that in times of uncertainty and a "lack of hope," it is essential to undertake collective projects and to plan shared hope. Thinking on youth experiences in pandemic the public bodies have to be able to sustain with actions and projects their need of connectedness with their own experiences and the world around them.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

Studies involving human participants were reviewed and approved by the University of Naples Federico II Department of Humanities' Ethics Board for Research in Psychology (March 15, 2020). Participants provided written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

Mental Symptoms and Stress of  
Hospitalized Schizophrenia Patients  
With 2019 Novel Coronavirus Disease:  
An Observation Study.  
Front. Psychiatry 12:557611.  
doi: 10.3389/fpsy.2021.557611

**Background:** The 2019 novel coronavirus disease (COVID-19) is an extremely rapidly spreading respiratory infection caused by SARS-CoV-2. Many schizophrenic patients were infected with COVID-19 in Wuhan City, Hubei Province. This study took hospitalized schizophrenia patients with COVID-19 as the research subjects and observed the changes in psychopathology and stress of patients with COVID-19 and the accompanying social isolation.

**Methods:** To sort and isolate potential COVID-19-infected patients, an isolated ward was set up from January 30, 2020, to March 30, 2020. Schizophrenia patients with COVID-19 were referred to this ward, and long-term hospitalized cases were included in this study. The Positive and Negative Syndrome Scale and Perceived Stress Scale were used to evaluate the severity of mental symptoms and psychological stress in the early stage of the outbreak of COVID-19, after the diagnosis of COVID-19 and after recovery. At the time of diagnosis, we also extracted the patient's routine blood, biochemical and other indicators and asked the patient's perception of COVID-19.

**Results:** 21 hospitalized schizophrenia patients with COVID-19 were recruited in this study. The changes in PANSS scores were not significant ( $p = 0.225$  baseline vs. diagnosed,  $p = 0.399$  cured vs. diagnosed). The CPSS scores increased significantly after diagnosis and transfer to the isolation ward ( $p < 0.001$  baseline vs. diagnosed,  $p < 0.001$  cured vs. diagnosed). The course of schizophrenia was a protective factor of stress levels to cases ( $t = -3.25$ ,  $p = 0.006$ ), and patients' perception of COVID-19 was a risk factor ( $t = 2.48$ ,  $p = 0.038$ ). The final multiple linear regression model was statistically significant ( $F = 8.16$ ,  $p < 0.001$ ).

**Conclusion:** Hospitalized schizophrenia patients with COVID-19 had increased stress levels and negative symptoms but alleviated positive symptoms after medical isolated treatment. This reminds us that in the face of major epidemics, we must specifically alleviate the psychological burden at the peak of the epidemic and improve the prognosis of patients after the epidemic.

**Keywords:** COVID-19, schizophrenia, psychopathology, stress, medical isolation

## INTRODUCTION

The 2019 novel coronavirus disease (COVID-19) is an acute respiratory infectious disease caused by the new coronavirus (SARS-CoV-2) (1). In Wuhan, Hubei province, the actual number of SARS-CoV-2 infection cases might be much higher than that has been reported (2). The rapid spread of the COVID-19 and its serious consequences pose severe challenges to public health in China and around the world (3, 4).

Since the outbreak of COVID-19, researchers have made numerous reports on the epidemiological characteristics, clinical characteristics, and prognosis of infection cases (5–8). As a stressful event with unknown treatment efficacy, prognosis, and mortality in the early stage of the epidemic, the population exposed to COVID-19 faced the severe challenge of psychological tolerance. According to a recent report by Wang et al. (9), in the early stage of the COVID-19 outbreak, more than half of the respondents in the general population were rated as moderate-to-severe in their psychological impact, and approximately one-third exhibited moderate-to-severe anxiety. Meanwhile, Hao et al. also confirmed that the strict lockdown measures accompanied by COVID-19 have a serious negative impact on psychiatric patients (10). A recent Italian study also reported that the COVID-19 pandemic has brought negative emotions to patients with bipolar disorder (11). For mental patients, stressful events are important factors that aggravate mental symptoms (12, 13).

Owing to the highly contagious nature of viruses, a considerable number of severe mental patients in Wuhan City, Hubei Province, have not been spared, including long-term hospitalized schizophrenic patients. However, due to the special management of mental diseases and requirements for epidemic prevention and control, few researchers have studied the effects of COVID-19 on the mental symptoms of severe psychotic patients. Hence, we examined schizophrenia patients with COVID-19 in a psychiatric specialty hospital located in Wuhan, Hubei Province, and conducted a study on the effect of COVID-19 and the accompanying social isolation on psychopathology and stress.

## METHODS

### Subjects

We collected long-term hospitalized psychiatric patients who were required to meet the diagnostic criteria of schizophrenia in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5). They were between 20 and 65 years old, had stayed in the hospital for more than 2 years, and had hospital-acquired infections and were diagnosed with COVID-19. Polymerase chain reaction (PCR) testing for SARS-CoV-2 was positive, and chest CT scans showed patchy or frosted ground glass-like images, regardless of sex, unrestricted type, and measurement of antipsychotic drugs, and whether it was accompanied by common physical diseases such as hypertension, diabetes, and hyperlipidemia.

Patients with bipolar disorder, substance dependence, personality disorder, intellectual developmental disorder,

severe cognitive impairment, and mental disorders caused by physical diseases were excluded. In addition, critically ill patients with blood oxygen saturation below 93%, dyspnea, and patients with unstable vital signs were excluded. These patients were all transferred to designated hospitals for the treatment of severe diseases. Patients who were unable to cooperate with isolation treatment, such as severe violence and suicide, were also excluded, and these patients were transferred to special wards with a dedicated work team for intervention.

This study was reviewed and approved by the ethics committee of the medical institution where the patients were housed. All enrolled patients received written consent from the patient's family.

### Instruments

The electronic medical records were used to extract clinical characteristics, chest imaging characteristics, blood convention, biochemical indicators, and C-reactive protein (CRP) of the patients. The Positive and Negative Symptom Scale (PANSS) was used to assess the psychopathological changes of the included patients, and the Chinese Perceived Stress Scale (CPSS) was used to assess patients' perception of stress. According to PANSS's classification of mental symptoms, PANSS has three subscales: PANSS positive symptom subscale (PSS, items P1-7), PANSS negative symptom subscale (NSS, items N1-7), and PANSS General Psychopathology scale (GPS, items G1-16).

We added seven additional questions to assess the perception of COVID-19 in the included cases (called the COVID-19 perception questionnaire, CPQ), which were as follows:

1. Have you heard of the 2019 novel coronavirus disease?  
Options setting: yes and no
2. Do you know that the patients around you are also infected with this disease?  
Options setting: yes and no
3. Do you know why you transferred to this ward?  
Options setting: yes and no
4. Are you worried about the treatment effect after infection?  
Options setting: very worried, general, not worried
5. Are you worried about the dress of medical workers?  
Options setting: very worried, general, not worried
6. Are you worried about your family being infected?  
Options setting: very worried, general, not worried
7. Do you know the epidemic trend of the 2019 novel coronavirus disease?  
Options setting: yes and no

Scoring principle: We mark "yes" and "generally" equal to 1 point, "no" or "not worried" equal to 0 points, and "very worried" equal to two points. The higher the total score, the more comprehensive the patient's perception of COVID-19, and vice versa.

### Procedures

This study was designed as a clinical observation study. As early as January 2020, when the epidemic had not been reported on a

large scale, we completed the initial assessment of PANSS and CPSS for the long-term hospitalized schizophrenic patients. At that time (baseline), the patients were uninfected. As the epidemic continued to spread, isolation wards were set up in a certain psychiatric institution in Wuhan, Hubei Province, China on January 30, 2020, for the isolation and treatment of psychotic patients who were diagnosed with or suspected to have COVID-19. The isolation ward is set up ranging from 1 to 3 patients per room. After a week's work of ward reconstruction, the admission of patients began. From then on, the cured cases would be transferred out of the isolation ward, and at the same time, newly infected patients would be transferred into the isolation ward. We selected the confirmed cases of COVID-19, from transferred to the isolation ward to cured and transferred out for further follow-up observation. All medical services followed the Diagnosis and treatment of corona virus disease-19 issued by the National Health Commission of China. According to the guidelines, the drugs taken are antiviral, anti-inflammatory, and Chinese patent medicine. The second PANSS and CPSS were estimated within 3 days of diagnosis after the patient was transferred to the isolation ward. At this time, the routine blood, C-reactive protein, and biochemical indexes of the patient were extracted from the electronic medical record and CPQ were estimated. After the cases were cured, before they were transferred out of the isolation ward, the third PANSS and CPSS evaluation were performed. The raters in this study were all psychiatrists with professional training and experience in managing psychopathological tests.

We used a table to show the detailed characteristics of the general clinical data and longitudinally compared the differences in the total score of PANSS, the scores of the three subscales of PANSS and CPSS at different time points. We also analyzed the factors affecting the stress levels of the included patients.

## Data Analysis

According to the characteristics of the final data, if the continuous measurement data obtained were normally distributed, they were expressed as the mean and standard deviation (SD). The categorical variables were expressed as counts and percentages. Paired *t*-test was performed on continuous variables with normal distribution, and multiple linear regression was used to analyze stress factors. The significance level of all statistical tests was set as  $p < 0.05$  (two tails). Data analysis was performed using IBM SPSS version 26.0 statistical software (SPSS Inc., Chicago, IL, USA), and figures were plotted using GraphPad Prism version 8.4 software (GraphPad Software Inc., La Jolla, CA, USA).

## RESULTS

### General Clinical Treatment Characteristics

A total of 57 patients entered the ward for screening because of suspected or confirmed COVID-19, and 21 schizophrenic patients with COVID-19 were cured and discharged. Following the requirements of epidemic control,

**TABLE 1 |** Clinical characteristics of schizophrenia patients with COVID-19.

Index	COVID-19 patients ( <i>n</i> = 21)
<b>Age - years</b>	
Mean (SD)	43.1 (2.6)
Range	24–61
<b>Sex</b>	
Female	12 (57.1%)
Male	9 (42.9%)
Length of stay – years (SD)	4.2 (3.4)
Course of schizophrenia-years (SD)	6.8 (5.6)
Duration of healing – days (SD)	31 (10.2)
Take an antipsychotic drug- <i>n</i> (%)	5 (23.8%)
Take two antipsychotic drugs- <i>n</i> (%)	16 (76.2%)
Protective constraint – <i>n</i>	0
<b>Infection symptoms</b>	
Asymptomatic throughout	4 (23.8%)
Respiratory symptoms	8 (38.1%)
Digestive symptoms (diarrhea)	1 (4.8%)
Only one symptom of fever	8 (38.1%)
<b>First chest CT findings - <i>n</i> (%)</b>	
Unilateral	10 (47.6%)
Bilateral	11 (52.4%)
<b>Worsening infection following chest CT reexamination</b>	
Yes	16 (76.2%)
No	5 (23.8%)
<b>Routine blood test - <i>n</i> (%)</b>	
Leukopenia	4 (19.0%)
Lymphocytopenia	6 (28.6%)
Both	11 (52.4%)
Elevated CRP	4 (19.0%)
Normal CRP	17 (81.0%)
Additional intravenous antibiotic therapy	4 (19.0%)
<b>Adjustment of antipsychotic drugs during isolation</b>	
Increase in the doses	1 (0.5%)
Increased benzodiazepines	2 (1%)
Decrease in the doses	2 (1%)

the transfer of the last cured patient to the designated site for continued observation was completed at 6 p.m. on 30 March 2020.

The general clinical characteristics of the 21 patients who completed this study are shown in **Table 1**.

### The Difference of the PANSS and Its Subscales and CPSS

There were no significant differences in PANSS scores of the included patients at the three time points of the early stage of the epidemic (baseline), within 3 days after diagnosis with COVID-19 and transported to the isolation ward (diagnosed) and cured (cured) ( $p = 0.225$  baseline vs. diagnosed,  $p = 0.399$  cured vs. diagnosed) (**Figure 1A**). In addition, the positive symptom subscale scores of “diagnosed” were significantly lower than those of “baseline” ( $p < 0.001$ ) (**Figure 1B**). The

**TABLE 2 |** Multiple linear regression analysis of influencing factors of patients’ psychological stress.

Variable	Coefficient	Standard deviation	Standardized coefficients	95% CI	t	p
Constant	41.18	7.47		(25.16, 57.20)	5.51	0.000
Sex (female vs. male)	-4.77	2.73	-0.40	(-10.62, 1.08)	-1.75	0.102
Age	0.06	0.13	0.11	(-0.23, 0.35)	0.42	0.684
Course of schizophrenia	-0.49	0.15	-0.81	(-0.82, 0.17)	-3.25	0.006*
Duration of hospitalization	-0.14	0.48	-0.06	(-1.17, 0.89)	-0.29	0.774
Years of education	-0.40	0.33	-0.21	(-1.11, 0.32)	-1.19	0.254
Symptoms associated with infection (without vs. with)	5.77	3.05	0.39	(-0.77, 12.31)	1.89	0.079
CPQ	2.08	0.84	0.66	(2.65, 3.91)	2.48	0.038*

\*p < 0.05 (CPQ, COVID-19 perception questionnaire, Mean ± standard deviation: 6.19 ± 1.91; 95% CI, 95% Confidence Interval).

negative symptom subscale scores were significantly higher when “diagnosed” compared to “baseline” ( $p < 0.001$ ) and “cured” compared to “diagnosed” ( $p < 0.001$ ). The CPSS scores of “diagnosed” patients were significantly higher than those of “baseline” ( $p < 0.001$ ) and “cured” ( $p < 0.001$ ) (Figure 1C).

### Multiple Linear Regression Analysis of Influencing Factors of Patients’ Psychological Stress

Multiple linear regression analysis was used to analyze the psychological pressure of patients (CPSS) when diagnosed as a dependent variable, and gender, age, course of schizophrenia, duration of hospitalization, years of education, symptoms associated with infection and COVID-19 perception questionnaire (CPQ) were independent variables, as shown in Table 2. The course of schizophrenia was a protective factor of stress levels to cases ( $p = 0.006$ ), and patients’ perception of COVID-19 was a risk factor ( $p = 0.038$ ). The final multiple linear regression model was statistically significant ( $F = 8.16, p < 0.001$ ).

### DISCUSSION

To the best of our knowledge, this is the first clinical study on schizophrenia patients with COVID-19, investigating the changes in psychological pressure and psychiatric symptoms in cases with COVID-19 infection and isolation therapy. We found that patients with COVID-19 did experience increased stress levels and negative symptoms but alleviated positive symptoms. The course of schizophrenia was a protective factor of stress levels in cases; in contrast, patients’ perception of COVID-19 was a risk factor.

As a global pandemic impacting public safety, the general population is susceptible to COVID-19. The rapid spread of the virus and the uncertainty of the virus significantly increased the psychological burden of the general population (9). People with stable clinical symptoms after COVID-19 infection also showed obvious symptoms of posttraumatic stress (14). Another study recently studied people who developed psychiatric symptoms and found that psychotic episodes were significantly associated with coronavirus exposure (15). The latest research suggests that more than one-third of psychiatric patients might fulfill the diagnostic criteria post-traumatic stress disorder (PTSD) during

the peak of COVID-19 epidemic with strict lockdown measures (10). Another study from the United Kingdom showed that those who have or had COVID-19-related symptoms are more likely to develop general psychiatric disorders (16). In addition, the general population without a history of psychiatry also showed psychotic symptoms with structured delusions mixed with confusion as a common feature after being infected with COVID-19 (17). However, none of these studies could specifically target schizophrenia patients with COVID-19. SARS-CoV-2, a novel coronavirus with similar neurotrophic effects (18), was only reported for the first time after the outbreak. To date, we have not had enough time to track the future incidence of mental disease of nonpsychotic patients who were exposed to COVID-19 and the long-term impact of psychiatric symptoms on schizophrenic patients exposed to COVID-19. As far as this study, there were no significant changes in psychiatric symptoms in schizophrenia patients with COVID-19 during short-term follow-up observations. However, this is not the end, as COVID-19 may have a long-term impact on the mentally ill, and we will perform in-depth follow-up observations.

Regardless of the effect of nervous system infection on mental illness, stressful events have always been considered one of the important factors for the occurrence and deterioration of mental illness (12, 13). An interaction between external stressors and intrinsic vulnerability was one of the longest standing pathoetiological explanations for schizophrenia, also known as Diathesis-Stress Hypothesis (19). The hypothesis suggest that psychosocial stress may promote pathological microglia activation, which may lead to excessive synapse pruning and loss of cortical gray matter. Based on this, if the stress-sensitive area is damaged, this may lead directly to cognitive and negative symptoms; and loss of cortical control may also lead to disinhibition of subcortical dopamine—thereby leading to positive psychotic symptoms.

In this study, we confirmed that COVID-19 and transfer to isolation wards significantly increased the perception of psychological pressure. However, the increase in psychological pressure may not only be limited to COVID-19 itself, which also includes the strict isolation measures that have led to more narrow living spaces and the impact of environmental changes such as the different dress of the medical staff during wards rounds. Analysis of the factors that affect patients' psychological stress found that the course of schizophrenia constitutes an independent influencing factor for the reduction in psychological stress, that is, the longer the course of illness, the less psychological stress the patient would feel. A 6-year follow-up study found that the cognitive function of long-term hospitalized schizophrenia patients will gradually deteriorate over time (20). Based on this, we infer that the cognitive capacity of the enrolled patients decreased significantly due to the longer course of schizophrenia, thereby reducing the patients' awareness of the threat and danger of COVID-19, and thus reducing the psychological stress they presented. It should be emphasized that this psychological stress only manifested in the early stage of diagnosis of COVID-19, and the adaptation to the environment after a longer period of isolation may alleviate the patient's perception of stress.

Our study found that the severity of psychiatric symptoms of patients during isolation did not change significantly, which corresponds with the fact that the dosage of antipsychotic drugs is rarely adjusted during isolation therapy. This is different from the results of previous studies (21–23), which supposed stress and the severity of psychiatric symptoms were significantly related. However, without exception, all the previous studies took daily stress events as research elements. These stress events are more moderate in intensity, longer in time, and less threatening. This is the biggest difference between daily stress events and the stress events of this epidemic and may be the main reason for the difference in research results. This is the biggest difference between daily stress events and stressful events in the context of this epidemic. This may also be the main reason for the difference in research results. Additionally, positive symptoms were reduced, while negative symptoms were increased during the study. An animal study showed that socially isolated mice exhibited schizophrenia-like behaviors, such as a negative symptom phenotype (24). We speculated that the deterioration of negative symptoms in patients was the result of long severe social isolation and lack of adequate interpersonal communication caused by the COVID-19.

This article also has certain deficiencies. Due to the need for epidemic prevention and control, the patients in the group were transferred to the designated place for further isolation and observation after reaching the discharge standard. Therefore, our observation of the patients is short-lived, and the long-term impact of COVID-19 infection on schizophrenic patients needs further follow-up observation. To prevent cross-infection, it is difficult to carry out a larger sample study at present. A smaller sample size also harms the statistical efficiency of the study.

In conclusion, hospitalized schizophrenia patients with COVID-19 had increased stress levels and negative symptoms but alleviated positive symptoms after medical isolated treatment. This suggests that effective measures should be taken to relieve the psychological pressure of exposing patients with schizophrenia during the outbreak of a major epidemic, and targeted relief of negative symptoms of the patients is needed after the epidemic.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by The Ethics Committee of Wuhan Mental Health Center is affiliated to Wuhan Mental Health Center. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

LL and XL made substantial contributions to conception and design of the study. LZ and RL collected and collated the data. JM analyzed and interpreted data and drafted and revised the manuscript. Strange Days: Adult Physical Activity  
and Mental Health in the First Two  
Months of the COVID-19 Pandemic.  
*Front. Public Health* 9:567552.  
doi: 10.3389/fpubh.2021.567552

**Background:** In addition to its physical health benefits, physical activity is increasingly recognized as a means to support mental health. Regular moderate-to-vigorous physical activity (MVPA) is associated with improved mental well-being, reduced likelihood of developing mental illness, and improved symptom management. Despite these benefits, most people fail to achieve minimum recommended levels of MVPA. Population levels of physical activity have further declined since the onset of the COVID-19 pandemic and implementation of public health measures (e.g., shelter-in-place protocols). The potential impact of this decline on mental health outcomes warrants ongoing investigation.

**Purpose:** To investigate associations between changes in MVPA and mental health (depressive symptoms, anxiety symptoms, and life satisfaction) in adults impacted by the COVID-19 pandemic.

**Method:** Research followed a cross-sectional design. English-speaking adults were invited to complete an online questionnaire. MVPA was assessed retrospectively (before COVID-19) and currently (during COVID-19) with the International Physical Activity Questionnaire. Mental health was assessed with the Patient Health Questionnaire, 9-Item (PHQ-9), the Generalized Anxiety Disorder, 7-Item (GAD-7), and the Satisfaction with Life Scale (SWLS). Regression was used to assess relationships between MVPA and mental health. ANOVA with follow-up tests examined whether participants who differed in mental health status (e.g., no symptoms vs. severe symptoms) differed in their change in MVPA. *T*-tests were used to examine differences in mental health symptomatology between participants who were sufficiently (i.e., achieving MVPA guidelines of  $\geq 150$  min/week) vs. insufficiently active.

**Results:** Prior to COVID-19, 68.2% of participants were classified as being sufficiently active, vs. 60.6% during COVID-19. The majority of participants reported experiencing some level of depressive symptoms (62.0%) or anxiety symptoms (53.7%). After controlling for covariates, changes in MVPA accounted for significant variability in the PHQ-9 (7.7%), GAD-7 (2.5%), and SWLS (1.5%). Participants with clinically significant mental health symptomatology reported greater declines in MVPA than those who reported no symptoms. Conversely, participants who were sufficiently active during COVID-19 reported significantly lower depression and anxiety, and higher life satisfaction.

**Conclusion:** Participants who experienced the greatest declines in MVPA reported relatively greater psychological distress and lower life satisfaction. While preliminary, these findings suggest the importance of maintaining and promoting physical activity during a period of pandemic.

**Keywords:** depression, anxiety, life satisfaction, public health, moderate-to-vigorous physical activity

## INTRODUCTION

Regular participation in physical activity has long been recognized for its physical health benefits. For instance, moderate-to-vigorous physical activity (MVPA; e.g., brisk walking, lap swimming) is known to both prevent and manage chronic conditions like cardiovascular disease, type-2 diabetes, and cancer (1); whereas balance/flexibility activities (e.g., yoga, tai chi) are associated with improved mobility and functional abilities (2–4). Similarly, physical activity is increasingly embraced as a means through which to support mental health. Not only does physical activity promote well-being (5), but it is associated with reduced risk of developing mental illness (6) and improved symptom management in those with a pre-existing condition (7). The benefits of physical activity have been observed across diverse psychiatric and neurological conditions, such as anxiety (8), post-traumatic stress disorder (9), attention-deficit hyperactivity disorder (10), and dementia (11, 12). Recently, exercise has been recommended as a first-line treatment for mild-to-moderate depression and as an adjunctive treatment of moderate-to-severe depression (13).

Various national (14, 15) and international (16) physical activity guidelines recommend that adults engage in at least 150 min of MVPA per week to achieve health benefits. Muscle strengthening and balance/flexibility activities are also recommended. Surveillance studies consistently illustrate that populations fail to achieve this minimum level of activity. In the United States, ~23% of adults meet both aerobic and muscle-strengthening physical activity guidelines (17). Similarly, in a device-based study of Canadians, only 15% of participants achieved national physical activity guidelines, whereas only 5% achieved them on a regular basis (18). Such low levels of PA have notable implications for the health and wellness of nations.

### Physical Activity in the Time of COVID-19

The novel coronavirus disease, COVID-19 (“COVID”), was first identified in the Wuhan region of China in December 2019 (19, 20). It was subsequently declared a global pandemic on March 13, 2020. In an effort to control the spread of the virus, many nations have implemented widespread and significant public health measures such as closing non-essential businesses, closing international borders, banning large gatherings of people, mandatory self-isolation, and requiring individuals to maintain a minimum physical distance with others.

An inadvertent consequence of COVID public health protocols has been a decline in physical activity. A systematic review of 66 studies examining physical activity and sedentary behavior during COVID demonstrated consistent declines

in physical activity during the initial COVID-19 lockdown regardless of subpopulation or methodology used (21). Such observations are not unexpected given widespread closure of recreation facilities and public parks, a shift to working from home, and shelter-in-place protocols. In Canada, declines of ~13, 15, and 13% were observed in device recorded MVPA, light physical activity, and step counts, respectively (22). Though public health measures are necessary for reducing disease transmission, there is concern that the resulting reductions in physical activity may have implications for physical and mental health (23, 24). In response, individuals have been encouraged to remain active during the COVID pandemic (25–27), such as through outdoor exercise or home-/apartment-friendly activities (28, 29).

### Physical Activity, Mental Health, and COVID

The existent evidence for the mental health benefits of physical activity stems from studies that have been conducted under “regular conditions.” The unique characteristics of the COVID pandemic – including the rapid speed at which changes are occurring and the disruption in regular daily routines – are unprecedented in their scope and impact. Literature from early in the COVID pandemic indicates that symptoms of anxiety and depression (16–28%) and stress (8%) are common psychological reactions to COVID (30). The extent to which physical activity may buffer against the psychosocial impact of COVID remains less studied. In Canada, individuals who were inactive during the COVID pandemic reported lower mental well-being and higher anxiety compared to active individuals (31) and women reported significantly higher generalized anxiety than men (32). The purpose of the current study was to extend this work and examine associations between MVPA and other mental health outcomes in the early phases of the COVID pandemic. It was hypothesized that a negative relationship would be observed between changes in MVPA and psychological distress (anxiety and depressive symptomatology); and that a positive relationship would be observed between changes in MVPA and life satisfaction.

## MATERIALS AND METHODS

### Participants and Design

The current study followed a cross-sectional, observational design. All study protocols received approval from The University of British Columbia Research Ethics Board (#H20-00899). Individuals were eligible to participate if they were age 18 years or older and able to communicate in English. Given the classification of COVID as a pandemic at the time of study

launch, no restrictions were placed on individuals' country of residence. With an alpha level of 0.05, power of 80%, and anticipating a small effect size (33), a total of 395 participants were required for regression analyses and 302 participants for ANOVA (34).

## Measures

### Sociodemographic Variables

Basic sociodemographic information, such as educational attainment and employment status, were collected for descriptive purposes. Additionally, age, gender, and body mass index (BMI; from self-reported height and weight) were collected to serve as covariates in regression analyses (35–38).

### Physical Activity

Self-reported MVPA was assessed with a modified International Physical Activity Questionnaire, Short Form (IPAQ) (39). The IPAQ is a validated measure of physical activity that is commonly used in epidemiological studies. The questionnaire invites participants to report the number of days per week and the amount of time per day (in hours and minutes) spent in vigorous physical activity, moderate physical activity, and light physical activity. Weekly minutes of vigorous- and moderate- intensity physical activity were calculated by multiplying by daily minutes by number of days. Subsequently, weekly minutes of MVPA were calculated by adding minutes of moderate-intensity and vigorous-intensity activity, with maximum scores truncated to 1260 min as guided by IPAQ scoring protocols (<https://sites.google.com/site/theipaq/scoring-protocol>). In the current study, participants reported physical activity twice: before COVID ("pre-COVID") and over the past 7 days ("during-COVID"). For the pre-COVID measure, participants were asked to report their level of activity on a typical week *before* COVID-related restrictions were implemented. Participants were reminded that COVID was declared a pandemic on March 13, 2020; and that their reference period would likely be late February or early March.

### Depressive Symptomatology

Depressive symptomatology over the last 2 weeks was assessed with the Patient Health Questionnaire, 9-Item (PHQ-9) (40). The PHQ-9 has nine items, which correspond with the criteria for major depressive disorder as outlined in the Diagnostic and Statistical Manual of Mental Disorders (DSM) (41). Responses are made on a 0 to 3 scale (maximum score of 27), with greater values indicating greater symptom severity. Scores of 5, 10, 15, and 20 are indicative of mild, moderate, moderate-severe, and severe major depressive symptoms, respectively. Using a threshold of  $\geq 10$ , the scale has 0.88 sensitivity and 0.88 specificity for major depressive disorder (40).

### Anxiety Symptomatology

The occurrence of general anxiety symptoms over the last 2 weeks was assessed with the Generalized Anxiety Disorder, 7-Item (GAD-7) (42). The GAD-7 has 7 items which correspond with the symptom criteria for generalized anxiety disorder as outlined in the DSM (41). Like the PHQ-9, responses are made on a 0 to

3 scale (maximum score of 21), with greater values indicating greater symptom severity. Scores of 5, 10, and 15 are indicative of mild, moderate, and severe anxiety symptoms, respectively. Using a threshold of  $\geq 10$ , the scale has 0.89 sensitivity and 0.82 specificity for generalized anxiety disorder (42).

### Life Satisfaction

Participants' overall sense of well-being was assessed with the Satisfaction with Life Scale (SWLS) (43). The SWLS was developed as a measure of the cognitive component of subjective well-being: that is, an individual's judgement regarding whether their life is good or poor. Participants are presented with 5 items, such as "The conditions of my life are excellent." Items are rated on a five-point Likert scale, ranging from 1 (Strong Disagree) to 5 (Strongly Agree), with higher scores indicative of greater perceived quality of life. Though the scale is recommended for use as a continuous variable, it is also possible to score categorically (44) with classifications ranging from extremely satisfied (scores of 31–35) to extremely dissatisfied (scores of 5–9).

### Procedure

Participants were recruited online through social media advertisements (Twitter, Facebook, Instagram, LinkedIn) and alumni newsletters. Recruitment occurred between March 24 and May 8, 2020. Interested volunteers were directed via hyperlink to an online survey. After completing eligibility items and providing informed electronic consent, participants were presented with three clusters of questionnaire items: sociodemographic variables, the IPAQ, and the three mental health scales. At the end of the questionnaire, participants were debriefed, thanked for their participation, and were provided the opportunity to enter their name into a draw.

### Data Analysis

Data screening and management procedures were conducted in accordance with the recommendations of Tabachnick and Fidell (45). All analysis was conducted using SPSS Statistics, v.25 (IBM, US). Two groups of analyses were conducted. The first utilized hierarchical regression to examine associations between MVPA and mental health. Age, gender, and BMI were entered as covariates (35–38). Change in self-reported MVPA, calculated as the difference between during-COVID MVPA and pre-COVID MVPA, served as the predictor variable. Thus, negative values indicate a decrease in MVPA whereas positive values indicate an increase in MVPA. The outcome variables were PHQ-9, GAD-7, and SWLS continuous scores.

The second group of analyses examined between-group differences. With regards to mental health, participants were categorized according to standard interpretive thresholds for the PHQ-9 (40), GAD-7 (42), and SWLS (44). ANOVA was used to examine between-group differences in change in MVPA. With regards to MVPA, participants were classified as being sufficiently active if they self-reported  $\geq 150$  min MVPA per week, and insufficiently active if they reported  $< 150$  min MVPA (14–16). ANOVA was used to examine between-group differences in mental health outcomes (PHQ-9, GAD-7, SWLS) between these

groups. Analyses were conducted twice, to examine pre-COVID and during-COVID MVPA status. Bonferroni correction was applied to control for Type I error. In all analyses, equal variance was not assumed.

## RESULTS

### Participants

The online survey was accessed 1,005 times, of which 9 individuals were ineligible due to being age 17 or younger; 9 individuals were ineligible due to not being able to communicate in English; and five individuals declined consent to participate. A further 340 did not proceed beyond the eligibility screening questionnaire, primarily due to “bot” traffic. A total of 665 individuals accessed the intake survey, of which 248 provided incomplete data. There were no differences in survey completion based on age, gender, or BMI ( $t = 0.367$ ,  $p = 0.713$ ;  $t = 0.344$ ,  $p = 0.731$ ; and  $t = 1.814$ ,  $p = 0.07$ , respectively).

The final sample had an average age of 32.2 ( $SD = 13.6$ ) years. Most participants self-identified as being a woman (86.8%) and well-educated (62.7% with an undergraduate degree or greater), and were employed either full- or part-time (42.3%). The majority were classified in the normal range of BMI (62.7%). One-third (32.3%) of the sample identified they were of North American descent, such as Quebecois or American. Full sample details can be found in **Table 1**.

### Physical Activity

Participants self-reported a mean of 406 ( $SD = 380$ ) minutes of MVPA per week prior to COVID, compared to 361 ( $SD = 388$ ) minutes of MVPA per week after COVID. The mean reported change in MVPA was  $-45$  ( $SD = 389$ ) minutes. Approximately half of the sample (45.4%) reported a decrease in MVPA, while a quarter (22.7%) reported no change in MVPA, and the remainder (31.8%) reported an increase in MVPA.

Prior to COVID, 68.2% of participants self-reported being sufficiently active for health benefits (i.e.,  $>150$  min 193 MVPA per week). This decreased to 60.6% of participants during the initial period of the COVID pandemic.

### Mental Health

Participants reported a mean PHQ-9 score of 7.4 ( $SD = 6.0$ ), indicative of mild depressive symptomatology. While a large minority (38.0%) reported experiencing no significant depressive symptoms, 33.9% reported mild symptoms, 14.4% moderate, 8.4% moderate-severe, and 5.3% severe. Similarly, participants reported a mean GAD-7 score of 6.5 ( $SD = 5.6$ ). A large minority (46.3%) reported experiencing no significant anxiety symptoms, whereas 27.2% reported mild symptoms, 14.9% moderate, and 11.6% severe. With regards to well-being, participants reported a mean SWLS score of 24.1 ( $SD = 6.8$ ). The majority (76.4%) of participants reported scores at or above the scale midpoint.

### Regression Models

All regression models controlled for age, gender, and BMI. Three separate models were examined: the relationship between (1)

MVPA and PHQ-9, (2) MVPA and GAD-7, and (3) MVPA and SWLS.

Overall, the models provide evidence for associations between MVPA and mental health during COVID. For depression and anxiety, a self-reported decrease in MVPA was associated with higher scores on the PHQ-9 and GAD-7 (Pearson correlation =  $-0.284$ ,  $p < 0.001$ ; and  $-0.161$ ,  $p = 0.001$  respectively). Increases in MVPA were associated with higher levels of life satisfaction (Pearson correlation =  $0.126$ ,  $p = 0.007$ ). Please see **Table 2** for correlation tables for all variables included in models.

For mental health, significant variability was explained by change in MVPA from pre-COVID to during-COVID. After controlling for age, gender, and BMI, changes in MVPA accounted for 7.7 % variability in PHQ-9 scores ( $F = 26.182$ ,  $R = 0.470$ , *adjusted*  $R^2 = 0.212$ ,  $R^2$  change =  $0.077$ ,  $p < 0.001$ ), 2.5 % variability in GAD-7 scores ( $F = 11.478$ ,  $R = 0.333$ , *adjusted*  $R^2 = 0.101$ ,  $R^2$  change =  $0.025$ ,  $p = 0.001$ ), and 1.5 % variability in SWLS scores ( $F = 6.960$ ,  $R = 0.265$ , *adjusted*  $R^2 = 0.060$ ,  $R^2$  change =  $0.015$ ,  $p = 0.017$ ). For the full model statistics, please see **Table 3**.

## Mental Health Status and Change in MVPA

ANOVAs were conducted to examine whether degree of mental health symptomatology (e.g., none, mild, moderate, or severe) was associated with the extent to which MVPA changed from pre-COVID to during-COVID. In all analyses, significant differences were found. Bonferroni corrected *post-hoc* testing uncovered differences within the classifications of depressive symptoms, anxiety symptoms, and life satisfaction. Graphs displaying between-group differences can be found in **Figure 1**.

**TABLE 2** | Correlations between mental health, gender, age, BMI, and change in MVPA.

	PHQ-9	Gender	Age	BMI	MVPA (change)

\*Significant with Bonferroni correction.

## PHQ-9

For the PHQ-9, significant between-group differences were found ( $F = 62.206$ ,  $p < 0.001$ ). Follow-up analysis indicated significant differences between participants with no symptoms relative to those with mild ( $MD = -155.730$ ,  $SE = 45.256$ ,  $p = 0.006$ ), moderate ( $MD = 286.193$ ,  $SE = 41.403$ ,  $p < 0.001$ ), moderate-severe ( $MD = -285.345$ ,  $SE = 69.902$ ,  $p = 0.001$ ), and severe symptomatology ( $MD = 718.765$ ,  $SE = 61.576$ ,  $p < 0.001$ ).

Additionally, significant between-group differences were found between PHQ-9 severity of mild in comparison to moderate ( $MD = 441.923$ ,  $SE = 50.438$ ,  $p < 0.001$ ) and severe ( $MD = 874.495$ ,  $SE = 67.689$ ,  $p < 0.001$ ). There were also significant between-group differences found between PHQ-9 severity of moderate in comparison to moderate-severe ( $MD = -571.538$ ,  $SE = 73.094$ ,  $p < 0.001$ ) and severe ( $MD = 432.571$ ,  $SE = 65.176$ ,  $p < 0.001$ ). Finally, there was also a significant between-group difference found between PHQ-9 severity of moderate-severe in comparison to severe ( $MD = 1004.110$ ,  $SE = 86.140$ ,  $p < 0.001$ ).

## GAD-7

For the GAD-7, significant between-group differences were found ( $F = 4.026$ ,  $p = 0.008$ ). Follow-up analyses indicated significant differences between participants with no anxiety symptoms relative to those with mild ( $MD = 137.031$ ,  $SE = 49.703$ ,  $p < 0.037$ ) and moderate symptoms ( $MD = 186.781$ ,  $SE = 68.671$ ,  $p = 0.041$ ).

## SWLS

In terms of the SWLS, significant between-group differences were found ( $F = 13.840$ ,  $p < 0.001$ ). Follow-up analyses identified

<sup>b</sup>Predictors (Age, Gender, BMI, MVPA (change)).

significant difference between those who were extremely satisfied in comparison to satisfied ( $MD = 327.472$ ,  $SE = 84.411$ ,  $p = 0.004$ ), neutral ( $MD = 632.609$ ,  $SE = 103.992$ ,  $p < 0.001$ ), slightly dissatisfied ( $MD = 458.609$ ,  $SE = 95.646$ ,  $p < 0.001$ ), dissatisfied ( $MD = 446.894$ ,  $SE = 99.916$ ,  $p < 0.001$ ) and extremely dissatisfied ( $MD = 842.609$ ,  $SE = 123.199$ ,  $p < 0.001$ ).

Additionally, significant between-group differences were found between the SWLS rating of satisfied in comparison to neutral ( $MD = 305.137$ ,  $SE = 73.348$ ,  $p < 0.001$ ) and extremely dissatisfied ( $MD = 515.137$ ,  $SE = 98.709$ ,  $p < 0.001$ ). Significant between-group differences were found between the SWLS rating of slightly satisfied and neutral ( $MD = 408.500$ ,  $SE = 76.468$ ,  $p < 0.001$ ), slightly dissatisfied ( $MD = 234.500$ ,  $SE = 64.662$ ,  $p = 0.007$ ), dissatisfied ( $MD = 222.786$ ,  $SE = 70.825$ ,  $p = 0.037$ ) and extremely dissatisfied ( $MD = 618.500$ ,  $SE = 101.050$ ,  $p < 0.001$ ). Significant between-group differences were found between the SWLS rating of slightly dissatisfied and extremely dissatisfied ( $MD = 384.000$ ,  $SE = 106.887$ ,  $p = 0.008$ ). Finally, a significant between-group difference was found between SWLS rating of dissatisfied and extremely dissatisfied ( $MD = 395.714$ ,  $SE = 110.724$ ,  $p = 0.008$ ).

## MVPA Guidelines and Mental Health

*T*-tests were completed to determine if differences in total score of mental health measures (PHQ-9, GAD-7, SWLS) existed between individuals who were sufficiently active for health benefits vs. those who were insufficiently active. Analyses were conducted twice, on pre-COVID and during-COVID levels of activity. Graphs displaying between-group differences can be found in **Figure 2**.

### PHQ-9

Participants who were sufficiently vs. insufficiently active pre-COVID did not significantly differ in their during-COVID PHQ-9 scores ( $t = 1.234$ ,  $df = 288.272$ ,  $p = 0.218$ ,  $MD = 0.800$ ). However, significant differences were observed between individuals who were sufficiently vs. insufficiently active during COVID ( $t = 13.400$ ,  $df = 237.514$ ,  $p < 0.001$ ,  $MD = 8.074$ ), with sufficiently active individuals reporting lower PHQ-9 scores.

### GAD-7

Participants who were sufficiently vs. insufficiently active pre-COVID did not differ in their during-COVID GAD-7 scores ( $t = 3.427$ ,  $df = 165.512$ ,  $p = 0.001$ ,  $MD = 2.372$ ). Significant differences were observed between individuals who were sufficiently vs. insufficiently active during COVID ( $t = 10.907$ ,  $df = 238.454$ ,  $p < 0.001$ ,  $MD = 5.706$ ), with sufficiently active individuals reporting lower GAD-7 scores.

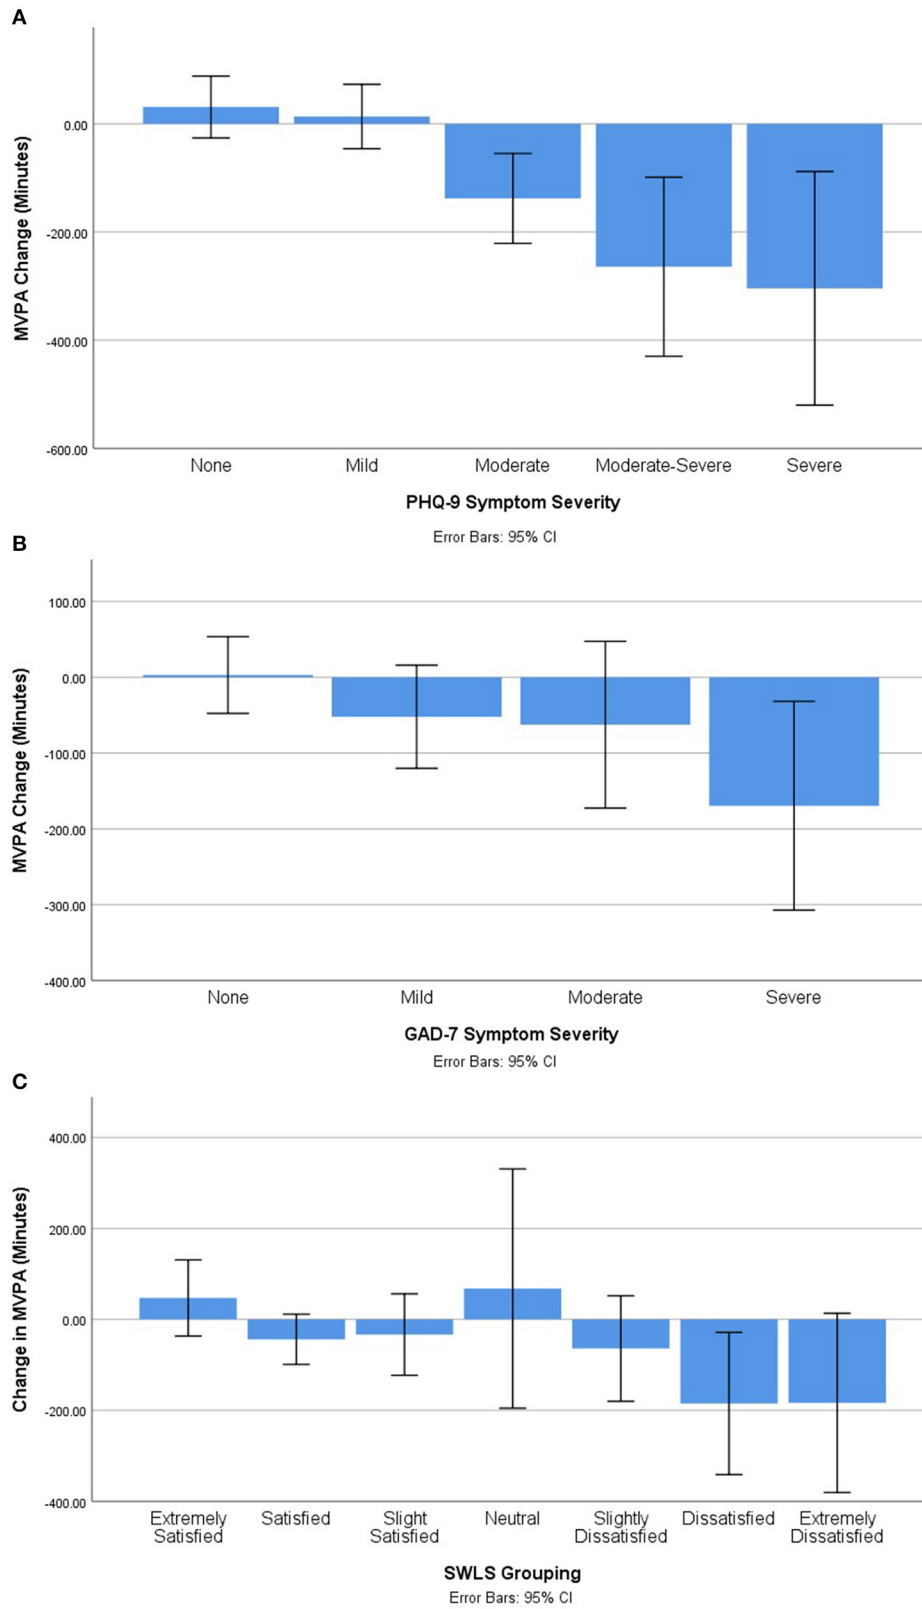

### SWLS

Participants who were sufficiently vs. insufficiently active pre-COVID did not differ in their during-COVID SWLS scores ( $t = -1.335$ ,  $df = 180.246$ ,  $p = 0.183$ ,  $MD = -1.026$ ). Significant differences were observed between individuals who were sufficiently vs. insufficiently active during COVID ( $t = -4.832$ ,  $df = 217.060$ ,  $p < 0.001$ ,  $MD = -3.332$ ), with sufficiently active participants reporting higher life satisfaction.

## DISCUSSION

The COVID-19 pandemic is an unprecedented public health event that presents a significant risk to human health and well-being (19, 20, 30). Efforts to slow the pandemic have required significant changes to “everyday life,” with one unintentional consequence being reductions in PA (22, 46). The purpose of the current manuscript was to investigate whether changes in MVPA during the early stages of the COVID pandemic were associated with mental health outcomes, specifically, depressive symptomatology, anxiety symptomatology, and life satisfaction.

Overall results suggest a positive association between mental health and change in MVPA among this sample of highly active participants. Individuals who reported larger decreases in MVPA pre- to during-COVID reported relatively poorer mental health as indicated by higher depression and anxiety symptoms, and lower life satisfaction. Between-group analyses found significant differences across mental health categorizations, where individuals with the poorest mental health reported relatively greater changes in MVPA. For instance, with regards to depressive symptomatology, participants who reported no or mild symptoms reported small increases in MVPA. Those

**FIGURE 1 |** Change in self-reported MVPA by mental health status. **(A)** Self-reported change in MVPA by depressive symptom severity. **(B)** Self-reported change in MVPA by anxiety symptom severity. **(C)** Self-reported change in MVPA by life satisfaction grouping.

with moderate, moderate-severe, and severe symptoms reported reduced MVPA in a gradient fashion that corresponded with symptom severity (Figure 1A). Similar trends were observed with regards to anxiety symptoms and life satisfaction.

Our findings are consistent with those reported in a rapid review that has not yet undergone peer review. Wolf et al. (47) reviewed evidence examining the association between physical activity and depression and anxiety during the COVID-19 pandemic. They identified a total of 21 observational studies (four longitudinal, one cross-sectional with retrospective analysis, and

16 cross-sectional). Their synthesis suggests that people who participated in physical activity on a regular basis with higher volume and frequency and kept their physical activity routines stable in the first few months of the pandemic, showed less symptoms of depression and anxiety. Specifically, those reporting a higher total time spent in moderate to vigorous PA had 12 to 32% lower chances of presenting with depressive symptoms and 15 to 34% lower chances of presenting with anxiety.

A significant body of research conducted prior to COVID indicates a positive relationship between mental health and physical activity (6, 7, 13). The results of the current study and the greater literature (47, 48) suggest that such associations hold true during a period of pandemic and significant socioeconomic disruption. Indeed, given both the extent and severity of disruptions, it is remarkable that a significant proportion of depressive symptomatology – 7.7% of variance accounted for – was associated with MVPA. Though relatively small at an individual level, MVPA may serve as a significant contributor to poor mental health when expanded to the population (49). Additionally, there have been significant and sustained reduction in light physical activity (LPA) during the COVID pandemic (22). LPA is also associated with poor mental health outcomes even when MVPA is controlled for (50), which was not accounted for in the current study. We strongly encourage future research to examine longitudinal associations between all types of physical activity and mental health across the duration of the COVID pandemic.

### The Role of Past Activity

Between-group analyses of sufficiently and insufficiently active individuals revealed an intriguing pattern of results. Whereas, previous research has found MVPA to be protective against psychological distress and mental illness (6, 51–53), participants' retrospectively-reported MVPA did not appear to mitigate mental health symptomatology reported during COVID. That is, participants who were sufficiently vs. insufficiently active *prior to* COVID did not differ in their mental health outcomes *during* COVID. In contrast, significant between-group differences were observed cross-sectionally between sufficiently vs. insufficiently active individuals, with sufficiently active individuals reporting better mental health. The non-significant effect of pre-COVID MVPA may be due to study methodology, in that participants were asked to retrospectively recall their level of physical activity before COVID (54, 55). Alternatively, the COVID pandemic and its resulting impact on mental health (30) may have presented participants with unique biopsychosocial stressors, which dampened the benefits of pre-COVID MVPA on mental health. Further investigation into this observation is warranted.

### Psychological Distress

Within the current study, the majority of participants reported some degree of psychological distress: 62.0% reporting depressive symptoms and 53.7% reporting anxiety. A notable minority reported depressive and/or anxiety symptoms at or above the PHQ-9 and GAD-7 threshold scores of 10: 28.1 and 26.5%, respectively. The occurrence of clinically significant psychological distress in this study is significantly higher than

what is typically found in surveys of the general population. For instance, Kocalevent et al. (56) found 5.6% of individuals reported a PHQ-9 score  $\geq 10$ ; whereas Lowe et al. (57) found that 5.1% of individuals reported a GAD-7 score  $\geq 10$ . Notably, the results from the current study – with a predominantly North American sample – are similar to those reported in China (58) and the United Kingdom (59) during the COVID pandemic. While further investigation is required, the consistency of findings (30) suggest that a five-fold increase in the prevalence of psychological distress may be typical during a period of pandemic.

## Strengths and Limitations

The current paper examines relationships between physical activity and mental health during a period of pandemic in an English-speaking population. Additional strengths include the use of validated clinical mental health measures that included measures of both psychological distress (PHQ-9 and GAD-7) and mental well-being (SWLS), and a validated self-report measure of physical activity. With regards to limitations, participants in this study were primarily younger adults, female, well-educated, from North America, and reported relatively high levels of physical activity (pre- and during-COVID). Consequently, results may not be generalizable to other populations. As this is a cross-sectional study, cause-effect relationships cannot be inferred from results. Additionally, there are a significant number of other factors that may account for poor mental health during the pandemic, such as less socialization, that were not controlled for in the current study. Further research utilizing more diverse samples and a longitudinal design will be useful for understanding associations between physical activity, health, and mental health during COVID.

## Implications for Health and Public Health Professionals

There is growing evidence that the COVID pandemic has negatively impacted both mental health (30, 58, 59) and physical activity (22, 46). The results of this research illustrate a positive association between mental health and MVPA in the early stages of the COVID pandemic, with sufficiently active individuals reporting lower depressive and anxiety symptoms, and higher quality of life. Conversely, individuals with poorer mental health reported greater decreases in MVPA. While the cross-sectional nature of these results prevents examination of causation, the consistency of associations between physical activity and mental health outcomes is noteworthy. Given what is known about the physical (1) and mental health (5–7) benefits of physical activity, it is prudent to promote physical activity involvement as a mechanism for promoting health and well-being during the COVID pandemic. Individuals who maintained their levels of physical activity demonstrated less psychological disturbance. A priority for future research is examining factors that support this resilience. For example, some active adults may have been creative in their home-based leisure activities, using online health and/or physical activity apps, or getting outdoors as much as possible (while following public health requirements). Implementing safe physical distancing measures that provide extra space for everyone to walk or cycle are likely essential.

This could include temporary reallocation of roadway space and keeping expansive green spaces open to public access.

## CONCLUSIONS

The purpose of the current study was to examine associations between physical activity, mental health, and mental illness during the COVID-19 pandemic. In line with emerging literature (47), individuals who maintained their levels of physical activity demonstrated less psychological disturbance. Results indicate a positive association between changes in MVPA and mental health, where those who experienced the greatest decline in MVPA reported relatively greater psychological distress and lower life satisfaction. Though further research is required to examine longitudinal trends, these early findings speak to the importance of maintaining and promoting physical activity during a period of pandemic. Public health initiatives that support safe physical activity while ensuring physical distancing are likely an important foundation for many adults to initiate or maintain physical activity in the case of future waves of the COVID pandemic, or in the case of future pandemics.

## DATA AVAILABILITY STATEMENT

The data that support the findings of this study are available from the authors upon reasonable request.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by The University of British Columbia Research Ethics Board (#H20-00899). The participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

MG and NR conceived and designed the study and methods. MG and MF cleaned, analyzed, and interpreted the data. MG drafted the manuscript. All authors provided feedback on study design and assisted with participant recruitment and manuscript revisions.

## FUNDING

There is no specific funding associated with this project. This research was made possible through Canadian Institutes of Health Research-Public Health Agency of Canada (CIHR-PHAC) support.

## ACKNOWLEDGMENTS

We would like to thank to Kate Castelo, Joshua Kamijan, and Shamit Rahman for their assistance with participant recruitment. We would also like to thank the UBC Office of Research Ethics for their support during a time of significant institutional change. Lastly, a big “Thank-You!” to our study participants, without whom this work would not be possible.

## BACKGROUND

The World Health Organization declared the novel coronavirus disease 2019 (COVID-19) outbreak a global health emergency in January 2020. Rates of infection and consequently, mortality have risen rapidly, resulting in a global pandemic. With no evidence-based treatments available, most countries have implemented quarantine measures to mitigate the spread of the virus. The world has largely focused on the physical suffering associated with COVID-19. However, the mental health sequelae of the pandemic are beginning to gain deserved attention. COVID-19 poses unique challenges to population mental health, given the colossal societal impact of nationwide lockdowns and health services struggling to cope. Mental health and well-being have been adversely affected by direct exposure to the virus (e.g., depression, anxiety, grief, suicidality) and from the social and economic upheaval that is occurring at an individual and population level (Reger et al., 2020; Wind et al., 2020). The economic down turn in the context of COVID-19 is a major concern, with psychological distress and suicide rates potentially rising on the back of sustained financial stress (Reger et al., 2020). The Severe Acute Respiratory Syndrome (SARS) epidemic of 2003 has taught us that psychological distress can affect both patients and clinicians treating them during an outbreak and continue in its aftermath (Lee et al., 2007). Amidst COVID-19, health services have had to adapt rapidly, implementing new ways of working to meet the rising demands of the population. However, across health settings, there is considerable variation with some institutions lacking the necessary resources, infrastructure, training, and support to allow clinicians to deliver mental health care in an era of physical distancing. Based on collective clinical experience, we provide a commentary on the rapid transition from in-person or traditional psychiatric care, to virtual mental health care (telepsychiatry) in response to COVID-19 and discuss the advantages, disadvantages and implications of digital psychiatry now and in the post-pandemic world.

## COVID-19 AND THE ACCELERATION OF DIGITAL PSYCHIATRY

Over the past two decades, digital psychiatry has continued to evolve as a cost-effective means to improve access to care for psychiatric patients. Digital psychiatry is an umbrella term that includes digital interventions delivered through applications (web and mobile based) as well as the delivery of telemental health care through virtual (videoconferencing) platforms. The majority of this commentary focuses on the latter, which we will refer to as telepsychiatry and virtual care.

The burden of mental disorders has not been matched by the appropriate resources and services necessary to treat them, resulting in a large mental health treatment gap. There is hope that digital psychiatry can bridge this gap, improving access to treatment, and hence outcomes for people with mental disorders. Evidence supports the use of digital psychiatry as a feasible platform, acceptable to users as well as effective in improving outcomes and quality of life across a variety of mental disorders (Bashshur et al., 2016). Literature is primarily based on mood and anxiety disorders, with an under-representation of psychosis (Bashshur et al., 2016). Furthermore, the intervention modality most commonly used in digital mental health studies is Cognitive Behavior Therapy (CBT) (Bashshur et al., 2016). Therefore, caution must be exercised when generalizing the enthusiasm of digital mental health care across the spectrum of severe mental illness. Nonetheless, there are published best practice guidelines on the use of virtual platforms for the delivery of care by the American Telemedicine Association and the American Psychiatric Association (Shore et al., 2018). In Ontario, Canada, the Ontario Telemedicine Network (OTN) a non-profit initiative was formed in the late 1990's as a means to connect individuals in remote areas to quality care (Brown, 2013). Telepsychiatry has continued to develop over the past two decades with evidence supporting its equivalence to face-face care with regards to therapeutic alliance and patient satisfaction (Hilty et al., 2013; Parish et al., 2017). Although there are few randomized controlled trials comparing traditional in-person mental health care with virtual care, evidence from systematic reviews and meta-analyses have indicated that treatment effects are largely equivalent when both approaches are compared (Bashshur et al., 2016; Langarizadeh et al., 2017; Batastini et al., 2020).

Although telepsychiatry has faced a number of obstacles to implementation, in the context of the COVID-19 pandemic, many perceived barriers to the adoption of virtual care have now been overcome across the world (Mann et al., 2020; Perez Sust et al., 2020). The meteoric rise of telepsychiatry has been felt world over. In the UK, the National Health Service facilitated the rapid ramp up of virtual psychiatric care despite pre-existing cautionary guidance from the Royal College of Psychiatrists (Dave et al., 2020). The Australian health service provider, Medicare, moved to support telehealth solutions to allow mental health services to provide care seamlessly despite physical distance restrictions being placed on the population (Davenport et al., 2020). In the 6-weeks between mid-March and April, 2020 when Medicare began funding telemental health, 35 million Australian dollars were spent on these services (Rosenberg et al., 2020). Countries like Israel, Singapore, Korea and Taiwan have successfully managed the COVID-19 pandemic by responding rapidly and relying heavily on technology (Salvador-Carulla et al., 2020). Although low and middle-income countries have seen a rise in telepsychiatry as well, the full potential of using virtual platforms in these settings is yet to be realized (Naeem et al., 2020). Telepsychiatry represents a viable resource in overcoming the significant mental health gap in low and middle-income countries. However, the proliferation of telepsychiatry in these contexts is often undermined by lack of telehealth infrastructure, national telehealth policies, data governance frameworks and

lack of training and education on the use telehealth technologies for the health-workforce (Naeem et al., 2020).

## VIRTUAL CARE AT THE CENTRE FOR ADDICTION AND MENTAL HEALTH (CAMH)

The COVID-19 pandemic poses a serious challenge for mental health services across the globe. There has been a rapid uptake of virtual healthcare delivery by a number of mental health providers in preparation for the mental health pandemic that is likely to follow COVID-19. Pre-pandemic, the Centre for Addiction and Mental Health (CAMH), Canada's largest mental health teaching hospital, prioritized the innovation and expansion of telepsychiatry services. However, the implementation of these services across the organization had taken years to fully establish. Since the start of the COVID-19 pandemic, the acceleration of telepsychiatry has been meteoric, with virtual platforms being utilized to deliver patient care. In the US this uptake of virtual care has been facilitated by the relaxation of privacy legislation, augmentation of physician remuneration policies, and prescribing policies (Torous et al., 2020). Similarly, in Canada there has been a change in regulations and the introduction of COVID-19 specific billing codes as a means to increase access to virtual care across medical specialties (Ontario Ministry of Health Ministry of Long-Term Care, 2020). CAMH became entirely digitized in a matter of days, successfully expanding virtual care provision to meet the mental health demands of the population. In 2019 CAMH delivered virtual care to over 3,000 patients from over 550 communities across Ontario (D'Andrea, 2020). This figure increased by over 750 percent from March to April of 2020, with over 3,000 virtual care visits being provided per month (D'Andrea, 2020). The number of mental health providers trained to deliver virtual care also increased from 30 practitioners to over 400 (D'Andrea, 2020). CAMH is an example of the adaptability mental health services need to display in order to meet the demands of the populations they serve. In our experience, feedback from colleagues and patients has been overwhelmingly positive. Clinical staff are finding that remote working has provided more flexibility in their clinical schedules as well as making them more time-efficient. Feedback from service users echo the flexibility and convenience aspect, but also report cost and time saving (less waiting, no cost of transport or parking). Dr. Catherine Zahn, President and CEO of CAMH, has stated that "*virtual health platforms will be a permanent and growing fixture of the healthcare system, and be offered as an accessible, flexible and secure mental health care option for patient care going forward.*" CAMH is now creating training programs for other hospitals and community-based healthcare providers to help scale capacity to deliver mental health services virtually elsewhere.

## POTENTIAL PITFALLS OF DIGITAL PSYCHIATRY

Despite its advantages, telepsychiatry is not a panacea, and there are potential harms that must be considered. Virtual care is

inherently associated with a degree of risk where data breaches and compromise to patient confidentiality and privacy are concerned (Lustgarten et al., 2020). The use of virtual platforms with built-in data encryption, adware, and malware protection, as well as firewalls, has been endorsed as a means to mitigate risks of data breaches (Barnett, 2019). Furthermore, ensuring robust consent procedures is of utmost importance. During this process, the risks to privacy and confidentiality should be clearly explained to patients, along with the limitations of the safeguards that are in place to prevent breaches. Patients should be advised to engage in consultations in a private space as confidential information may be discernable to individuals in their proximity. When delivering telepsychiatric care there are legal implications related to jurisdiction and licensure, where provision of care must be restricted to the province or state that the practitioner is licensed in. Confirmation of identity and identity fraud is another legal concern. There are also implications with regards to involuntary admissions and collaborative arrangements with law enforcement, health and social services to facilitate them. Ultimately, there is the inevitable risk of being unable to respond to psychiatric emergencies in a timely manner. All virtual health platforms inherently carry this risk and therefore guidance from the APA and the OTN pertain specifically to it, with advice that clinicians should ensure there is consistency in where the patient is located during sessions, along with having access to emergency contact information (a friend or family member of the patient) and knowledge of local resources in the event of a crisis (e.g., police, emergency medical services etc.) (Shore et al., 2018).

It is important to recognize that though virtual platforms can improve access to care for some individuals, others may not be able to take advantage of them (Strudwick et al., 2020). There are many barriers to successful uptake of telepsychiatry services including accessibility (e.g., access to internet and smartphones), user ability, provider competency, as well as language and cultural appropriateness (Strudwick et al., 2020). Patients with schizophrenia are known to have cognitive impairment (Husain et al., 2018), which may hinder their ability to engage with telepsychiatry. People experiencing homelessness may also be disproportionately excluded from accessing appropriate care and interventions if largely delivered virtually. Individuals in later life may be less proficient with virtual platforms. To address these factors, a collaborative approach with all relevant stakeholders (service users, clinicians, academics, policymakers) is necessary to develop telepsychiatry services that are inclusive and meet the diverse needs of the population. We must be cautious not to widen the existing mental health gap for already hard-to-reach groups, including people from racialized communities and those living in rural areas where connectivity may be limited. Hard-to-reach individuals are often those with the highest need for care and it is essential that future developments in telepsychiatry ensure parity of access.

We acknowledge that telepsychiatry is not a “one size fits all.” There may well be certain patient groups that are not suitable for virtual care but the literature on the unintended harms of telepsychiatry is scant. Although telepsychiatry has been reported to be effective and satisfactory to addiction

medicine patients, there are no reports to our knowledge on the use of virtual platforms for individuals with internet or gaming addiction. There is a need to develop the evidence base for potential unintended harms associated with virtual care in the future. How much is too much? The potential impact of screen time on cognitive function and executive function is yet to be determined (Minielly et al., 2020). Nonetheless, in the context of the ongoing global pandemic at present the balance remains in favor of telepsychiatry, vs. no care at all.

## DIGITAL PSYCHIATRY IN THE POST-PANDEMIC SETTING

Although the rapid uptake of virtual care has been a product of necessity, the COVID-19 pandemic may have fundamentally changed the way mental health care is delivered. Historically, reluctance to accept telepsychiatry has been centered around the building of rapport and therapeutic relationships (Torous and Wykes, 2020). Appropriate investment is needed for clinician training to deliver virtual care, which has the potential to help the many who will experience mental health fallout from the COVID-19 pandemic but may also redefine “*digital mental health as simply mental health*” in the post-pandemic era (Torous et al., 2020). Furthermore, investment is required in the development of new technologies alongside the development and testing of apps to support the delivery of digital health. We must consider the enhancement and repurposing of existing infrastructure, for example phonebooths equipped with built-in tablet devices that would allow individuals without access to digital platforms to engage. Parity of care could also be achieved by initiatives that offer mobile devices to those unable to afford them. “Virtual walk-in centres” can also be developed by allocating spaces in hospitals and walk-in centres where patients can utilize designated computers or tablet devices. Digital health literacy needs to be enhanced through targeted education interventions to reduce the disparity in access to digital care. These strategies would enhance digital inclusion and potentially address health inequality in the future where digital platforms are likely to form a large part of healthcare delivery (Farooq et al., 2015). The evolution of digital health care requires clinicians, academics, funders, developers and policy makers to collaborate and develop the evidence base of real-world pragmatic effectiveness trials of virtual care platforms, e-therapies, apps, wearable technology and actigraphy. Future directions for research include rigorous and robust clinical effectiveness trials that compare virtual care with in-person care, as well as clinical trials including a variety of mental health presentations and service settings. We will only then be able to determine what works best for who. More research is also needed on the use of mobile applications and artificial intelligence (AI). AI informed mobile applications have the potential to offer personalized real time intervention and provide immediate response to the changing needs of the patient. We have achieved Digital Psychiatry 1.0, allowing us to connect better with our patients (virtual care vs. in person). Digital Psychiatry 2.0 needs to move past connection and toward the

empowerment of patients through remote monitoring of their mental health and real-time interventions by clinicians. Such a platform would not only improve access to mental health care, but invariably lead to a more responsive mental health care system that would improve patient outcomes in the post-pandemic world.

Coronavirus Awareness and Mental  
Health: Clinical Symptoms  
and Attitudes Toward Seeking  
Professional Psychological Help.  
*Front. Psychol.* 12:549644.  
doi: 10.3389/fpsyg.2021.549644

The current study analyzed the relationship between Coronavirus (COVID-19) Awareness, mental health, and willingness to seek professional psychological help. This was made through a quantitative approach, using online questionnaires to collect data from 855 subjects. The questionnaires included the Brief Symptom Inventory (BSI-53) to measure mental health indicators, the Attitudes Toward Seeking Professional Psychological Help Scale–Short Form, and the Coronavirus Awareness Scale-10 (CAS-10). An Exploratory Factor Analysis suggests that three factors underlie the CAS-10: Coronavirus Concern, Exaggerated Perception, and Immunity Perception. Results indicate a significant positive correlation between Coronavirus Concern and both general anxiety and phobic anxiety symptoms. Immunity Perception is positively related to paranoid ideation and psychotic symptoms. A Mediation Analysis determined that Coronavirus Concern has a significant positive direct effect on Openness to Seeking Psychological Treatment (OSPT), while Exaggerated Perception and Immunity Perception scores have significant direct negative effects on the Value and Need in Seeking Treatment (VNST) scores. Indirectly, the relationship between Coronavirus Concern and OPST is significantly mediated by anxiety symptoms. Similar results were found for the VNST subscale. There is a negative significant effect of Immunity Perception over OSPT mediated by Paranoid Ideation. However, the overall model only achieved small  $r^2$  coefficients for the OSPT (0.060) and VNST (0.095) scores. Comparisons in Coronavirus Awareness between sex, age, and the presence of children and older adults at home were also made. These results are discussed regarding their practical implications for mental health providers and policymakers.

**Keywords:** pandemics, mental health, psychological help, health psychology, public health

## INTRODUCTION

### Origins of COVID-19

Coronavirus is one of the most important pathogens that causes respiratory infections in humans. On December 2019, an outbreak of pneumonia of unknown cause was reported in the city of Wuhan, China. By January 2020, the pathogen was isolated from these patients and was identified as a novel Coronavirus (Severe Acute Respiratory Syndrome-Coronavirus 2). It was highly suspected that the outbreak started in a Huanan seafood market, a place where live animals such as bats, birds, snakes and frogs were sold (Shereen et al., 2020). This disease is highly contagious, initially from zoonotic transmission, and later from human to human, by coughing, sneezing or having close contact with an infected person's respiratory droplets (Rothan and Byrareddy, 2020; Shereen et al., 2020).

The most common symptoms of COVID-19 illness are fever, cough, dyspnea, and myalgia. Populations at higher risk include older adults and people with underlying conditions like diabetes, hypertension, or coronary heart disease (Mesa Vieira et al., 2020). In such cases, health complications can quickly progress to Acute Respiratory Distress Syndrome (ARDS) or end-organ failure (Wu et al., 2020).

On the other hand, the evidence shows that only a small number of children that are COVID-19 positive develop a severe health condition. However, asymptomatic children could be playing a relevant part in the spread of the virus (Dervrim and Bayram, 2020). It's important to reduce the increasing cases to avoid a higher fatality rate, especially for healthcare systems that are not prepared for this kind of pandemic, like in the Latin American region (Rodríguez-Morales et al., 2020).

### Prevalence of COVID-19

The World Health Organization (2020a) at the beginning of 2020 considered the outbreak of COVID-19 an international public health emergency. The virus kept spreading quickly in a great number of territories around the world, by March of 2020 it was cataloged as a pandemic. By May 27th, 2020, this number increased considerably, registering 5,491,678 confirmed cases and 349,190 deaths worldwide, with a great prevalence of cases in the American region (World Health Organization, 2020b). The spreading of Coronavirus in Latin American countries has presented an aggressive dynamic that suggests a difficult scenario for low-income nations (Caicedo-Ochoa et al., 2020). In the case of Honduras, by the date data for this research was collected (16th–23rd of March), the virus was just beginning to spread, with 30 confirmed cases and 0 deaths. By May 27th, 2020, these numbers increased alarmingly, reaching 4,401 confirmed cases and 188 fatalities (Honduras Health Secretary, 2020).

### Mental Health in the Context of COVID-19

According to the World Health Organization (2003), mental health is an important part of the human condition, along with the physical and social domains. Mental health concepts are related to subjective well-being, autonomy, the capability of

identifying one's potential, the ability to manage stress, work in a productive way and be capable of contributing to their social environment. Mental health is associated with a balance between the person and the environment. This is influenced by a series of biological, psychological, social, and cultural factors (Korkeila et al., 2003). Recent outbreaks such as SARS, Zika, MERS, and Ebola have shown that a health crisis is a stressful situation. These concerns may be related to the risk of acquiring the virus or passing it on to others, the presence of symptoms of other health conditions that could be confused with COVID-19, and physical and mental health deterioration in vulnerable populations. Other concerns are related to the uncertainty of the long-term consequences in the health, social and economic domains (Huremović, 2019; Inter-Agency Standing Committee, 2020; Wang et al., 2020).

The constant fear of becoming infected or dying, as well as seeing other people die, are just one of the effects caused by outbreaks of epidemics and pandemics on mental health. People who become infected may be attacked and marginalized because they are perceived as "contaminated" (Huremović, 2019; Wang et al., 2020). Likewise, there is a direct correlation between the growing crisis and the negative impact on the economy, health and educational systems (Sim et al., 2010; Van Bortel et al., 2016). This vulnerability can also be related to mental health issues to specific populations like older adults (El Hayek et al., 2020).

One of the most relevant public health measures to reduce the number of people infected with COVID-19 has been social distancing and quarantine (Wilder-Smith et al., 2020). Quarantine has shown to have negative psychological effects on people with and without pre-existing mental health problems. People under quarantine may experience symptoms related to anxiety, depression, and post-traumatic stress symptoms (Brooks et al., 2020). In addition, media can influence the public by doing "agenda-setting," which occurs when a problem receives massive coverage, making it more important to the public (Rubin et al., 2010; Rubin and Wessly, 2020). People's lack of knowledge about a disease leads to misinformation and the spread of rumors, which could lead to harmful effects on mental health (Fernández Poncela, 2012).

Although there are many instruments designed to screen psychological symptoms, the Brief Symptom Inventory-53 (BSI-53) has been widely used in different contexts. The BSI-53 measures symptoms related to Anxiety, Depression, Phobic Anxiety, Hostility, Interpersonal Sensitivity, Obsessive-Compulsive traits, Paranoid Ideation, Psychoticism, and Somatization (Derogatis, 1993). The following description provides a brief overview of these symptoms during the pandemic and confinement period:

- Anxiety: the contextual presence of different diseases or viruses can cause anxiety in the general population. Specific outbreaks (like Zika, Ebola, etc.) may detonate diverse patterns of health anxiety responses (Blakey and Abramowitz, 2017). Recent research made within the COVID-19 outbreak suggests a high prevalence of anxiety symptoms among the population (Rajkumar, 2020).

- Depression: has been described as one of the most prevalent symptoms among the general population during the current COVID-19 pandemic (Rajkumar, 2020).
- Phobic anxiety: recent studies have concluded that the fear of COVID-19 is related to variables such as perceived infectability and germ aversion (Kwasi Ahorsu et al., 2020).
- Hostility: during the SARS outbreak of 2003, health-care workers who were in quarantine reported high levels of anger, frustration, and annoyance (Brooks et al., 2020).
- Interpersonal sensitivity: is defined as a disproportionate awareness of other people's conducts and emotions (Mushtaq et al., 2017). Limited research is available on the topic of interpersonal sensitivity in the context of COVID-19. However, there is evidence that suggests that such construct is an important factor when promoting social functioning in help-seeking individuals (Masillo et al., 2015).
- Obsessive-Compulsive symptoms: the COVID-19 outbreak may trigger such symptoms. This can be exacerbated by the biosecurity measures taken to prevent COVID-19, such as hand washing (quality and frequency), interaction with others with suspected exposure, excessive mediatic information, etcetera (Debanjan, 2020).

Paranoid Ideation: recent research suggests that subjects with a history of paranoid ideation may report high levels of fear related to COVID-19 transmission (Vinkers et al., 2020). A study in Indian population reported that a significant percentage of respondents showed health-related paranoia regarding COVID-19 (Roy et al., 2020).

- Psychoticism: a recent study concluded that some subjects who tested positive on COVID-19 presented stress-triggered psychotic symptoms. However, further research is yet needed on the subject to explore alternatives explications to this reaction (Ferrando et al., 2020).
- Somatization: is characterized by the presence of physical symptoms related to dysfunctional concerns. Recent evidence suggests that the current fear of COVID-19 infection may aggravate pre-existing conditions related to somatic symptom disorders (Colizzi et al., 2020).

However, the Latino population have a tendency to underestimate the relevance of mental health care (Liu et al., 2020; Torres et al., 2020). Latin American population tends to avoid seeking psychological help for fear of the diagnosis they may receive and its associated social stigma (Mascayano et al., 2015). Added to the above, are the religious and cultural beliefs in Latin America which could play an important role in the decision of not seeking psychological help (Caplan, 2019). Despite this cultural resistance, the School of Psychological Science of the National Autonomous University of Honduras, launched an online chat service to provide psychological help amidst the COVID-19 crisis. As of June 11, 2020, more than 711 persons had been attended through the application (School of Psychological Sciences, 2020). This data evidences the demand for mental health services among the Honduran population.

## COVID-19 Awareness

The present study takes into consideration Coronavirus Awareness in relation to mental health and attitudes toward seeking professional psychological help. Coronavirus Awareness is defined as the degree in which people are conscious of the meaning, implications, prevention strategies, and seriousness of the spreading of COVID-19. Recently, a study used Google Trends to analyze the search volume of queries regarding COVID-19 and related terms. The results indicate that people respond temporarily to local propaganda regarding the virus (indicating awareness), however, this attention spam had a short duration (Hu et al., 2020).

Research suggests that demographic variables, such as sex, may be related to Coronavirus Awareness. A study made within the United States of America (USA) context compared the proportion of female and male respondents who reported to be concerned about the COVID-19 situation. Results indicate that when compared to men, there is a higher proportion of women that claim to be concerned about their risk of exposure to COVID-19. Women are also more concerned about contagion risk in their families, loss of economic income and access to COVID-19 testing and treatment (Frederiksen et al., 2020).

Household configuration may also be related to Coronavirus Awareness. Men and women with children are more likely to report COVID-19 related concerns (risk of exposure and loss of economic income), when compared with people who do not have children (Frederiksen et al., 2020). In addition, older adults have a high COVID-19 physical vulnerability (Mesa Vieira et al., 2020) and are also exposed to the social, psychological and economic repercussions of the pandemic. Furthermore, quarantine measures have also promoted intergenerational cohesion, improving the bond older adults have with their own family members as well as with non-related younger people (Morrow-Howell et al., 2020). Age is another variable to consider when analyzing COVID-19 Awareness. Previous research in the United States concluded that the proportion of older adults (>60 years) reporting health-related concerns about the COVID-19 situation was higher than in younger adults (<60 years) (Hamel et al., 2020). However, no data is yet available for the Central American context.

## Purpose of the Study

Reflecting on what has been previously stated, the current study assumes the following premises: (a) the COVID-19 situation is considered a stressor (Wang et al., 2020), (b) stress is strongly related to the presence of mental health disorders (Wu et al., 2020), (c) subjective needs play an important role in help-seeking behaviors (Nagai, 2015); therefore, we propose to analyze a causal model based on these assumptions contextualized within the COVID-19 crisis (see **Figure 1**).

Consequently, the purpose of this study was to analyze the relationship between Coronavirus (COVID-19) Awareness with mental health indicators and the attitude toward seeking professional psychological help. Additional information regarding Coronavirus Awareness and demographic variables were also analyzed, such variables included: age, sex, presence

of children and older adults at home. To our knowledge, there are no studies in Honduras or the Central American region that evaluate the impact of the COVID-19 situation in mental health.

## MATERIALS AND METHODS

### Participants

#### Sampling Method

A total of 855 participants from Honduras answered an online survey that was spread through social media and by snow-ball sampling. This online method was selected given the country's quarantine regulations. Each survey was accompanied by an online informed consent which stated the purpose of the study, a confidentiality clause and the main researcher's contact information. The selection criteria for the participants included: (a) being 18 years or older, (b) currently residing in Honduras and, (c) agreeing with the informed consent statement; any violation of these criteria was considered a motive for exclusion.

#### Characteristics of the Participants

Of all the respondents, 307 (35.9%) were male and 548 (64.1%) female. The average age for male participants was of 27.619 years ( $SD = 10.284$ ), while female mean age was 28.755 ( $SD = 10.878$ ), however, this difference is not statistically significant,  $t(853) = -1.494$ ,  $p = 0.135$ . On the other hand, 645 (75.4%) respondents were single, while the remaining 210 (24.6%) were married. Regarding household configuration, 444 (51.9%) respondents reported to live at home with children under 12 years old, while 327 (38.2%) lived at home with people 60 years or older.

### Measures

#### Brief Symptom Inventory-53

The Brief Symptom Inventory-53 (BSI-53) is a self-reported questionnaire designed to screen the presence of clinical symptoms, specifically Depression ( $\alpha = 0.892$ ), Anxiety ( $\alpha = 0.849$ ), Phobic Anxiety ( $\alpha = 0.795$ ), Somatization ( $\alpha = 0.876$ ), Interpersonal Sensitivity ( $\alpha = 0.836$ ), Obsessive-Compulsive traits ( $\alpha = 0.900$ ), Hostility ( $\alpha = 0.851$ ), Paranoid Ideation ( $\alpha = 0.799$ ), and Psychoticism ( $\alpha = 0.804$ ). The BSI-53, consist on 53 items, each of them scored in a 5-point Likert scale format (Derogatis, 1993), scores closer to 0 indicate a lower symptomatic prevalence, while scores near 4 indicate a higher prevalence. Other authors report good reliability scores for the BSI-53, with an overall Cronbach's alpha of 0.972 (Mohammad et al., 2019). Previous studies have concluded that the BSI-53 is an objective and precise tool to evaluate the presence of psychopathological symptoms (Ruckenstein and Staab, 2001).

#### Attitudes Toward Seeking Professional Psychological Help Scale-Short Form

The Attitudes Toward Seeking Professional Psychological Help Scale-Short Form (ATSPPH-SF) consists of 10 items with Likert-type responses (Fischer and Farina, 1995). Scores closer to 1 indicate a negative attitude, while scores near 4 indicate a favorable attitude toward seeking professional psychological help

(1 = disagree, 2 = somewhat disagree, 3 = somewhat agree, 4 = agree). The scale has also been validated for a Latino adult population, in which an Exploratory Factor Analysis (EFA) suggested the presence of two different dimensions: Openness to Seeking Treatment ( $\alpha = 0.640$ ; average inter-item  $r = 0.396$ ) and the Perceived Value and Need in Seeking Treatment (VNST) ( $\alpha = 0.756$ ; average inter-item  $r = 0.526$ ). The overall scale had a Cronbach's alpha of 0.758 and an average inter-item  $r$  of 0.461. A Confirmatory Factor Analysis (CFA) based upon the data of the current research validates the two-dimensional nature of the scale proposed by Torres et al. (2020), CFI = 0.972, TLI = 0.963, RMSEA = 0.040.

#### Coronavirus (COVID-19) Awareness Scale

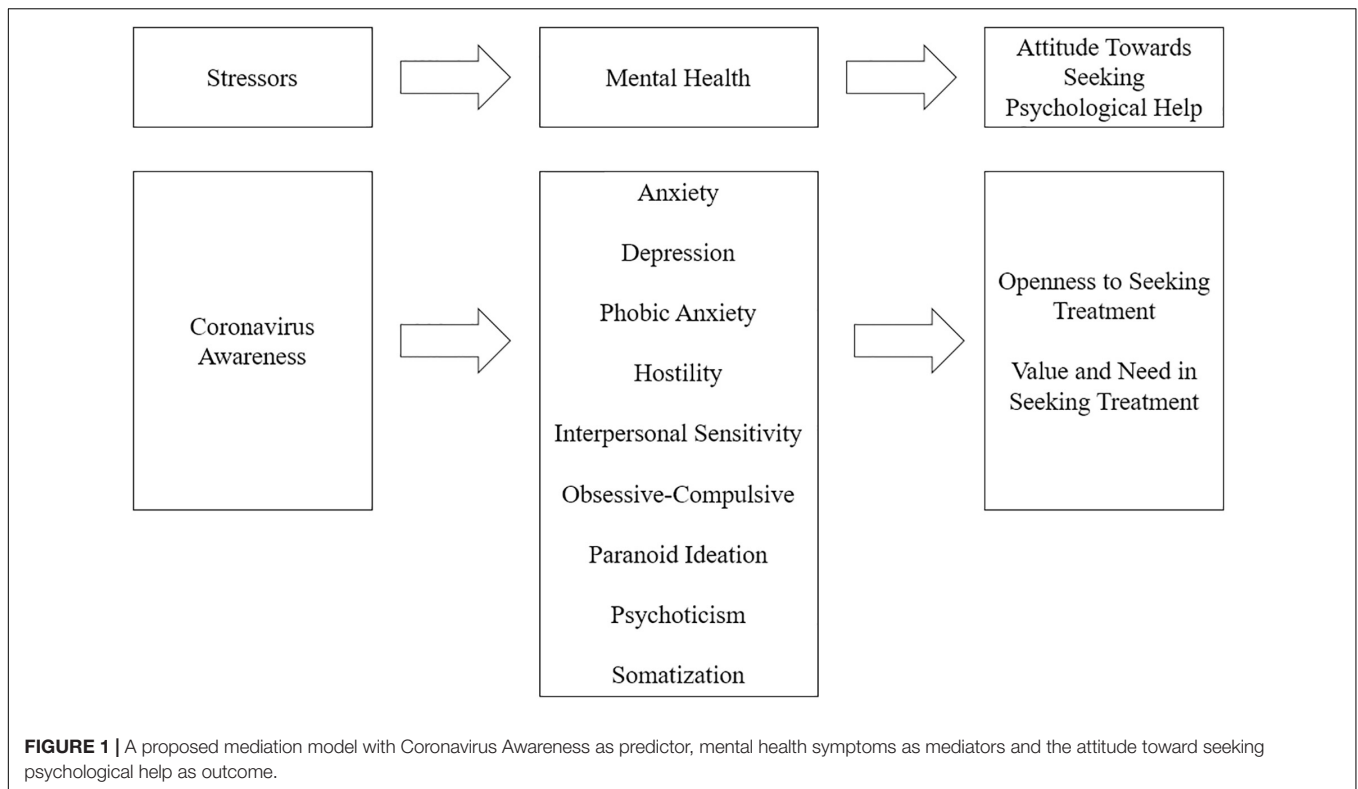

The Coronavirus Awareness Scale-10 (CAS-10) is a 10-item questionnaire built by the authors of the current study, each author individually proposed items, which were later discussed by the research team, the more pertinent and well-structured items were selected to be applied in the selected sample. The CAS-10 has a Likert type response set of 5 points (0–4). An EFA analysis with a maximum likelihood extraction method and an oblimin rotation was executed to detect the underlying factorial structure of the scale. This oblique rotation method allows factors to correlate with each other (Field, 2009), as is the case for many psychological constructs. The Bartlett's Test of Sphericity [ $\chi^2 = 1,917.893$  ( $df = 45$ ),  $p < 0.001$ ] and the KMO Measure of Sampling Adequacy (0.804) have an acceptable performance (see **Table 1**). The three resulting factors are Coronavirus Concern (refers to the preoccupation about getting infected with COVID-19), Exaggerated Perception (the belief that the media and governments are overreacting with the COVID-19 situation) and Immunity Perception (the belief that one is not likely to get infected by COVID-19).

Each factor mean is built by averaging the corresponding items raw scores (without reverse coding). Considering item orientation, a higher Coronavirus Concern score (which only contains positive oriented items) indicates a higher Coronavirus Awareness. While high scores on the Exaggerated Perception and Immunity Perception subscales indicate low Coronavirus Awareness. The CAS-10 has a Cronbach's alpha of 0.762, which is considered acceptable (Coolican, 2004). However, given that this coefficient is affected by the number of items in the scale, average inter-item correlations were also obtained for the overall CAS-10 items (0.436). Specifically, the Coronavirus Concern subscale had the highest Cronbach's alpha score ( $\alpha = 0.715$ ; average inter-item  $r = 0.487$ ), followed by the Exaggerated Perception ( $\alpha = 0.667$ ; average inter-item  $r = 0.436$ ) and Immunity Perception subscales ( $\alpha = 0.550$ ; average inter-item  $r = 0.381$ ). Given that these average inter-item correlations are between the 0.15 and 0.50 limits, the subscales are considered to be adequately consistent (BrckaLorenz et al., 2013), despite the low number of items included.

### Statistical Analysis

Data was analyzed using Jamovi 1.1 (The Jamovi Project, 2019). First, demographic variables were described using relative and absolute frequencies as well as mean scores and standard

**TABLE 1 |** Factor loadings for the CAS-10.

Item	Factor			Uniqueness
	Coronavirus concern	Exaggerated perception	Immunity perception	
C4. I am concerned about the spread of Coronavirus (COVID-19).	<b>0.844</b>	0.016	-0.008	0.293
C2. I am afraid of catching Coronavirus (COVID-19).	<b>0.653</b>	0.063	-0.101	0.549
C10. Coronavirus (COVID-19) is a serious problem.	<b>0.539</b>	-0.210	0.090	0.611
C1. I am constantly informed about the situation of the Coronavirus (COVID-19).	<b>0.431</b>	-0.009	0.031	0.821
C6. I have taken precautions to avoid getting the Coronavirus (COVID-19).	<b>0.406</b>	-0.081	0.063	0.821
C9. I feel like this Coronavirus issue (COVID-19) is more paranoia than anything else.	-0.007	<b>0.861</b>	-0.003	0.256
C8. I believe that quarantine measures to prevent the spread of Coronavirus (COVID-19) are exaggerated.	-0.058	<b>0.533</b>	0.106	0.620
C3. The media exaggerates about the danger of contagion of the Coronavirus (COVID-19).	0.039	<b>0.492</b>	0.020	0.765
C7. I am not worried about getting Coronavirus (COVID-19).	-0.011	0.009	<b>0.989</b>	0.005
C5. I do not think I can get Coronavirus (COVID-19).	0.068	0.248	<b>0.301</b>	0.811

"Maximum likelihood" extraction method was used in combination with an "oblimin" rotation. RMSEA = 0.053; TLI = 0.943, these values are above the threshold values (RMSEA ≤ 0.08 and TLI ≥ 0.90) used in similar studies (Li et al., 2018). Items C3, C5, C7, C8, and C9 have a negative orientation. "Coronavirus Concern" accounts for 18.204% of the variance, "Exaggerated Perception" for 14.717% and "Immunity Perception" for 11.448%, for a total cumulative percentage of 44.369. Significant item loadings (>0.30) are presented in bold letter.

deviations. Items from the CAS-10 and the ATSPPH-SF with negative orientation were inversely recoded and their structural properties determined with EFA and CFA, respectively. The relationships between CAS-10, BSI-53, and age were determined

by Pearson's *r* coefficient. Between-group comparisons for sex were made through a MANOVA test, while comparisons for household configuration were determined through a Student's *t*-test.

Finally, a Mediation Analysis was used to study the relationship between Coronavirus Awareness (predictor), BSI-53 symptoms (mediators) and Attitudes Toward Seeking Professional Psychological Help (outcome). This analysis included Delta method standard errors and bias-corrected percentile bootstrap confidence intervals based on 1,000 replications. Such method provides stable and precise coverage rates and has an overall good performance (Biesanz et al., 2010).

## Ethical Considerations

The current research was made in accordance with the Ethical Guidelines provided by the master's degree in Clinical Psychology of the National Autonomous University of Honduras, which approved the present study. An online informed consent was presented to all potential participants, it included information regarding the purpose of the study, an anonymity statement, potential risks and benefits, the name and e-mail of the main researcher. At the end of the survey participants were presented with a web link which redirected to a free online psychological assistance website supported by the National Autonomous University of Honduras.

## Coronavirus Awareness and Demographic Variables

### General Description of Scores

Most respondents are aware of COVID-19 and its implications. For example, 55.7% of the respondents totally agreed with the item "I am constantly informed about the Coronavirus

situation" and 69.1% completely agreed that COVID-19 is a serious problem. Nonetheless, a considerable number of participants (30.4%) believed that the media makes exaggerated claims about the COVID-19 dangers (see **Table 2**). The overall CAS-10 mean score was of 3.007 ( $SD = 0.651$ ), as for the subscales, higher mean scores correspond to Coronavirus Concern ( $M = 3.356$ ,  $SD = 0.641$ ), followed by Exaggerated Perception ( $M = 1.502$ ,  $SD = 1.072$ ) and Immunity Perception ( $M = 1.105$ ,  $SD = 1.048$ ).

### Coronavirus Awareness and Sex

A MANOVA analysis suggests that there is no statistically significant difference ( $p < 0.05$ ) on the Coronavirus Awareness scores compared to the respondent's sex. In this sense, the Coronavirus Concern scores for men ( $M = 3.320$ ,  $SD = 0.610$ ) do not differ significantly when compared to female respondents ( $M = 3.377$ ,  $SD = 0.657$ ),  $F(1; 673.939) = -1.244$ ,  $p = 0.205$ . Male ( $M = 1.596$ ,  $SD = 1.120$ ) and female subjects ( $M = 1.449$ ,  $SD = 1.042$ ) report no significant difference in the Exaggerated Perception scores,  $F(1; 596.423) = 1.928$ ,  $p = 0.059$ . Similarly, the scores in Immunity Perception do not vary significantly between men ( $M = 1.085$ ,  $SD = 1.025$ ) and women ( $M = 1.116$ ,  $SD = 1.062$ ),  $F(1; 652.178) = -0.417$ ,  $p = 0.674$ .

### Coronavirus Awareness and Household Configuration

Respondents who dwelled with children (12 years or younger) had significantly ( $p < 0.05$ ) higher scores in the Exaggerated Perception and the Immunity Perception subscales than people

**TABLE 2** | Descriptive statistics for each CAS-10 item.

CAS-10 items	Totally disagree n (%)	Disagree n (%)	Neither agree nor disagree n (%)	Agree n (%)	Totally agree n (%)	Mean (SD)
C1. I am constantly informed about the situation of the Coronavirus (COVID-19).	5 (0.60%)	23 (2.7%)	98 (11.5%)	253 (29.6%)	476 (55.7%)	3.371 (0.834)
C2. I am afraid of catching Coronavirus (COVID-19).	64 (7.5%)	70 (8.2%)	133 (15.6%)	190 (22.2%)	398 (46.5%)	2.922 (1.272)
C3. The media exaggerates about the danger of contagion of the Coronavirus (COVID-19).	152 (17.8%)	117 (13.7%)	173 (20.2%)	153 (17.9%)	260 (30.4%)	2.295 (1.469)
C4. I am concerned about the spread of Coronavirus (COVID-19).	15 (1.8%)	12 (1.4%)	79 (9.2%)	194 (22.7%)	555 (64.9%)	3.476 (0.854)
C5. I don't think I can get Coronavirus (COVID-19).	352 (41.2%)	185 (21.6%)	195 (22.8%)	73 (8.5%)	50 (5.8%)	1.163 (1.218)
C6. I have taken precautions to avoid getting the Coronavirus (COVID-19).	11 (1.3%)	19 (2.2%)	52 (6.1%)	236 (27.6%)	537 (62.8%)	3.484 (0.812)
C7. I'm not worried about getting Coronavirus (COVID-19).	432 (50.5%)	154 (18.0%)	139 (16.3%)	57 (6.7%)	73 (8.5%)	1.047 (1.305)
C8. I believe that quarantine measures to prevent the spread of Coronavirus (COVID-19) are exaggerated.	502 (58.7%)	147 (17.2%)	85 (9.9%)	51 (6.0%)	70 (8.2%)	0.877 (1.284)
C9. I feel like this Coronavirus issue (COVID-19) is more paranoia than anything else.	351 (41.1%)	160 (18.7%)	141 (16.5%)	114 (13.3%)	89 (10.4%)	1.333 (1.392)
C10. Coronavirus (COVID-19) is a serious problem.	12 (1.4%)	13 (1.5%)	77 (9.0%)	162 (18.9%)	591 (69.1%)	3.529 (0.831)

The table shows raw scores for negative items (C3, C5, C7, C8, and C9).

whose households did not have children. No such difference was found in the Coronavirus Concern subscale ( $p = 0.896$ ).

Participants who reported that in their household lived people over the age of 60 had a significantly lower Immunity Perception score than subjects that didn't have older adults at home ( $p = 0.010$ ). No statistically significant difference was found for the Coronavirus Concern subscale ( $p = 0.162$ ) nor the Exaggerated Perception subscale ( $p = 0.074$ ). **Table 3** summarizes the descriptive and comparative statistics for the CAS-10 scale regarding household configuration.

### Coronavirus Awareness and Age

Results suggest that there is a significant correlation between the respondent's age and the Coronavirus Awareness subscales. For instance, Coronavirus Concern scores are positively related to the respondent's age ( $r = 0.116$ ,  $p < 0.001$ ); indicating that increases in Coronavirus Concern scores are weakly associated with increases in age and vice versa. There are also weak negative relationships between the Exaggerated Perception and Immunity Perception subscales regarding the respondent's age ( $r = -0.171$ ,  $p < 0.001$ ;  $r = -0.097$ ,  $p = 0.004$ , respectively). It is worth noting that Pearson's  $r$  coefficients for all variables are stronger in men than in women (see **Table 4**).

## Coronavirus Awareness and Mental Health

### Description of BSI-53 Symptoms

The most intense symptoms reported by the respondents correspond to the Obsessive-Compulsive domain ( $M = 1.595$ ,  $SD = 1.054$ ), followed by Anxiety ( $M = 1.592$ ,  $SD = 0.92$ ) and Interpersonal Sensitivity ( $M = 1.46$ ,  $SD = 1.071$ ). The less intense symptoms included: Hostility ( $M = 1.440$ ,  $SD = 1.021$ ), Social Phobia ( $M = 1.435$ ,  $SD = 1.005$ ), Depression ( $M = 1.378$ ,  $SD = 1.035$ ), Paranoid Ideation ( $M = 1.339$ ,  $SD = 0.937$ ),

Psychoticism ( $M = 1.222$ ,  $SD = 0.981$ ), and Somatization ( $M = 1.061$ ,  $SD = 0.897$ ). The Overall BSI-53 score was of 1.391 ( $SD = 0.856$ ).

### Relationship Between Coronavirus Awareness and BSI-53

Significant ( $p < 0.001$ ), although weak, relationships were found between the Coronavirus Concern subscale and symptoms of Anxiety, Depression, Phobic Anxiety and Psychoticism. Additionally, Exaggerated Perception relates significantly to symptoms of Anxiety, Depression, Hostility, Interpersonal Sensitivity, Obsessive-Compulsive scores, Paranoid Ideation, Psychoticism, and Somatization. Immunity Perception scores are significantly correlated with Paranoid Ideation and Psychoticism. Nonetheless, it's worth mentioning that all subscale correlation coefficients have a small effect size ( $r < 0.30$ ) (Cohen, 1992). All correlation coefficients between the CAS-10 and the BSI-53 are presented in **Table 5**.

### Coronavirus Awareness and Attitudes Toward Seeking Professional Psychological Help

Coronavirus Concern scores have a significant ( $p = 0.003$ ) and positive ( $\beta = 0.178$ ) direct effect on Openness to Seeking Psychological Treatment (OSPT). Moreover, the Exaggerated Perception ( $\beta = -0.124$ ,  $p < 0.001$ ) and Immunity Perception scores ( $\beta = -0.104$ ,  $p = 0.003$ ) have significant direct negative effects on the VNST scores (see **Table 6**).

Indirectly, the relationship between Coronavirus Concern and Openness to Seeking Treatment is significantly mediated by Anxiety scores ( $\beta = 0.060$ ,  $p = 0.006$ ). Similar results were found for the VNST subscale ( $\beta = 0.036$ ,  $p = 0.007$ ). On the other hand, there is a negative significant effect of Immunity Perception over Openness to Seeking Treatment mediated by Paranoid Ideation ( $\beta = -0.040$ ,  $p = 0.005$ ) (see **Table 7**). Overall, Immunity Perception had a negative and significant total indirect effect on Openness to Seeking Treatment ( $\beta = -0.029$ ,  $p = 0.005$ ) (see **Table 8**).

Coronavirus Concern had a significant positive total effect on Openness to Seeking Treatment ( $\beta = 0.193$ ,  $p < 0.001$ ), while both Exaggerated Perception ( $\beta = -0.153$ ,  $p < 0.01$ ) and Immunity Perception ( $\beta = -0.109$ ,  $p = 0.002$ ), had significant negative total effects on the VNST scores (see **Table 9**). However, the overall model only achieved an  $r^2$  of 0.060 for the OSPT and an  $r^2$  of 0.095 for the VNST scores.

**TABLE 3** | Descriptive and comparative statistics for CAS-10 scores according to household configuration.

Scale	Group	Mean	SD	F	df 1; df 2	p
<b>Presence of children at home (&lt;12 years)</b>						
Coronavirus concern	No	3.353	0.615	0.017	1; 853.00	0.896
	Yes	3.359	0.664			
Exaggerated perception	No	1.422	1.094	4.410	1; 840.615	0.036
	Yes	1.576	1.047			
Immunity perception	No	1.021	1.026	5.121	1; 851.552	0.024
	Yes	1.182	1.064			
<b>Presence of older adults at home (&gt;60 years)</b>						
Coronavirus concern	No	3.332	0.643	1.962	1; 697.628	0.162
	Yes	3.395	0.635			
Exaggerated perception	No	1.553	1.079	3.196	1; 701.942	0.074
	Yes	1.419	1.057			
Immunity perception	No	1.176	1.076	6.702	1; 732.372	0.010
	Yes	0.989	0.993			

From the total sample size, 444 respondents report the presence of minors (<12 years) at home, while 411 do not. On the other hand, 528 report to live with older adults (>60 years) and 327 do not.

**TABLE 4** | Relationship between CAS-10 subscales and age, compared by the respondent's sex.

Overall BSI-53 score	<i>r</i>	-0.019	0.157***	0.034
	<i>p</i> -value	0.588	< 0.001	0.317

The BSI-53 subscales measure the prevalence of symptoms, but do not constitute a clinical diagnosis. Pearson's *r* coefficient was used to correlate the variables. \**p* < 0.05, \*\**p* < 0.01, \*\*\**p* < 0.001.

## DISCUSSION

Our study concluded that individuals who live with older adults (age > 60) had significantly lower Immunity Perception scores than subjects that do not. Complementarily, respondents who live with children (age < 12) tend to endorse the Immunity Perception and the belief that COVID-19 situation is being exaggerated; such beliefs may detonate risky health behaviors in such populations. Results showed that increases in Coronavirus Concern scores are associated with increases in age and vice-versa. This could be related to the fact that older age is considered a risk factor for ARDS and death (Rothan and Byrareddy, 2020). On the other side, younger age has been related to mild disease

and better health outcomes (Verity et al., 2020). That is not to say that young people are immune to the virus, therefore, adolescents and young people should receive information about COVID-19. This can be achieved through digital platforms that promote age-friendly content (United Nations Population Fund, 2020).

The most intense symptoms reported by respondents were related to the obsessive-compulsive domain, followed by anxiety and interpersonal sensitivity. These findings are consistent with other studies that reported that individuals exposed to information related to outbreaks experienced higher anxiety symptoms related to health and obsessive-compulsive behavior (Brand et al., 2013). Congruently, our study found a significant positive, although weak, correlation between Coronavirus Concern, anxiety and social phobia. Given the epidemiologic nature of COVID-19, prevention strategies are partly based on social distancing, implying that people should be at least a meter apart from each other (World Health Organization, 2020a). In this sense, many countries around the world recommend their citizens to avoid public spaces (Public Health Ontario, 2020), therefore an increase in social phobia indicators is a natural response to such circumstances.

Another of our findings determined a small negative relationship between the presence of depression symptoms and Coronavirus Awareness. To understand this, the reader must consider that apathy is a common characteristic of depressive disorders (American Psychiatric Association, 2013). In certain populations, respondents with higher depression scores may be less concerned about health issues, indicating a higher level of self-neglect (Hansen et al., 2017). However, these results should be considered with caution as the BSI-53 only screens for symptoms of depression and does not constitute a clinical diagnosis.

Hostility and interpersonal sensitivity symptoms are positively related to the belief that the COVID-19 impact and responses are being exaggerated. Previous research suggests that these traits are highly associated with passive coping strategies (Mao et al., 2003), however, more research is still needed to clearly understand this dynamic. Another symptom of interest corresponds to the paranoid ideation domain, which correlates positively with both the Exaggerated Perception and the Immunity Perception subscales. Respondents with higher paranoid ideation and psychoticism could distrust public media and the government position regarding the impact of COVID-19 in society, minimizing its repercussions. In this sense, prior

research has determined a link between paranoid ideation, distrust (Kirk et al., 2013), and the endorsing of conspiracy theories (Darwin et al., 2011).

A similar trend has been suggested for psychoticism and its relationship to medical mistrust and conspiracy theories during pandemic outbreaks (Moukaddam and Shah, 2020), this could help understand the positive relationship between COVID-19 Exaggerated Perception subscale and psychotic symptoms. Although there is a clear relationship between stress exposure and psychotic symptoms (Van Winkel et al., 2008), our research found a negative and weak relationship between Coronavirus Concern and psychoticism. This lack of concern may be explained by the positive correlation of psychoticism with Exaggerated Perception and Immunity Perception. Therefore, respondents who score higher on psychotic symptoms are also less preoccupied with the COVID-19 situation and are more likely to believe that the media exaggerates this situation and that they are not likely to get infected with COVID-19.

This study revealed that most individuals are constantly informing themselves about the COVID-19 current situation and they believe it is a serious problem. However, there is a significant number of respondents that believe the media is exaggerating the situation. Such set of beliefs clearly poses contagion risks that should be addressed by local governments. This could be achieved by promoting health literacy and epidemic prevention strategies (Wang and Wang, 2020), by constantly informing the public about the prevalence and incidence of COVID-19 cases and implementing campaigns designed to educate citizens regarding self-protection measures (Hu et al., 2020).

A relevant finding was that Coronavirus Concern had a positive and direct effect on OSPT, this relationship was significantly mediated by anxiety scores. This is consistent with a study that reported that people who experience anxiety

symptoms have, more often, a better attitude toward seeking psychological help (Roness et al., 2005). This could be related to the fact that anxiety symptoms can quickly progress and become harder to manage by oneself in comparison to other disorders. Immunity Perception had a negative effect on OSPT. In this sense, previous research has found that the presence of subjective needs is positively related to attitudes toward seeking psychological help (Nagai, 2015). Translated to our study, this can signify that respondents with high Immunity Perception scores do not feel the need to seek psychological attention. However, given the small determinant coefficients of the results, other variables besides the presence of psychological symptoms should be considered to understand people's attitudes toward seeking professional psychological help (Nunes Baptista and Zanon, 2017).

Health care systems should take into consideration that the COVID-19 crisis may exacerbate symptoms related to anxiety, depression, and obsessive-compulsive behavior. A way to mitigate this situation could be to provide professional psychological help through the use of online resources, such as they did in China in different stages of the pandemic. In this sense, two simultaneous activities during crisis intervention may be considered: (1) mitigate the fear of the disease and, (2) help coping with difficulties in the adaptation process (Zhang et al., 2020). Since the current pandemic is affecting mental health, the Honduran health care system should take technology as an advantage to reach patients that are experiencing these negative symptoms. Given our results, such response system should focus on interventions designed to mitigate anxiety symptoms. In this sense, recent studies have found that the use of mobile-phone applications based on coach-supported platforms are effective in treating symptoms of anxiety (Graham et al., 2020).

The current research did not take into consideration the potential effects of social distancing and quarantine measures that may impact mental health; more research is yet needed in this subject. Future studies should also focus on specific groups that, given the nature of their work, are in constant risk of infection. Frontline workers (like health care professionals and police force members) have more probabilities of experiencing stressors related to stigmatization, biosecurity procedures, an increased workload and the fear of transmitting COVID-19 to others. Additional variables such as lifestyle and physical activity should also be considered in future studies (Zhou et al., 2020). A mixed-methods approach may provide a more profound comprehension of this phenomenon.

The cross-sectional nature of the current study, which focused on the initial stages of the COVID-19 pandemic, only gives a limited glimpse of the relationship between pandemic outbreaks and mental health indicators of the affected populations. More longitudinal data is still needed on the subject to better determine the causal relationships between variables. Data collection for this research was made between the 16th and the 23rd of March, during this time Honduras reported 30 confirmed COVID-19 cases with 0 fatalities. However, as of May 27th, 2020, the country reported 4,401 confirmed cases and 188 deaths (Honduras Health Secretary, 2020), this increase in COVID-19 cases, in addition to the effects of social confinement and the restriction of liberties, are not accounted for in our research. Another limitation of our study is the non-probabilistic sampling method that was used, which may restrict the inferential capability of our results. Future studies should also explore alternative data analysis, such as non-parametric and Bayesian approaches to further corroborate the results presented in the current research.

The proposed mediation model stated an unidirectional influence of Coronavirus Awareness, mental health indicators and attitudes toward seeking psychological help. However, this relationship could be bidirectional. In this sense, COVID-19 awareness may influence the prevalence of psychopathological indicators. But, such indicators may also have an impact on Coronavirus Awareness itself (as was discussed regarding depression and paranoid ideation symptoms). Further studies

are still needed to clarify this dynamic. On the other hand, the BSI-53 measures the prevalence and intensity of different psychological symptoms, but it does not constitute a clinical diagnosis. Finally, given that the current research had a limited psychopathological-based approach to mental health, future studies should include positive and protective variables like resilience, subjective well-being, among other factors that respond to a more holistic, humanistic, and positive concept of mental health.

**Background:** By March 2020, the World Health Organization declared the COVID-19 crisis as a worldwide pandemic and many local governments instituted stay-at-home orders and closed non-essential businesses. Within the United States, tens of millions of workers lost their jobs and financial security during the first few weeks of the national response, in an attempt to slow the global pandemic. Because of the enormity of the pandemic and its potential impact on mental health, the objective of the present study was to document the prevalence of mental health problems and their association with pandemic-related job loss during the third week of the nationwide shutdown.

**Methods:** Mental health was assessed via online questionnaires among a representative sample of 1,013 U.S. adults on April 9–10, 2020. Rates of clinically significant mental health outcomes were compared between participants who lost their job as a result of COVID-19 restrictions (17.4%) vs. those who did not (82.6%). Bivariate multiple logistic regression identified factors that were predictive of, and protective against, mental health problems.

**Results:** The prevalence of clinically significant symptoms was significantly higher than prior population estimates, ranging from 27 to 32% for depression, 30 to 46% for anxiety disorders, 15 to 18% for acute/post-traumatic stress, 25% for insomnia, and 18% for suicidal ideation. Prevalence estimates were 1.5–1.7 times higher for those who reported job loss due to COVID-19 restrictions than those who did not. Mental health problems were predicted by worry over financial instability, insomnia, social isolation, and alcohol consumption, while getting outside more often, perceived social support, and older age were protective against these problems.

**Conclusions:** During the first 3 weeks of lockdowns/stay-at-home restrictions, mental health problems, including depression, anxiety, insomnia, and acute stress reactions were notably elevated relative to prior population estimates. Job loss related to the nationwide shutdown was particularly associated with poorer mental health. These findings provide a baseline of mental health functioning during the first weeks of the national emergency and lockdown orders in response to COVID-19.

**Keywords:** COVID-19, depression, generalized anxiety, PTSD, insomnia, mental health, job loss, financial worries

## INTRODUCTION

During the first weeks of the COVID-19 pandemic, nations around the globe implemented unprecedented measures to mitigate the transmission of the SARS CoV-2 virus (1, 2). The United States reported the first COVID-19-related death on February 29, 2020, and <2 weeks later, a national state of emergency was called. In response, local and state governments closed schools, shut down all non-essential business, and enacted shelter-in-place orders, with the first state-wide shutdown occurring in California on March 19, 2020. Within a matter of weeks, every state in the country had enacted some form of restriction (3), with most of the U.S. population asked to remain at home and to severely limit physical proximity to others. As a consequence, most employment activities deemed “non-essential” by local governments had ceased or rapidly shifted to remote telecommuting or work-from-home options. This soon led to large scale furloughs and job losses for a large segment of the population (4). Despite the clear public health necessity of the stay-at-home orders and physical distancing strategies to slow the spread of the virus, there is no question that these efforts profoundly altered the basic foundations of the social and occupational lives of much of the population. Consequently, the potential long-term effects of the pandemic and associated restrictions on mental health will likely be a focus of research for years to come.

The financial consequences of the shelter-in-place mitigation strategies were rapidly felt throughout the country. Within the first 6 weeks of state-wide stay-at-home orders in the U.S., more than 33 million Americans had filed new unemployment claims, a level of job loss that had not been seen since the Great Depression (4). This extraordinary surge in unemployment was troubling in light of the well-established findings that that job loss, financial stresses, and lack of social support are leading contributors to suicide, substance abuse, domestic violence, and other mental health issues (5, 6). The rampant uncertainty surrounding the potential course of the pandemic and widespread concerns over financial instability stemming from the lockdown orders led to rising concerns that a surge in mental health problems may be looming on the horizon (7, 8). Fear of the virus, its transmissibility, and its potential lethality contributed to panic and generalized anxiety (9), and raised concerns that post-traumatic stress symptoms could persist long after the pandemic had resolved (10), as has been seen in other countries (11). Quarantines enacted in prior disease outbreaks have also been shown to significantly elevate symptoms of PTSD and depression among the population (12). Moreover, prolonged stay-at-home requirements and social distancing measures may have unintended mental health consequences, as they restrict many of the facets of daily existence that provide emotional resilience, social connection, and satisfaction with life (13). The enormity of the pandemic and its effects on daily existence led many experts to voice concern that that mental health problems may be a lingering issue for years to come (7, 14).

Effective recovery from the pandemic will require a well-documented and comprehensive understanding of the mental health effects that emerged during the acute stages of the crisis.

To that end, we studied the point prevalence of mental health problems in a nationally representative sample of adults in the U.S. collected at the very outset of the pandemic, during the third week of the nationwide stay-at-home restrictions. We identified overall rates of mental health concerns in this sample and determined the differences in mental health outcomes between those who had lost their primary employment due to the economic shutdown and those who had not. We believe that these data will be critical for documenting the mental health status of the population during the initial phase of the COVID-19 pandemic and will serve as a benchmark for future research on the long-term psychiatric outcomes of the crisis.

## METHODS

### Participants

Here, we summarize mental health data from an online assessment collected over a 28-h period between April 9 and April 10, 2020. This date was selected because it was, at that time, projected to be the peak of expected U.S. deaths due to COVID-19 according to the University of Washington Institute for Health Metrics and Evaluation (IHME; <https://covid19.healthdata.org/united-states-of-america>) model during the preceding week. Using the Amazon Mechanical Turk (MTurk) online crowdsourcing platform (15), a total of 1,074 participants were screened and provided small financial compensation for their time. All participants were geographically located within the United States (verified by IP address geo-coordinates), were at least 18 years of age, and reported English as their primary language. A brief screen for reading comprehension excluded 48 volunteers from further participation. The remaining 1,026 individuals then completed the online questionnaires. Data from 13 participants were excluded for failing to correctly answer imbedded attention check questions. This resulted in a final sample of 1,013 participants with complete and valid data, which formed the basis of the present analysis. The sampling of participants from each state was closely proportional to state population according to the 2019 U.S. Census, suggesting a nationally representative sample of U.S. adults. Specifically, we calculated the proportion of participants from each state, relative to the national population total for the sample and for the U.S. Census data for each state. The mean absolute difference in sampling proportions and census data proportions across states was 0.004 (i.e., <0.5% point). Further, we found that all sampled state proportions differed from the census data by 1.5% points or less, except for Texas (which was underrepresented in the current sample by 3% points). The intraclass correlation coefficient (ICC) between the sample proportions and the census data across states was quite high (ICC = 0.95,  $p < 0.0001$ ), suggesting that these data are likely representative of the larger population. All participants provided electronic acknowledgment of informed consent after being provided with a full description of the study. This study was approved by the institutional review board of the University of Arizona.

## Questionnaires and Primary Outcomes

Our goal was to provide a source of reliable documentation of the initial mental health prevalence estimates during the first weeks of the pandemic response, which would provide a benchmark for future research efforts. In an effort to be comprehensive, we included several outcome metrics that assessed similar constructs (e.g., we collected two measures of depressive mood, one longer and more extensive, and another as a brief screener). Outcomes were focused on major mental health symptoms that could potentially result from concerns surrounding the COVID-19 pandemic and/or societal attempts to mitigate the spread of the illness. These included current symptoms (i.e., present within the past week to month) of a major depressive disorder, generalized anxiety disorder (GAD), and acute/post-traumatic stress disorder. Using established instruments, we calculated mean scores and the percentage of the sample exceeding published cut-off scores. Depressive symptoms were assessed with the Beck Depression Inventory-II ( $\geq 20$ ) (16) and the Patient Health Questionnaire-9 ( $\geq 10$ ) (17). We also examined separately the suicidal ideation scores on each of these depression scales (i.e., Item 9 scores  $\geq 1$ ). Generalized anxiety disorder (GAD) symptoms were measured with the GAD-7 ( $\geq 8$ ) (18, 19), the Zung Self-Rated Anxiety Scale (SRAS;  $\geq 36$ ) (20, 21), and the state and trait portions of the Spielberger State-Trait Anxiety Inventory (STAI;  $\geq 46$ ) (22, 23). To assess acute/post-traumatic stress, we administered the National Stressful Events Survey Acute Stress Disorder Short Scale (NSESSS;  $\geq 2$ ) (24, 25), and the Primary Care Post-Traumatic Stress Disorder (PC-PTSD) scale ( $\geq 3$ ) (26, 27). We also measured the severity of insomnia symptoms using the Insomnia Severity Index (ISI;  $\geq 15$ ) (28, 29). To examine potential moderators of the mental health outcomes described above, we also collected data on a variety of demographic factors, particularly related to job loss from the shutdown and socioeconomic status, and specific concerns relevant to the ongoing COVID-19 pandemic. These variables are detailed in **Table 1**.

## Statistical Analysis

We proposed an initial sample size of 1,000 participants, which would provide 88% power to detect effects of interest at a two-sided significance criterion of  $\alpha = 0.05$ , assuming small effect sizes. The data were analyzed using SPSS software (version 26). Means and descriptive statistics were calculated for the sample as a whole, as well as for subgroups of individuals who reported job loss as a result of the societal responses aimed at mitigating the spread of COVID-19. Mean values between job status groups were compared with analysis of covariance (ANCOVA) statistically controlling for pre-pandemic income level, education level, and potential exposure to COVID-19 (i.e., “have you noticed that you are shown symptoms of COVID-19?” and “has anyone in your household been diagnosed with COVID-19?”). For clinically relevant scales where published cut-off points were available, we calculated the percentage of the sample and subgroups that met or exceeded those values. Chi-squared statistics were calculated to compare the percentage of individuals exceeding the cut-offs in each group. Finally, binomial multiple logistic regression analyses, with forward

selection using the Likelihood Ratio, were used to identify key concerns, traits, and behavioral factors associated with meeting criteria for a probable mental health issue. Multiple comparisons were controlled by false discovery rate (FDR) adjustment of significance, which was calculated using the Benjamini-Hochberg procedure, as implemented via the online FDR (tool: <https://tools.carboaction.com/FDR>). The corrections were applied uniformly for all comparisons within each table.

## RESULTS

### Demographics

Primary demographic characteristics of the sample were well-matched to the larger U.S. population (see Methods section). While an upper restriction on age was not set, those who responded to the survey included adults ranging in age from 18 to 82 years and females were slightly over-represented (i.e., 56.4%). Overall, 65.9% of the sample reported a previous year household income of \$75,000 or less.

### Overall Mental Health Outcomes

For the sample as a whole, the proportions of individuals screening positive for probable mental health problems was notably higher than would be expected in a similar sample based on prior research (30, 31). For those screening positive for moderate to severe depression (**Figure 1**, **Table 2**), the prevalence ranged from 27.2% (BDI-II) to 32.2% (PHQ-9). Across four different scales commonly used to screen for GAD and other clinically significant anxiety disorders, the screen-positive prevalence ranged from 29.8% (STAI-State) to 45.8% (SRAS). Further, 15.2% of the sample screened positive for probable Acute Stress Disorder (NSESSS), while 17.9% screened positive on a brief measure of possible PTSD symptoms (PC-PTSD). Critically, 17.6% of the sample screened positive for some evidence of suicidal ideation on two different scales (BDI-II Item 9; PHQ-9 Item 9), while 25.1% of the sample screened positive for clinically significant insomnia on the ISI.

### COVID-19 Job Loss and Mental Health Outcomes

When asked the question “Have you lost your primary job/income due to COVID-19?”, 17.4% of the respondents answered “yes,” while 82.6% answered “no.” As evident in **Table 2**, individuals who lost their job due to COVID-19 scored significantly higher on measures of depression (BDI-II and PHQ-9). Moreover, 38.1% of those who reported job loss due to COVID-19 exceeded the cut-off for moderate to severe depression on the BDI-II, whereas 25.2% of those who had not lost their job met that criterion. This was even more notable for the PHQ-9, with 44.3% of those who lost their job scoring in the clinically significant range, compared to 29.6% who did not. These differences were significant even after controlling for pre-pandemic income level, education, and the perception of close exposure to COVID-19.

Similar patterns were observed for measures of GAD and other anxiety disorders. Most notably, 57.4% of those who lost their job during the pandemic met the cut-off for a probable

**TABLE 1 |** Demographic characteristics and COVID-19 concerns of groups of individuals who lost or did not lose their primary employment due to the pandemic.

\*Items included as potential predictors of mental health in the binomial logistic regression (as well as job loss category and insomnia severity, which are not listed).

anxiety disorder on the Zung SRAS, compared to 43.3% who had not lost their job.

Evidence of probable acute stress and post-traumatic stress reactions was evident in 22.9% and 25.0% of those who lost a job due to the coronavirus outbreak, respectively, compared to 13.5% and 16.4%, respectively, among those whose jobs were not affected.

While suicidal ideation on Item 9 of the BDI-II was not different between job-loss groups, there was a significant difference in suicidal ideation on Item 9 of the PHQ-9, with 25% of those who reported losing their job endorsing some level of suicidal ideation, compared to 16% of those who had not.

Finally, the data in **Table 2** also show that 32.4% of those who lost their job met or exceeded the cut-off for clinically significant insomnia on the ISI, while 23.5% of those who had not lost their job met this level of severity.

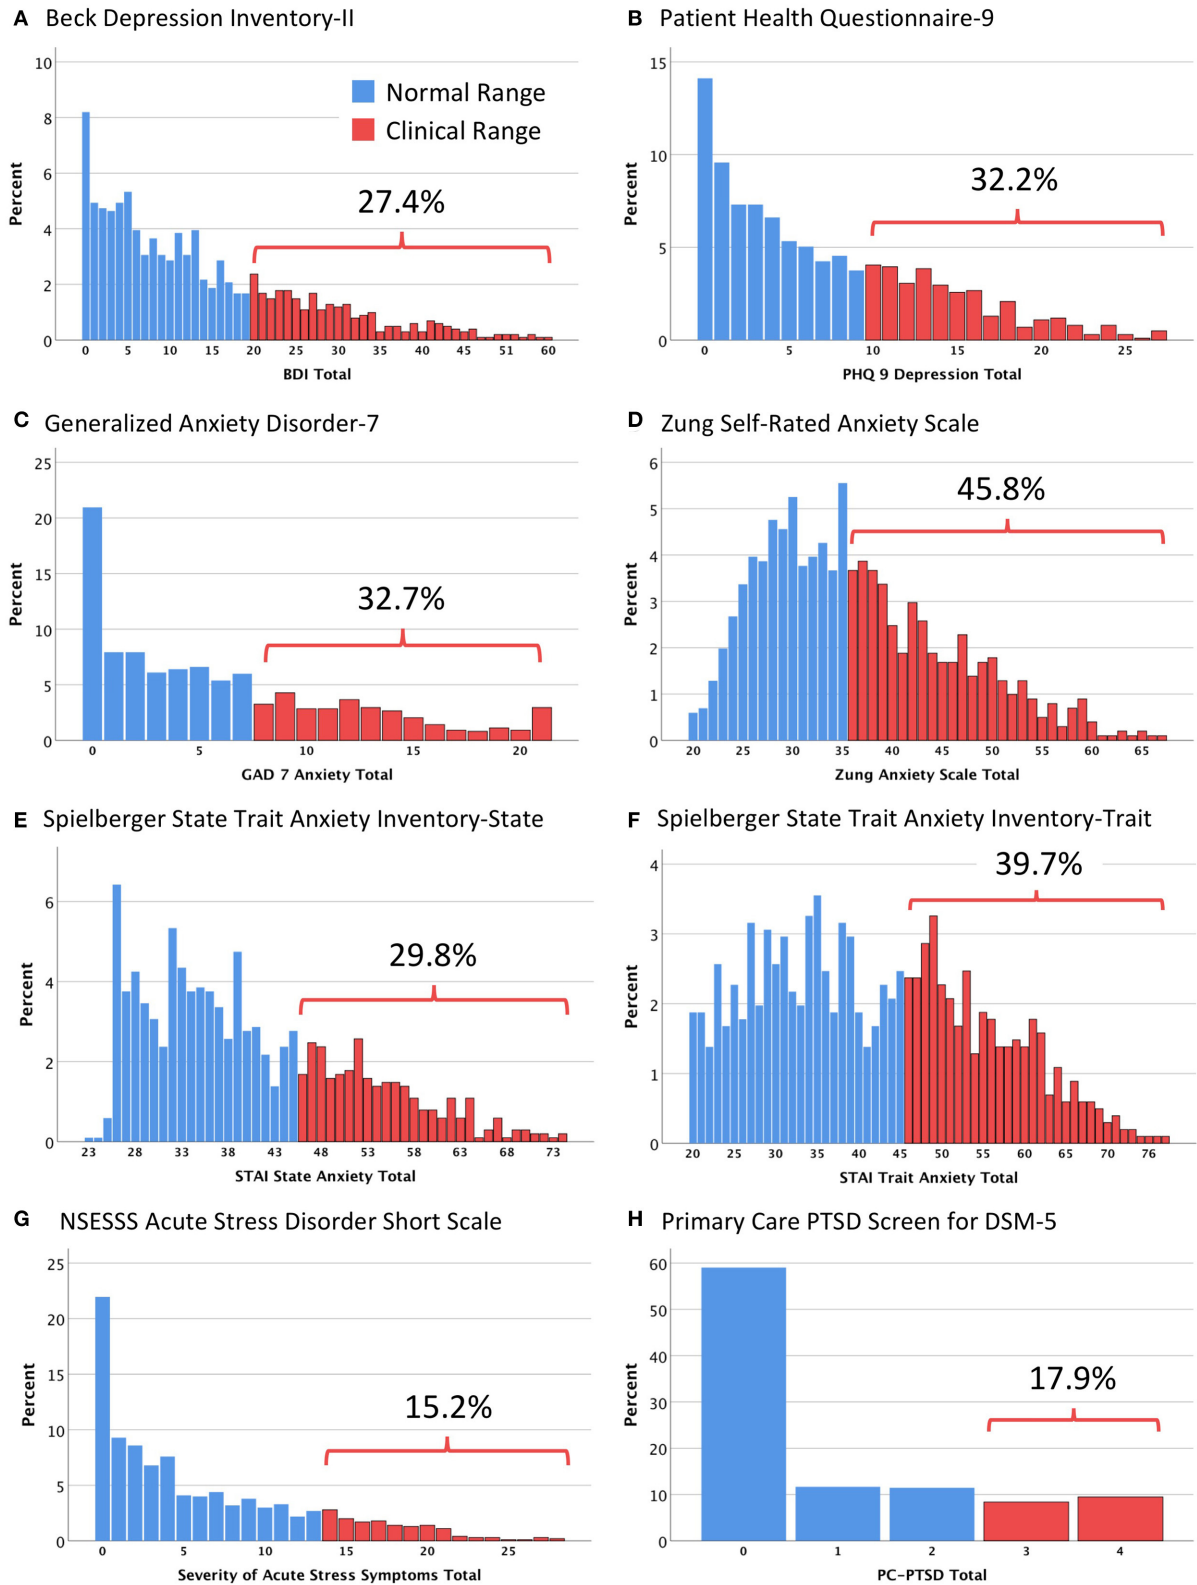

## Contributing Factors to Mental Health Outcomes

To identify some potential factors that may mitigate or exacerbate mental health problems during the pandemic, we queried participants on a series of questions related to concerns about COVID-19 (see **Table 1**). While it is acknowledged that no single set of variables will provide a comprehensive explanation of mental health issues, we selected a set of items focused on COVID-19 concerns that we believed would likely play a role in mental health responses to the pandemic. This approach, using background knowledge to aid in variable selection is considered to be an accepted approach to regression analysis (32). For the sample as a whole, a total of 28 potential variables of interest were initially included based on their relevance to pandemic-related concerns at the time, including fears of the virus itself, being in close proximity to someone with the virus, perceived social support, daily activities, alcohol consumption, and basic demographics. The analysis included the asterisked items in **Table 1**, as well as variables assessing job loss due

to the pandemic and insomnia severity. These 28 variables were entered into a binomial multiple logistic regression with forward selection to predict the likelihood of meeting positive screening criteria for each of the 10 mental health outcome variables with published cut-offs (see **Table 2**). The variables surviving selection for each model are listed in **Table 3**. The most significant predictors of meeting criteria for moderate to severe depression on the BDI-II and the PHQ-9 included worry about the ability to financially support oneself or family, feeling socially isolated, and greater alcohol use, while spending more days each week outside in the sunshine and feeling that one had enough social support appeared protective against depression. As evident in **Table 3**, while there were a number of factors associated with screening positive for an anxiety disorder on the GAD-7, Zung SRAS, STAI-S, and STAI-T, the most consistent predictors across measures included endorsing worry about the ability to financially support self or family, feeling socially isolated, and problems with insomnia, while spending more days per week outside in the sunshine appeared most consistently protective. The probability of meeting criteria for acute stress or post-traumatic stress reaction on the NSESSS or PC-PTSD was greatest among those reporting worry about financial problems, feeling socially isolated, trusting others less, and endorsing more problems with insomnia. Finally, screening positive for suicidal ideation on Item 9 of the BDI-II and PHQ-9 was most associated with endorsing financial worries, greater alcohol use, and problems with insomnia, while protective factors against suicidal ideation included male sex, older age, and feeling that one had enough social support to get through the crisis.

## DISCUSSION

The reported prevalence of mental health problems during the first weeks of the pandemic response in the U.S. was notably higher than expected based on general population

**FIGURE 1 |** Histograms showing the distribution of scores on the eight major mental health assessment questionnaires. **(A)** Beck Depression Inventory-II (BDI); **(B)** Patient Health Questionnaire-9 (PHQ 9); **(C)** Generalized Anxiety Disorder-7 (GAD 7); **(D)** Zung Self-Rated Anxiety Scale; **(E)** Spielberger State Trait Anxiety Inventory-State (STAI State); **(F)** Spielberger State Trait Anxiety Inventory-Trait (STAI Trait); **(G)** NSESS Acute Stress Disorder Short Scale; **(H)** Primary Care PTSD Screen for DSM-5 (PC-PTSD). Bars represent the percentage of participants obtaining a particular score. Each histogram divides the sample into those who met published cut-off points for clinical significance (blue, normal range; red, clinical range).

<sup>†</sup> Significant at false discovery rate (FDR) correction,  $p < 0.05$ ; Mean comparisons corrected for prior income, formal educational attainment, and potential exposure to COVID-19 (i.e., personally showing symptoms of COVID-19; someone in household diagnosed with COVID-19).

estimates collected over the decade prior to the pandemic. Prior research has estimated that the 12-month prevalence for mental health problems in the general population to be approximately 9.3% for any major depressive episode, 2.9% for GAD, and 4.4% for PTSD (30), while reported suicidal ideation ranges from 2.0 to 3.7% (31). Our findings suggest that the prevalence of probable mental health problems at this early phase of the pandemic was higher than estimates from prior years. Consistent with other contemporaneous research (33), we found that major depression was 2.9–3.5 times higher than before the pandemic; GAD 10.3–15.8 times higher; and acute-stress/post-traumatic stress 3.5–4.0 times higher. Moreover,

suicidal ideation was found to be 4.8–8.8 times higher than prior population estimates. It should be kept in mind that brief screening methods such as those used here may tend to overestimate mental health prevalence rates relative to gold-standard clinical interviews (34), and that the comparison data were, in many cases, collected years earlier. Nonetheless, with due consideration to this risk, the magnitude of the findings raise serious concerns about the mental health status of the general U.S. population during the early phase of the COVID-19 pandemic.

As a result of necessary and vital efforts to slow the spread of the novel coronavirus, non-essential businesses were closed

and tens of millions of Americans found themselves out of work. Consistent with the unemployment data from the first month of the shutdown restrictions, 17.4% of the participants in this study reported having lost their primary job as a direct result of the COVID-19 pandemic. While mental health problems were notably high for the sample as a whole, those who lost their primary job directly as a result of the pandemic consistently showed greater severity across all measures of

depression, anxiety, and stress responses. The prevalence of clinically significant mental health problems was 1.5–1.7 times higher among those who reported a COVID-19-related job loss than those who did not report such a loss. Large meta-analyses have shown that mental health problems are about twice as prevalent among individuals who are unemployed than those who are employed (35). Our findings suggest that the difference in the rates of mental health problems between those who did

and did not lose their jobs appears to be very similar to those of prior studies, but perhaps slightly smaller in the magnitude of difference, probably due to elevated rates of general pandemic-related concerns even among those who did not experience a COVID-related job loss. Unemployment and financial insecurity are well known contributors to poorer mental health, including depression and suicide (6). Our data are consistent with the existing literature and suggest that the rise in unemployment during the pandemic is associated with significantly elevated mental health problems.

For the sample as a whole, poorer mental health outcomes tended to be predicted by greater worry about the ability to financially support oneself or loved ones, feeling socially isolated, greater severity of insomnia symptoms, and consuming more alcohol. On the other hand, consistent with prior research, protective factors included spending more days per week outside in the sunlight, perceiving enough social and emotional support to get through the crisis, and older age. The contributory role of each of these factors is not surprising and all have been supported by considerable research (13, 36–43). In particular, numerous studies suggest that younger age groups have exhibited greater mental health problems as a result of the pandemic (40–43). Ways to encourage safe outside activities and facilitate social and emotional support need to be explored and encouraged to help individuals maintain resilience and wellbeing during the pandemic stay-at-home period.

How can these data inform psychiatric care and public health policy? The data suggest that subjective reports of financial worry represented the most consistent and predictive factor associated with meeting criteria for clinically significant mental health problems. Because of the extraordinarily high level of job loss produced as a direct consequence of the pandemic response, these findings suggest that efforts to address the personal financial impacts of the pandemic are going to be pivotal contributors to averting an impending mental health crisis. Social isolation and a sense of insufficient social support each also contributed significantly to mental health problems. This is consistent with other data suggesting that loneliness has increased during the course of the pandemic, and is associated with suicidal ideation and other mental health issues (36, 44, 45). Clearly, any successful psychiatric mitigation strategy will need to address the profound issues surrounding the current reduction in face-to-face human interaction and the widespread experience of loneliness (46). Problems with insomnia were also highly predictive of poorer mental health, suggesting that sleep assessment should be incorporated into routine clinical contacts and behavioral and medical efforts aimed toward facilitating better sleep health should be a priority (47). Further, suicidal ideation was predicted by greater alcohol intake in combination with financial worries. This is particularly concerning, as recent evidence suggests that alcohol purchases, consumption, and dependence behaviors increased dramatically for those under lockdown during the first 6-months of the pandemic (39, 48, 49). For those at risk of suicidal ideation, alcohol intake should be minimized/avoided (5). Finally, spending more days outside in sunlight was frequently a predictor of positive mental health outcomes. Light exposure is important for enhancing mood and maintaining a healthy sleep schedule (50). Even during prolonged

stay-at-home mandates, it is recommended that individuals find ways to increase daylight exposure and, when appropriate, to engage safely and responsibly in appropriately socially distanced outdoor activities to maintain mental health and wellbeing.

A small, but interesting finding is also worthy of note. In **Table 3**, we found that scores on the GAD-7 were lower among individuals who also reported that they lived with someone in the household who had been diagnosed with COVID-19. We interpret this counterintuitive finding as the effect of seeing COVID-19 first-hand, which may have reduced anxiety over the unknown. During the early weeks of the pandemic, not much was known about the virus, which led to much speculation and widespread worry. Since the vast majority of people who contract COVID-19 tend to be asymptomatic or experience only mild illness, the experience of direct exposure to someone who has been diagnosed and potentially recovered may actually have reduced their anxiety by making the illness concrete. Of course, this is *post-hoc* speculation, and will require further research.

While the present sample was collected to be representative of the general U.S. population, it is important to keep in mind that the data may not be representative of the mental health responses in other areas of the world. COVID-19 has affected every country on the globe, but the response to the pandemic has been different across cultures. For instance, cultures that adhere to tightly to social norms appear to have fared much better with regard to the number of COVID-19 cases and deaths than cultures that adhere much more loosely to such norms (such as the U.S.) (51). Consequently, the willingness to accept the necessity or legitimacy of the government lockdowns and their repercussions on social or occupational functioning may play a role in how job loss may be perceived and how it may affect mental health. The present research does not directly address this issue, but it will be one that is important for further study. In the meantime, the generalizability of these findings to other cultures with different values should be considered as tentative until validated with further research in other countries around the world.

This study was limited by its use of self-report measures and online questionnaires rather than in-person clinical interviews. Future work will involve more extensive clinical interviews and longitudinal data collection to monitor changes during the course of the pandemic. Furthermore, at the time when these data were first collected, there were no readily available validated COVID-19 metrics to assess mental health issues, which is a clear limitation. Since that time, validated metrics such as the Fear of COVID-19 Scale have become available (52), and are recommended for use in future COVID-19-related studies. The present findings are also limited by the fact that most of the large epidemiological samples to which we compared our findings were collected some time ago and may differ somewhat from the demographics of the current sample. Population prevalence rates for various disorders change over time and so it is possible that our findings overestimate the prevalence of these mental health issues. Additionally, the questionnaires we used were generally designed for screening purposes rather than comprehensive psychodiagnostic assessment. Such metrics are often designed for high sensitivity relative to specificity, and may lead to an overestimation of the prevalence of certain disorders (34).

These limitations notwithstanding, the present findings strongly suggest that the U.S. population experienced extraordinary mental health concerns in the first weeks after nationwide pandemic restrictions were enacted (14). It is conceivable that these mental health problems will persist or even increase in the coming months and years as the long-term occupational and personal financial fallout from the pandemic continues to be realized. Large scale efforts to mitigate the effects of financial instability and facilitate social connectedness will be crucial to minimizing the long-term impact of the pandemic on mental health.

Muhamad AB, Pang NTP, Salvaraji L, Rahim SSSA, Jeffree MS and Omar A (2021) Retrospective Analysis of Psychological Factors in COVID-19 Outbreak Among Isolated and Quarantined Agricultural Students in a Borneo University. *Front. Psychiatry* 12:558591. doi: 10.3389/fpsy.2021.558591

**Introduction:** Much has been known about the psychological issues that can emerge in people who are quarantined and unable to move freely. The COVID-19 pandemic has no contrast from previous outbreaks like SARS and MERS regarding their ensuing worries and boosted anxiety levels. This article seeks to examine the unique psychological changes that occur in students who have been quarantined inside a university campus and assess sociodemographic factors associated with certain psychological factors.

**Methodology:** The data was collected from students in an Agricultural Campus. In the first phase, the factor structure of the modified National Index Psychological Wellness (NIPW) was acceptable, and to establish statistical parameters for validation an exploratory factor analysis was done. In the second phase, Independent *T*-tests, ANOVA, and Hierarchical Multiple regression were performed. Data were analyzed using the Statistical Package for the Social Sciences (SPSS) version 26.0.

**Result/Discussion:** A total of 46 male and 76 female students enrolled in this study. The Bartlett's test of sphericity was significant ( $p < 0.001$ ) and the Kaiser–Mayer–Olkin measure of sampling adequacy for the AUDIT-M was 0.901. The Cronbach's alpha of the entire modified NIPW was 0.657 which suggests reasonable internal consistency and subscales between 0.913 and 0.924. Raw scores of 12 positive items were higher for the quarantined group except for "I can do daily routines," "I understand what happens," and "I understand the action that is performed is fair." Raw mean scores of eight negative scoring items were higher in the quarantined group, except for "I feel angry" (2.88 vs. 2.89 for non-quarantined group). There were statistically significant differences between year groups for the questions "I understand what happens," "I understand the action that is performed is fair," and "I think everyone is good."

**Conclusion:** Movement control orders or compulsory quarantine orders can be distressing and may cause understandable psychological sequelae. Holistic

management of a quarantine center that addresses the needs and health of an individual student will give a positive impact on psychological wellness. Quarantining facilities can be a place of positivity, allowing people to live a shared experience together, provide peer support for each other, and give each other hope.

**Keywords:** sociodemographic factors, quarantine status, indices of psychological, wellness, Borneo Agricultural Campus

## INTRODUCTION

COVID-19, a pandemic from the coronavirus family, was first described in December 2019 in China. Malaysia had its first confirmed case on the 25th of January 2020. Subsequently, as the cases continued to rise in March 2020, Malaysia was placed under a strict nationwide movement restriction order (MRO) beginning 18 March 2020 in order to flatten the curve via state-sanctioned social distancing (1).

Hence, public university students who are studying far away from their hometowns are put in a unique quandary. The majority of them, especially those studying in Sabah and Sarawak, are a 2.5 h flight away from home. Due to flight frequencies being dramatically reduced and strict movement controls between West and East Malaysia, a lot of them have been effectively isolated in the campus (2). Furthermore, there are a small subgroup of students who have been forced to quarantine for 14 days, as they are either “persons under investigation” due to possible COVID-19 symptoms, or “persons under surveillance” due to direct or indirect contact with an individual suspected of COVID-19. In this case, quarantine involves separating groups who are potentially exposed to the disease, hence reducing the risk of infecting others. Isolation, on the other hand, is physical separation of individuals confirmed to be infected by the contagious disease (3). This is further contrasted with students who are merely subjected to the standard movement control order (MCO), who are free to go to buy food and provisions individually but otherwise cannot travel in excess of 10 km. In this case, the population of the agricultural campus was largely under MCO, with a small group subjected to quarantine, and none under isolation. This compulsory quarantine practiced in the agricultural campus is different in nature from movement restriction, as individuals under nationwide movement restrictions are still allowed to go out to purchase food and daily necessities while practicing sufficient social distancing. Quarantined students, on the other hand, were not allowed to leave their quarantine centers, and hence everything was delivered contactless to their doorsteps. The term quarantine and isolation themselves are sometimes used interchangeably, but actually carry different meanings. Both terminologies involve physical separation from the community.

There have been many literatures detailing the psychological issues that can emerge in people who are unable to move freely, or even worse, quarantined (4). However, there is still scant literature for psychological sequelae of COVID-19 quarantining and movement restrictions globally. Previous studies done with Severe Respiratory Syndrome (SRAS) and Middle East Respiratory Syndrome (MERS) survivors suggest that levels of worry and anxiety are heightened (5). As a result of quarantined

cohort study with SARS survivors revealed DSM-IV psychiatric disorders was 58.9%. Furthermore, almost 25% of SARS survivors experienced Post-Traumatic Stress Disorder (PTSD) and 15.6% had significant depression (6). Older adult suicide deaths, as a proxy for diagnosable psychiatric disorders, was reportedly higher among individuals affected by SARS in 2003 and 2004 (7). There was also lower quality of life highlighted among MERS survivors that was influenced indirectly by longer duration (8). However, much of this data examined the population as a whole, instead of specifically examining the differences between the quarantined group and movement-restricted individuals.

There has been ample literature detailing the psychological issues that can emerge in people who are unable to move freely, or even worse, quarantined, including depression, insomnia, stress, anxiety, anger and fear (9). The focus on measures to prevent spread of COVID-19 may distract public attention to mental health issues, which can lead to long term health problems and even stigma if unchecked. Management of COVID-19 should hence be inclusive not only of the treatment and prevention of this pandemic, but also the mental health impact of patients and general population. One of the non-pharmacological approaches in reducing mental health issues in the population during this pandemic includes educating them to practice healthy lifestyle such as exercise. Physical activity has significant positive impacts on psychological health (10) and can enhance self-esteem, and reduce depression, anxiety, and stress.

An operational survey was performed among the students in the agricultural campus, to assess whether or not the students inside quarantine were experiencing similar, not elevated, psychological distress compared to those outside quarantine. As a result, it assessed whether those who were living outside and inside quarantine were having the same psychological experience.

The objective of this study is 2-fold. Firstly, it was to assess the levels of psychological well-being on 20 different domains. Secondly, it was to assess whether three sociodemographic factors—gender, year of study (a corollary to age), and quarantine status were associated with any differences in well-being on those domains. If the physical and psychological support for those in quarantine were similar to those outside quarantine, and there was no real deficit of experience being inside quarantine, it was then hypothesized that there should be no statistical difference in well-being, whether the individual was in or out of quarantine.

## METHODOLOGY

This was a retrospective analysis of data that was collected for operational purposes in the Agricultural Campus of a Bornean university during the beginning of the Movement Control Order

in Malaysia. Hence, it was not possible to select a questionnaire that was most suited for research purposes, and the researchers did not have the opportunity to intervene in the methods of selection of respondents. Students of the agricultural campus were approached by the operational team to take part in the questionnaire and provided written informed consent for participation. The inclusion criteria were as follows:-

- Above 18 years of age.
- Willing to participate in the study.
- Able to read and converse fluently in Malay language.

Apart from not consenting to join the study, there were no explicit exclusion criteria for the study, as the original data set was collected for operational, not research purposes, so no effort was made to exclude acute medical or psychiatric illness. The study participants completed two separate questionnaires: firstly, a simple demographic questionnaire containing age, gender, year of study, and whether or not the individual was quarantined or allowed to move freely; and secondly, a 20-item questionnaire adapted from the National Index of Psychological Well-being Malaysia (NIPW). Both questionnaires were in Bahasa Malaysia, the national language of Malaysia. The original NIPW is a Malay language questionnaire designed by the Public Services Department of Malaysia to assess psychological well-being for operational purposes in various governmental departments. It is used as a standard measure of well-being in University Malaysia Sabah, the site of this study. The original NIPW contains 36 questions about various aspects of wellness. For the purposes of the operational data collection, only 10 of the original questions were adopted directly, whereas eight other questions were adapted from the NIPW, and two new questions which did not measure items related to COVID-19 were added: "I feel lonely" and "I feel that the actions taken so far were reasonable." This yielded a 20-item modified version of the NIPW. Then the questionnaire was distributed in google form, for which the students were given a link. Those answering the questionnaire were required to log in via email, and their student's registration number was then inserted. After answering the questionnaire, they were unable to repeat or modify their answers once they logged out.

Data analyses were conducted using the Statistical Package for the Social Sciences version 26.0 (SPSS, Chicago, IL) by independent researchers unrelated to the operational team to reduce bias. In the first phase of data analysis, in order to examine if the factor structure of the MODIFIED NIPW was acceptable and to establish statistical parameters for validation, an exploratory factor analysis was done. Principal component analysis with direct oblimin rotation was done to explore the factor structure of the MODIFIED NIPW. Adopting eigenvalues  $>1$  and examining the scree plot were used to assess optimal number of factors. Examination of the pattern matrix was performed to examine respective factor loadings, and all factor loadings with correlations  $<0.3$  were excluded. Cronbach's alpha was used to assess the internal consistency of MODIFIED NIPW and its embedded subscales. Measures of concurrent validity were unfortunately not able to be done, as this was a retrospective analysis of collected data.

In the second phase of data analysis, the data was assessed using descriptive statistics, including skewness and kurtosis to examine for assumptions of normality. Independent *T*-tests were performed to examine if there was any significant difference in scores for all 20 items of the MODIFIED NIPW for gender and quarantine status. ANOVA was performed to examine if there was any significant difference in scores for all 20 items of the year of study (divided into Year 1, Year 2, Year 3, and postgraduate). Bonferroni correction was further performed after ANOVA to assess if any significant difference remained. Correlations were calculated between all 20 items of the scale. Hierarchical multiple regressions were performed for all 20 items of the MODIFIED NIPW, adjusting hierarchically for age, gender, and quarantine status.

Permission to conduct the retrospective analysis was obtained from the Medical Ethics Committee of University Malaysia Sabah. There was no conflict of interest or sponsorship from pharmaceutical companies. However, this project was performed as part of an operational screening for UMS students, so it was impossible to ensure that all participants were blinded against each other's answers.

## RESULT

### Descriptive Analysis of Data

A total of 122 participants were enrolled. There are 46 male and 76 female students. Skewness and kurtosis for all variables was  $<2.00$  suggesting a normal distribution. In terms of education levels, 100% of the respondents had completed secondary education, and there were 16 respondents that had completed first degree education.

### Factor Analysis

The Barlett's test of sphericity was significant ( $p < 0.001$ ) and the Kaiser–Mayer–Olkin measure of sampling adequacy for the AUDIT-M was 0.901 indicating acceptable sampling (11) (Table 2). Principal component analysis produced three factors  $>1.000$  when examining the eigenvalues. However, the third factor in the model had an eigenvalue barely exceeding 1.000. The second factor had an eigenvalue of 2.911, with the first two factors already accounting for 59.64% of the variance.

When examining the scree plot (Figure 1), a two-factor appears to be suitable too, as it is above the kink in the plot. Hence correlation matrices for the two-factor solution was examined.

When a two-factor solution was used, after excluding all factors with coefficients of 0.3 and below (Table 1). The first factor, accounting for 45.116% of the variance, consisted of the 12 questions with "positive" responses, e.g., "I am happy," and was called the "positive factor." The correlations were all  $>0.458$  and the Cronbach alpha for the first factor was 0.913. The second factor consisted of all the eight questions with "negative" responses, e.g., "I am angry," and was called the "negative factor," accounting for 14.56% of the variance. The correlations were all  $>0.590$ , with a Cronbach alpha of 0.924.

Observing the pattern matrix for correlations (Table 2), only one item in the "Positive factor": "I am happy" had correlations in both factors. On the other hand, also, only one item in the

**FIGURE 1 |** Scree plot for factor analysis of PWI-M. A two-factor appears to be suitable since it is above the kink in the plot.

**TABLE 1 |** Two factor solution analyze of questionnaire.

Component	Total	Initial eigenvalues		Extraction sums of squared loading			Rotation sums of squared loadings
		% of variance	Cumulative %	Total	% of variance	Cumulative %	Total
1	9.023	45.116	45.116	9.023	45.116	45.116	7.297
2	2.911	14.555	59.670	2.911	14.555	59.670	7.020
3	1.111	5.557	65.227				
4	0.974	4.868	70.095				
5	0.956	4.781	74.876				
6	0.736	3.678	78.5547				
7	0.550	2.749	81.303

18	0.162	0.812	98.786				
19	0.128	0.638	99.424				
20	0.115	0.576	100.000				

All factors with coefficients of 0.3 and below.  
Extraction Method: Principal Component Analysis.

“Negative factor”: “I am angry” had correlations in both factors. Otherwise, none of the other 18 questions had correlations in two factors. When examining a three-factor model, five different questions had cross-correlations across three different factors, so it was less suitable as a model.

### Internal Consistency

Cronbach’s alpha of the entire modified NIPW was 0.657 which suggests reasonable internal consistency. The Cronbach alpha of the subscales were between 0.913 and 0.924. Concurrent validity was not able to be performed in this study, as it was

**TABLE 2 |** Pattern matrix of questionnaire.

No.	Questionnaire	1	2
1.	I feel safe	0.676	
2.	I feel happy	0.458	-0.500
3.	I feel appreciated and protected	0.746	
4.	I feel lonely		0.819
5.	I feel negative		0.832
6.	I feel sad		0.816
7.	I feel disappointed		0.892
8.	I feel moody		0.773
9.	I'm feeling worried		0.701
10.	I'm feeling depressed		0.835
11.	I feel angry	-0.371	0.590
12.	My life is very good	0.687	
13.	I can do daily routines	0.550	
14.	I'm satisfied about my life right now	0.662	
15.	I can accept it as it is	0.711	
16.	I have something important in contributing to the country	0.589	
17.	I always involve myself in the community	0.706	
18.	I understand what happens	0.791	
19.	I understand the action that is performed is fair	0.780	
20.	I think everyone is good	0.775	

One item in the "Positive factor": "I am happy" had correlations in both factors. One item in the "Negative factor": "I am angry" had correlations in both factors. Extraction Method: Principal Component Analysis. Rotation Method: Oblimin with Kaiser Normalization. A Rotation converged in seven iterations.

I understand the action that is performed is fair	3.83 (1.018)	3.71 (1.273)	0.116 (-0.322, 0.554)	0.522	0.602
I think everyone is good	3.67 (1.034)	3.5 (1.238)	0.174 (-0.257, 0.605)	0.799	0.426

The t-test showed no significant difference between gender groups.

a retrospective analysis of a data set that was collected for operational purposes.

### Comparison of Means

There was no significant difference between the mean scores for all 20 questions, between quarantined and non-quarantined groups (Table 3). In the analysis of the 12 positive scoring items, the raw scores were higher for the quarantined group except for the following three items: (a) "I can do daily routines"; (b) "I understand what happens"; and (c) "I understand the action that is performed is fair." However, there was no statistical difference between both groups as mentioned. For the eight negative scoring items, similarly, all the raw mean scores were higher in the quarantined group, except for "I feel angry" (2.88 vs. 2.89 for non-quarantined group). Again the t-test showed no significant difference between gender groups (Table 4).

As there were four different year groups, ANOVA analysis was performed (Table 5). There were statistically significant differences between year groups for three of the questions: (a) "I understand what happens"; (b) "I understand the action that is performed is fair"; and (c) "I think everyone is good." Bonferroni correction and the differences between the groups were no longer significant except in between Post-graduate and Year 3 students for "I think everyone is good" (Table 6).

### Multiple Regression

No significant difference was encountered after hierarchical multiple regression.

## DISCUSSION

One of the main purposes of performing the initial operational study was to assess whether the efforts to provide a pleasant quarantine experience, both infrastructural and psychologically, were sufficient. From the results, it appears that there is no statistically significant difference in all psychological indices measured between quarantined and non-quarantined groups. Pandemics are known to affect more than the physical health of the population; there are also mental health sequelae secondary to poor physical health. Therefore, it is important to maintain good physical health. Before COVID-19, individuals can focus freely on their exercise and physical activity to maintain healthy lifestyles. However, during the Covid-19 pandemic, this is significantly reduced especially for those with underlying chronic illness (12). The total energy expenditure and physical activity are significantly reduced may be due to containment and quarantine. This is due to lack of equipment, lack of large spaces, and absence of personal trainers. This in turn may cause short- and long-term health issues especially involving cardiorespiratory health and may contribute to difficulties coping with stress and anxiety during the COVID-19 pandemic (3, 10, 13). Effective strategies on promoting physical activity and exercise, hence, should be considered and implemented by either developing new or utilizing and modifying existing programs with reference to particular standard operating procedures (SOP).

It is prudent for health authorities to ensure adequate, clear-cut, and strong bases for quarantine (14). Many factors, however, determine individuals' compliance to quarantine measures.

	Year 2	3.83 (1.107)		
	Year 3	3.22 (1.177)		
	Postgraduate	4.57 (0.535)		

There were statistically significant differences between year groups for questions "I understand what Happens," "I understand the action that is performed is fair," and "I think everyone is good".

These factors are largely classified into duration of quarantine and motivation to comply (15). In this sense, two questions in this operational study actually measure the latter: "I have something important in contributing to the country" and "I always involve myself in the community."

However, in this study, it was shown that not only did individuals comply to quarantine measures, but on raw scales of psychological wellness, their scores were statistically similar to those out of quarantine. No doubt these results could have come due to the small sample size ( $n = 14$ ) of the quarantined group. However, as this is an analysis of an operational study, and the entire quarantined group was captured in this study, there is no justifiable ethics basis in artificially quarantining more individuals to have statistically significant results, so this is a research limitation of the study.

Looking from another angle, it is arguable that the individuals in quarantine were given an experience virtually identical to those not under quarantine. They were all housed in double-story houses with living rooms and front yards, and food,

provisions and sanitary items were delivered to their doorstep on demand. Hence, physically, they may have even been more well off compared to those out of quarantine, who had to use their own money to purchase food and provisions, as they did not have any physical restrictions. Financial restrictions are a known factor for university student stress (15). Hence, this study demonstrates that it is crucial that quarantine facilities are made as indistinguishable as possible from normal life to ensure no difference, be it statistically or operationally, in psychological wellness between quarantine and non-quarantine individuals.

Psychologically, there is of course anxiety from being under investigation due to contact with COVID-19 individuals, and quarantine measures may actually have alleviated their anxiety more than standard home quarantine outside. They may also be afraid of being infected during the quarantine period, which is possible (16). In crisis, isolation is a big factor for individuals to psychologically decompensate. Conversely, in the agricultural campus, the students who were quarantined were allowed to live together in reasonably luxurious facilities. This would have

Bonferroni correction and the differences between the groups were no longer significant except in between Post-graduate and Year 3 students for "I think everyone is good".

\*The mean difference is significant at the 0.05 level.

provided the necessary peer support, sharing of lived experience as COVID-19 people under surveillance or investigation, which

they could not have had face to face if they had been home quarantined in their respective rooms at home. Hence there is

actually a sense of collective support that came out of being lodged in the quarantine center, which would have blunted the higher levels of anxiety from being suspected of being infected with COVID-19 (17). The duration of quarantine, otherwise, will increase problems in mental health, especially Post Traumatic Stress Disorder (PTSD) (18).

In comparison with their peers outside in MCO, they would have to stay in their own rooms, and be confined to their own four walls and subsist on virtual connections to talk to other individuals, as mass gatherings were strictly prohibited during the MCO. Hence, under these circumstances of collective restriction of movement, it would stand to reason that being quarantined formally is not actually as distressing or restrictive as it would be in peacetime. Moreover, quarantined individuals were given access to tele counseling services, who adopted groups of five students for individual consultations. Hence the provision of psychological services is also very crucial to reduce psychological distress in quarantine (17).

No doubt, there are other potential more insidious sequelae of quarantine or isolation that can sometimes occur. It is human nature that individuals may develop malingering or factitious disorder to expedite escape. Factitious disorder itself is sometimes difficult to diagnosed and sometimes may co-exist with true medical problems (19). From a statistical point of view, this poses a potential major research limitation, this may overestimate the presence of psychological distress in a quarantined or movement-restricted population. However, in this operational study, the focus was on comparing levels of wellness or distress rather than measuring psychological parameters against established cut-off points, as the instrument adapted did not have validated cut-off points. Qualitatively, rumor surveillance performed by doctors on the ground suggested that there was no increase in diagnosable mental disorders, as a walk-in psychiatry service was provided and tele counseling was offered to all quarantined individuals as secondary prevention.

Malingering, however is more related to background history of mental health issues or childhood health conditions (19). The other parallel situation to quarantine is that of being imprisoned; however, it is rare for quarantined or isolated individuals to develop borderline personality traits as compared to prisoners. This difference in prison settings may be due to other associated factors such as torture, personality of residents, hygiene, conduciveness, and others.

On the other hand, if malingering of psychiatric illness is present, it needs to be interpreted and judged very meticulously. Patients' symptoms need correlation with the risk factors and other history as per the standards of that illness. These subjective symptoms then require correlation with physical signs. Then further diagnoses can be established with adjunct investigations. For example, common clinical condition such as acute appendicitis, may even be missed following poor clinical judgement and an overly high index of suspicion of factitious illness (20). A diagnosis of a true psychiatric disorder needs to be performed after thorough exclusion of organic or biological disorders, as per practice within or without times of quarantine or movement restriction.

Such prolonged quarantine can no doubt result in increased fears of Covid-19 (21, 22), and have been associated with depression, anxiety, and stress in similar populations (23–25). Hence, it is crucial that early preventative measures at the university level be undertaken to increase surveillance at the alert phase (26, 27), especially taking into account the impact of digital learning on student burnout and mental health (28). Crucially, brief psychological interventions also need to be undertaken to reduce psychological morbidity, especially in rural areas (29, 30). Digital interventions can also be employed to expedite monitoring of quarantine and streamline surveillance to reduce unnecessary healthcare worker man-hours (31). However, digital tools must be judiciously used, as there is burgeoning evidence that social media itself can contribute to misinformation which can complicate the psychological health of the young people involved in the aforementioned quarantine, underpinning the importance of accurate and correctly pitched health risk communication (32). Lastly, it is imperative that culturally sensitive tools be employed to measure psychological distress to ensure accurate capture of psychopathology (33, 34).

A major limitation of the study is that we were not able to select a specific target of respondents, but rather considered any student on campus that complied with the three generic inclusion criteria, thus curtailing the generalisability of the findings. Due to the abrupt lockdown enforced by governments without warning, we were highly limited by what kind of respondents we could recruit. Hence, we had to opportunistically employ the undergraduate students who were suddenly locked down, which gave us real time data into the negative sequel of such abrupt measures. Though we were not able to include other individuals outside the campus to create a more homogenous sample, the respondents we were able to access in this time of great chaos and uncertainty gave us a valuable snapshot of the acute psychological states of acutely quarantined students at a historical moment in the time of the pandemic.

## CONCLUSION

Movement control orders or compulsory quarantine orders can be distressing and may cause understandable psychological sequelae. However, times of stress can also be a period of growth, and it is incumbent upon quarantining parties to ensure that the distress caused by both physical quarantining and the psychological effect of worries and fears regarding being suspected of having COVID-19 or being in contact with someone with COVID-19 is balanced out judiciously with both reasonable and comfortable physical amenities, telecommunications support, and psychological support. This paper demonstrates that in an agricultural campus in Borneo, on gross measures of psychological wellness covering both positive and negative items, there was no statistical difference between a quarantined and non-quarantined group. This reinforces the need to quarantine judiciously and quarantine well, under luxurious and privileged conditions, with ample amenities and life necessities. When properly done, quarantining facilities can

be a place of positivity, allowing people to live a shared experience together, provide peer support for each other, and give each other hope.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

Permission to conduct the retrospective analysis was obtained from the Medical Ethics Committee of University Malaysia Sabah. Students of the agricultural campus were approached by the operational team to take part in the questionnaire and provided written informed consent for participation.

The worldwide health emergency caused by COVID-19 is a new challenge for humanity which individuals respond to in a diversity of ways. The type of coping people use in such a situation could lead to positive or negative consequences to their health. Our objective was to analyze the use of coping strategies in the general population with attention to sociodemographic variables, and to test the capacity of these strategies for mediating in repercussions on mental health. The 1,160 adults who participated in this study answered the Cognitive Emotion Regulation Questionnaire (CERQ-S) and General Health Questionnaire (GHQ-28). The data were collected in a CAWI (Computer Aided Web Interviewing). The results suggest that the coping strategies they used the most differed depending on sociodemographic characteristics, such as age, sex and education. Furthermore, two mediation models were estimated for positive and negative coping strategies in the relationship between the presence of COVID-19 near them and mental health. The “negative” coping strategies were found to exert an indirect effect as mediators in the impact that COVID-19 positive cases near them had on their health. The consequences to mental health of the impact of coping with adverse situations should not be underestimated and it is important to design programs to educate the population in coping strategies that promote their health.

**Keywords:** coping, health, COVID-19, adult population, well-being

## INTRODUCTION

COVID-19 has led to a worldwide health crisis without precedent. The World Health Organization (WHO) declared it a global emergency on January 30, 2020 (1). Beyond the tensions inherent to the disease itself, the governmental instructions on mass home confinement are a new situation for the Spanish population and generate concern for how people will react, and the repercussions on their mental health this could lead to. A recent review on psychological effects in samples of people in quarantine revealed associated confusion, boredom, insomnia, stress, irritability and depression, some of which continued after it was over (2). Another study by Pérez-Fuentes et al. (3) in an adult Spanish population showed that confinement brought negative consequences to their well-being and negative affect increased both perception of threat from COVID-19 and negative

mood, which in turn, increased somatic complaints (4). During the pandemic, health problems were more frequent in young people and singles (5, 6).

During adverse situations threatening well-being, such as the COVID-19 pandemic we are now going through, people use their psychological resources to cope with the situation, developing different styles and strategies. Coping can be considered an effort to reduce or eliminate the negative effects of stress on one's well-being (7). Studies have demonstrated that effective coping strategies can protect people from mental illness when faced with adverse situations (5, 8–10). And the opposite is observed with maladaptive coping strategies, which influence their mental health predisposing them to alterations such as depression and anxiety (6, 11–15), so repercussions on well-being depend on the type of coping used (3, 16).

Based on the Threats and Coping Appraisal Theory (17), it may be said that individuals who are exposed to stressful situations respond with adaptive behavior, which provide them with immediate and long-term well-being, or with maladaptive coping, which distracts or alleviates them, making them feel better temporarily, but generating psychological distress later. However, it is not clear how some coping strategies behave in this relationship with health. Adaptive strategies such as positive reevaluation and refocusing in particular do not seem to have a continued effect over time (18, 19).

The gender perspective should not be forgotten. Coping styles can differ by gender. Women use more emotional coping strategies, such as social support, which could prevent depression (20–23). And men use self-distraction and self-blame more than women (22). One of our hypotheses was therefore the presence of differences in coping strategies between men and women in a context of threat from COVID-19. It has also been confirmed that young women caregivers are the group showing the highest stress levels (22) and those who perceive strong threat from COVID-19 (24). Age is a variable which also seems to influence the choice of coping strategies (22, 25, 26) as does education (24). However, no differences in the use of coping strategies by education level were found in the study by Amazue and Onyishi (27). Therefore, the second hypothesis posed is the existence of differences in coping strategies used by age and education.

Another hypothesis tested was the existence of differences in mental health based on coping style used. The use of cognitive and prosocial behaviors was associated with fewer mental health problems (9). Other variables that could be influencing people's well-being is the existence of positive cases of SARS-CoV-2 near them or staying in places where there has been a high incidence of the disease (6, 9). Therefore, it was expected that having someone nearby diagnosed with COVID-19 would affect their mental health, with coping strategies mediating in this relationship.

The main objective of this study was to analyze the use of coping strategies in the general population with attention to sociodemographic variables, and to test the capacity of these strategies to mediate in the repercussion on their mental health.

## MATERIALS AND METHODS

### Participants

A total of 1,688 adults originally filled in the survey. After a first review, 528 cases were eliminated from the sample either because the survey was incomplete, or because incoherent or random answers were identified.

The final sample was made up of 1,160 adults residing in Spain, with a mean age of 38.29 (SD = 13.71) in a range of 18–82. Of the whole sample, 30.1% ( $n = 349$ ) were men and 69.9% ( $n = 811$ ) women, with a mean of 41.16 (SD = 14.13) and 37.05 (SD = 13.34), respectively. Of these, 47% ( $n = 545$ ) were single and 53% ( $n = 615$ ) were not.

Apart from the above, and in regard to COVID-19, participants were asked whether they had any positive cases near them. The answer of 31% ( $n = 360$ ) of the participants was positive.

### Instruments

The following instruments were used to collect the data:

An *ad hoc* questionnaire was used for collecting sociodemographic characteristics. Items were included for sex, age, marital status and whether anyone near them was COVID-19 positive.

*Cognitive Emotion Regulation Questionnaire* (CERQ) (28), Spanish version (CERQ-S) (29). This consists of 36 items answered on a five-point Likert type scale (from 1 = almost never, to 5 = almost always). It evaluates nine cognitive strategies for coping with negative situations. Reliability found for the sample in this study was: self-blame ( $\omega = 0.71$ ; GLB = 0.73), acceptance ( $\omega = 0.71$ ; GLB = 0.75), rumination ( $\omega = 0.77$ ; GLB = 0.77), positive refocusing ( $\omega = 0.86$ ; GLB = 0.85), planning ( $\omega = 0.80$ ; GLB = 0.82), positive reappraisal ( $\omega = 0.84$ ; GLB = 0.88), putting into perspective ( $\omega = 0.68$ ; GLB = 0.74), catastrophizing ( $\omega = 0.72$ ; GLB = 0.78), and other-blame ( $\omega = 0.90$ ; GLB = 0.91).

*General Health Questionnaire* (GHQ-28) (30), Spanish adaptation validated by Lobo et al. (31). This scale has 28 items with four answer choices which provide information on somatic symptoms, anxiety and insomnia, social dysfunction and depression subscales. Among the scoring methods is a Likert-type scale, where each answer is scored 0–3. The instrument's reliability in our case was  $\omega = 0.93$  and GLB = 0.94 for the whole scale, and for the each of the subscales: somatic symptoms ( $\omega = 0.86$ ; GLB = 0.89), anxiety and insomnia ( $\omega = 0.90$ ; GLB = 0.95), social dysfunction ( $\omega = 0.81$ ; GLB = 0.82) and depression ( $\omega = 0.91$ ; GLB = 0.94).

### Procedure

Data were collected in a CAWI (Computer Aided Web Interviewing) interview after snowball sampling, specifically from 1 to 12 May 2020. Participation was voluntary and before starting to answer the questionnaire, on a first page, relevant information on the study and its purpose was provided. The participants gave their informed consent by marking a box for the purpose, which then allowed them to continue with the questionnaire. They were asked to answer sincerely, and were guaranteed the anonymity of their answers.

Random or incongruent answers were detected by control questions inserted throughout the questionnaire. This study was approved by the University of Almeria Bioethics Committee (Ref. UALBIO2020/032).

## Data Analysis

The McDonald's Omega coefficient was estimated to examine the reliability of the instruments, following Ventura-León and Caycho (32). The Greatest Lower Bound (GLB) was also calculated.

Then, the *t*-test for independent samples was applied to examine the differences between groups (age, sex, marital status, education, anyone COVID-19 positive nearby) with regard to coping strategies, and Cohen's *d* (33) was used to quantify the effect size. A Pearson's coefficient correlation analysis was performed to test the relationships between the variables, and the descriptive statistics were calculated.

Finally, the various mediation analyses were performed, taking presence of a COVID-19 positive case nearby as the predictor, and coping strategy mediators, and as result variables the health subscales (somatic symptoms, anxiety/insomnia, social dysfunction and depression). JASP version 0.11.1 (34) based on lavaan was used for this (35). Bias-corrected percentile bootstrap confidence intervals were applied as suggested by Biesanz et al. (36).

## RESULTS

### Coping Strategies for Threat From COVID-19: Sociodemographic Variables

First, a negative correlation was found between age and rumination ( $r = -0.23$ ;  $p < 0.001$ ; 95% CI  $-0.17, -0.28$ ). Other correlations with age, although less intense, were observed with acceptance ( $r = -0.07$ ;  $p < 0.05$ ; 95% CI  $-0.01, -0.13$ ) and putting into perspective ( $r = -0.07$ ;  $p < 0.05$ ; 95% CI  $-0.01, -0.12$ ). When the age variable was dichotomized, taking the sample mean of about 40 as the reference, differences were found between the under 40 (or young adults) (54.8%,  $n = 636$ ) and over 40 (or mature adults) (45.2%,  $n = 524$ ) age groups. In particular, statistically significant differences were observed in rumination [ $t_{(1,158)} = 6.46$ ,  $p < 0.001$ ,  $d = 0.38$ ].

**Figure 1** shows the results of the comparison of coping strategies by sex. As observed, women scored statistically significantly higher means than men in: acceptance [ $t_{(1,158)} = -2.97$ ,  $p < 0.01$ ,  $d = -0.19$ ], rumination [ $t_{(1,158)} = -4.91$ ,  $p < 0.001$ ,  $d = -0.31$ ], positive refocusing [ $t_{(1,158)} = -3.10$ ,  $p < 0.01$ ,  $d = -0.19$ ], and putting into perspective [ $t_{(1,158)} = -3.06$ ,  $p < 0.01$ ,  $d = -0.19$ ]; while men scored significantly higher in blaming others [ $t_{(1,158)} = 2.91$ ,  $p < 0.01$ ,  $d = 0.18$ ].

By marital status at the time of data collection, differences were found between the groups in rumination [ $t_{(1,158)} = 3.77$ ,  $p < 0.001$ ,  $d = 0.22$ ], where those who did not have a partner scored higher ( $M = 11.88$ ,  $SD = 3.63$ ) than those who had a partner ( $M = 11.08$ ,  $SD = 3.61$ ). No significant differences were observed in the rest of the strategies.

Finally, by education, differences were observed between the primary/secondary education, and higher or university education

groups (**Table 1**). Specifically, differences were found in favor of the group with higher or university studies in the following strategies: rumination, planning, positive reappraisal and putting into perspective. Those with primary/secondary education had significantly higher mean scores in self-blame, catastrophizing and other-blame strategies.

### Coping Strategies and Mental Health

**Table 2** shows the correlation matrix between coping strategies and the GHQ-28 subscales. Some strategies were positively correlated with the presence of health problems. Rumination and catastrophizing in particular, were positively correlated with all the health subscales, while self-blame and other-blame were positively correlated with the presence of somatic symptoms, anxiety/insomnia and depression. Acceptance was positively correlated, although less intensely, with social dysfunction and depression.

However, positive refocusing and positive reappraisal correlated negatively with all the GHQ-28 subscales, putting into perspective was related negatively to anxiety/insomnia, social dysfunction and depression, and planning was negatively correlated with social dysfunction and depression.

### COVID-19 Nearby, Coping and Mental Health: Mediation Models

Two mediation models were proposed. In both cases, the predictor was the presence or not of a positive case of COVID-19 nearby, and as the outcome variables, the four GHQ-28 subscales. Model 1, where the mediating effect of "negative" coping strategies (considered as such based on the positive association with the presence of mental health problems) such as rumination and catastrophizing, was hypothesized. Meanwhile, in Model 2, the existence of a mediating effect was hypothesized for the "positive" coping strategies (considered as such based on the negative association found with presence of mental health problems), which were positive refocusing and reappraisal.

In Model 1 (**Table 3**), a direct effect of positive cases of COVID-19 nearby on the presence of somatic symptoms was observed. As indirect effects, both rumination and catastrophizing mediated in the impact that presence of COVID-19 cases nearby had on health. The total effects were statistically significant for somatic symptoms, anxiety/insomnia and depression.

Model 2 (**Table 4**) showed significant direct effects of the presence of COVID-19 cases nearby on somatic symptoms and anxiety/insomnia. However, this second proposal was not significant for the indirect effects of positive refocusing and reappraisal as mediators in the relationship between the presence of COVID-19 positives nearby and its impact on health. That is, the use of these strategies did not mediate or buffer the relationship between predictor and outcome variables.

## DISCUSSION

As its main objective, this study analyzed the use of coping strategies by the general population, with attention to sociodemographic variables, testing the capacity for mediation

of these strategies in repercussions on mental health. Coping strategies focused on emotion, such as rumination, can be maladaptive, since the attempt to get more information on

the dysphoric mood causes one to think repeatedly about the same thing, without attempting to solve the problem (13). Our results support the first hypothesis posed, since it

GQ-SS, Somatic symptoms; GHQ-AI, Anxiety/insomnia; GHQ-SD, Social dysfunction; GHQ-D, Depression. \*\*\* $p < 0.001$ , \*\* $p < 0.01$ , \* $p < 0.05$ .

was observed that maladaptive strategies such as rumination correlated negatively with age and marital status, where young adults and singles were those who most used this coping strategy. A study done in the USA during confinement of the population also found that young adults used less adaptive coping strategies (21).

The results also corroborate our second hypothesis, as men and women used different coping strategies. Women's means were higher in acceptance, rumination, positive refocusing and putting into perspective. And men scored significantly higher other-blame. These results are shared by other authors that

have shown that women use more coping strategies focused on emotion, which could prevent depression, while men use more self-distraction and other-blame (20, 22).

Our results show that people use different coping strategies depending on their level of education as posed in Hypothesis 3. Those with a higher education use more rumination, planning, positive reappraisal and putting into perspective strategies. Individuals with a primary/secondary education scored higher in self-blame, catastrophizing and other-blame, coinciding with results found also by other authors (26).

 COVID-19, Anyone COVID-19 positive nearby; CERQ\_PF, Positive refocusing; CERQ\_PR, Positive reappraisal; GHQ-SS, Somatic symptoms; GHQ-AI, Anxiety/insomnia; GHQ-SD, Social dysfunction; GHQ-D, Depression (Delta method standard errors, bias-corrected percentile bootstrap confidence intervals).

It has been confirmed that home confinement due to health emergency has many effects on psychological well-being (2, 37–41). Our results are along this line, confirming our Hypothesis 4, as negative coping strategies, such as rumination and catastrophizing correlated positively with all the health subscales, while self-blame and other-blame strategies were positively related with the presence of somatic symptoms, anxiety/insomnia and depression. These results coincide with previous studies which reflected that negative coping strategies were related to health problems such as anxiety (5) and stress or depression (6).

Moreover, our results show that positive refocusing and reappraisal correlated negatively with anxiety/insomnia, social dysfunction and depression, and planning was negatively correlated to social dysfunction and depression. This is in agreement with the results of Guo et al. (9) and Goodarzi et al. (8) who observed that problem-focused coping was related to fewer health problems and greater well-being.

Similarly, the results of this study demonstrated that negative coping strategies exerted a mediating effect on the development of somatic symptoms, anxiety/insomnia and depression in those who had COVID-19 positive cases nearby. The mediating role of strategies such as rumination have already been described elsewhere (14). However, Model 2 shows that the use of positive strategies did not buffer the relationship between the presence of COVID-19 nearby and impact on health. Gruszczynska and Rzesutek (18) also described the relationship of positive reappraisal with well-being of persons is complex since they found well-being worsened with time. Therefore, the results of these coping strategies are not necessarily as unified and beneficial as supposed (19).

With these results we can discern that the use of certain coping strategies has a mediating role on the relationship between COVID-19 positive cases nearby and repercussions that it has on mental health as we proposed in the last hypothesis posed.

## Limitations and Future Research

The main limitation of our study is its cross-sectional design, which does not allow us to show how these variables behave over time. Future studies should have longitudinal designs that can show these. Another limitation refers to data collection, which was done using self-report questionnaires, and so there may have been subjective or reliability biases. The technological tools used for snowball sampling and to divulge the questionnaires and online collect the data may have conditioned the subjects who answered, and did not get to the whole population. So future studies could use other strategies for data collection to be able to access different populations.

## Practical Implications

The COVID-19 pandemic has implications for individual and collective health and emotional and social functioning of the population. In addition to providing health care, health services have to consider psychosocial needs. This study has relevant

practical implications that should be considered for intervention in the health of the population in adverse situations such as those triggered by the COVID-19 public health emergency. Interventions should be performed on levels of individuals to institutions, including coping strategies that are postulated as beneficial for the health, and further, consider that they must be adapted to the confinement situation. These interventions would serve as preventive measures for health problems, helping people to develop a wide repertoire of healthy coping strategies.

## CONCLUSIONS

Adverse situations such as those experienced during the worldwide health emergency caused by the SARS-CoV-2 coronavirus cause people to make use of different coping strategies to endure them. These could facilitate the appearance of health problems or act as buffers for them. The rumination coping strategy was the one most used by young adults and by singles. “Negative” coping strategies exerted an indirect effect as mediators on the impact that the presence of COVID-19 cases nearby had on health, however, this effect was not observed for “positive” coping strategies. Based on these results, it is important to design plans to help the population develop coping strategies that enable them to remain healthy in the face of the consequences derived from COVID-19. And also offer an intervention to familiars of patients COVID-19, when the illness is detected and he must to initiate the confinement protocol or if he is hospitalized even.

## DATA AVAILABILITY STATEMENT

The data that support the findings of this study are available from the corresponding author upon reasonable request.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by University of Almeria Bioethics Committee (Ref. UALBIO2020/032). Written informed consent to participate in this study was provided by the participants’ legal guardian/next of kin.

## AUTHOR CONTRIBUTIONS

MP-F, MM, and EF-M contributed to the concept, design, analysis, and interpretation of the data. ÁM contributed to the technical details and manuscript preparation. MP-F, MM, and EF-M contributed to collecting the data. JG contributed to critically revising the manuscript for important intellectual content and the final approval of the version to be published. All authors accept and agree that the work is original, any methods and data presented are described accurately and honestly, and any relevant interests have been disclosed.

Healthcare workers who are on the front line of coronavirus disease 2019 (COVID-19) and are also undergoing shift schedules face long work hours with few pauses, experience desynchronization of their circadian rhythm, and an imbalance between work hours effort and reward in saving lives, resulting in an impact on work capacity, aggravated by the lack of personal protective equipment (PPE), few resources and precarious infrastructure, and fear of contracting the virus and contaminating family members. Some consequences are sleep deprivation, chronic insomnia, stress-related sleep disorders, and post-traumatic stress disorder. These sleep alterations critically affect mental health, precipitating or perpetuating anxiety, stress, and depression, resulting in the inability to regulate positive and negative emotions. Pre-existing sleep disorders are an important risk factor for the development and maintenance of PTSD when individuals are exposed to an important stressor such as a COVID-19 pandemic. At the same time, how an individual regulates the emotion associated with worries during daytime functioning impacts nighttime sleep, precipitating and perpetuating difficulties in sleeping. All of these changes in sleep and emotional regulation also alter the immune system. Sleep deprivation is commonly associated with chronic inflammatory diseases, due to the desynchronizations in circadian rhythms, causing possible psychophysiological disorders and impaired neuroimmune-endocrine homeostasis. From this perspective, we clarify in this article how sleep disorders affect

the immune system and emotional regulation, explaining their phenomenological and neurobiological mechanisms, and discussing elements of cognitive and behavioral coping for health professionals to adopt and manage a healthier sleep pattern in the COVID-19 outbreak.

**Keywords:** sleep, emotional regulation, immune system, cognitive behavioral therapy, health professionals

## INTRODUCTION

The current severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the causative agent of the ongoing coronavirus disease 2019 (COVID-19) (Tay et al., 2020), has provoked a strong emotional reaction, which affects healthcare workers, symptomatic patients, and the general population. Healthcare workers who are on the COVID-19 front-line undergo shift schedules, have long and strenuous work hours with few breaks, experience circadian rhythm desynchronization, and an imbalance between effort of hours at work and reward in saving lives, resulting in an impact on work capacity, aggravated by the lack of individual protection equipment, fear of contracting the virus, or returning home and contaminating family members. Sleep disorders have been reported as one of the negative results (Belingeri et al., 2020a; Zhang et al., 2020).

The literature has reported how immune function decreases after affective states associated with stress in the face of stressful situations, such as natural disasters, among which depression, anxiety, and loneliness stand out (Ironson et al., 1997). These emotional states and the relationship with the immune response have been described and also associated with sleep disorders such as insomnia and drowsiness, as a result of sleep deprivation, establishing the important role of sleep in emotional regulation and its relationship with immune regulation (Brand et al., 2014; Irwin and Opp, 2017; Vandekerckhove and Wang, 2017).

Both emotional responses and sleep disturbances may be related to the current COVID 19 pandemic, where isolation measures, in addition to the workload, affect health professionals. Due to the burden of stress generated, sleep deprivation, little contact with their family, long hours, and concern for the future, healthcare workers could experience a decrease in their immune response and a lower response to future outbreaks in this sector of the population where COVID 19 has already claimed many victims (Alnofaiey et al., 2020; Conroy et al., 2021). These situations have already been explored in other types of populations (Dubey et al., 2020; Liem et al., 2020; Rajkumar, 2020; Rashidi Fakari and Simbar, 2020; Yang et al., 2020; Yao et al., 2020; Zhu et al., 2020).

Returning to how studies have addressed the relationship between sleep and emotional regulation in the immune system, it has been described as alterations in mitogenic responses, a decrease in the activity of NK cells and a phenotypic decrease in T cells, and the impact of catecholamines through  $\beta_3$  receptors on lymphocytes through the action of hypothalamic adrenal cortisol products (Ironson et al., 1997). What has not yet been analyzed is what occurs when peaks in cases rise, which has been happening in some

countries despite vaccination. These peaks cause a return to isolation measures and other precautions, which causes a stabilization of symptoms of stress and sleep disorders in health professionals, which will be reflected in the decrease in the immune response, for which the measures for both prevention against stress and sleep become valid and of vital importance (Lin and Chen, 2021).

For decades, the biopsychosocial impact of sleep disorders and sleep deprivation caused by shift work schedules has been discussed (Härmä, 1993; James et al., 2017; Cheng and Drake, 2018; Kerkhof, 2018). Much research has provided evidence of intervention possibilities, but the lack of appreciation of sleep complaints by managers persists, seen by the lack of public policies for sleep disorders. Paradoxically, the COVID-19 pandemic highlighted the importance of health professionals to face this situation, but it made visible the lack of care for them.

There is consensus on how to deal with sleep disorders by major organizations (World Sleep Society, European Sleep Research Society, Sleep Brazilian Society, and the Latin American Federation of Sleep Societies) (Sateia et al., 2017; Bacelar and Pinto, 2019; Altena et al., 2020; Federation Latin-American of Sleep Societies, 2020). Cognitive-Behavioral Interventions (such as sleep hygiene) have been elected as the technical gold standard non-pharmacological treatment for many sleep disorders and sleep deprivation. Through this formal recognition, the Latin American Association of Sleep Psychology (LASP) was organized as an association that brings together sleep psychologists in Latin America with goals that involve the identification of psychological factors contributing to the development and/or maintenance of sleep disorders, contributing information to establish the differential diagnosis, in the development and provision of evidence-based cognitive-behavioral assessment and intervention techniques, collaborating to prevent sleep disorders and promoting quality of life.

In this sense, the LASP is aware of its role in the current pandemic and has formulated recommendations for the sleep complaints of the population at different ages and different social contexts, considering cultural differences between the countries of this portion of the American continent. Regarding health professionals, LASP has been concerned with the high number of sleep disorders that are characterized as insomnia in China and the informal reports, although there are no data on sleep disorders from every country. Therefore, this article aims to discuss the impact of sleep disorders on emotional regulation and the immune system. It also aims to adequately characterize these sleep disorders; insomnia is not always Insomnia Disorder, but instead may be insomnia associated with acute stress or a symptom of Posttraumatic Stress Disorder (common in these

pandemic situations), or a symptom of Circadian rhythm sleep-wake disorder shift work type. Recommendations for health professionals to deal with sleep disorders are listed.

## Sleep Definition

Sleep is a global state and a universal mammalian behavior with multiple levels of biological organization (Hobson and Pace-Schott, 2002).

Sleep has been defined as a reversible state, and unlike hibernation and torpor, it is not dependent on the availability of food, water, or environmental temperature (Krystal et al., 2013).

Sleep plays an active role in processes such as synaptic plasticity and memory functions, emotional regulation, metabolic function, energy balance, macromolecule biosynthesis, removal of toxic substances and metabolic waste, and prophylactic cellular maintenance. It has also been postulated that is related to adaptive inactivity; sleep can be viewed as a process of meta regulation, that is a high order of regulation which accommodates a broad range of molecular, cellular, and network processes altogether providing optimal (adaptive) wakefulness (Vyazovskiy, 2015).

In Electrophysiology, normal human sleep is defined by two states—Rapid eye movement (REM) and Non-REM (NREM) sleep—that alternate cyclically across a sleep episode. NREM includes a variably synchronous cortical electroencephalogram (including sleep spindles, K complexes, and slow waves) associated with low muscle tonus and minimal psychological activity. REM sleep EEG is desynchronized, muscles are atonic, and dreaming is typical. On the other hand, behaviorally sleep is a reversible state of perceptual disengagement from and unresponsiveness to the environment (Carskadon and Dement, 2017).

Some factors that determine sleep manifestation, such as homeostatic and circadian timing system, environmental zeitgebers, stress, genetics, psychosocial, medical, and social features (i.e., work schedule), have been described (Borbely et al., 2016; Altona et al., 2020).

## Biological Rhythms

Molecularly, the circadian rhythm of sleep involves interlocking positive and negative feedback mechanisms of circadian genes (period -per 1,2,3-; cryptochrome -cry 1 and 2- clock and Bmal 1), and their protein products in cells of the suprachiasmatic nucleus (SCN) are entrained to ambient conditions by light. Subsequently, circadian information is integrated with information of homeostatic sleep need in the nuclei of the anterior hypothalamus (Hobson and Pace-Schott, 2002).

Episodic Ultradian rhythms have been defined as periodic rhythms that last for 20 min to 6 h, such as the patterns of the electrical activity of the brain and the heart. The functional significance of ultradian events might be in optimizing biological activities mainly by synchronizing compatible processes and preventing the simultaneous activation of incompatible processes, preparing biological systems to respond to stimuli such as cell-cell communication, and interacting with circadian rhythms (Goh et al., 2019).

Unlike ultradian rhythms, sleep and wakefulness have been named “sleep-wake cycle” and are defined as the circadian

(~24-h) rhythm. Sleep regulation has been explained with the two-process model, in which it is postulated that a homeostatic process (Process S) interacts with a process controlled by the circadian pacemaker (Process C), with time-courses derived from physiological and behavioral variables (Borbely, 2009).

The interaction between the homeostasis process (depending on sleep and wake) with a process controlled by the circadian pacemaker determines salient aspects of sleep regulation. REM Slow Wave Activity (SWA) represents the principal marker of Process S during sleep; core body temperature and melatonin rhythms are markers of process C (Borbely et al., 2016).

Process S increases in intensity, and any time that sleep occurs, it is reduced; a daytime nap, for example, causes an exponential decline in process S to the degree that it may interfere with sleep initiation at the usual bedtime. Process C influences the timing of sleepiness based on the endogenous circadian clocks (CC), the SCN of the hypothalamus, primarily by activation and deactivation of the system that promotes waking (Krystal et al., 2013).

In another sense, CC are biological fundamental functions that generate self-sustained 24 h rhythms endogenously (such as sleep-wake cycle) and help tune the organism’s physiology with the predictable cyclic environment generated by the alternation of day and night; unfortunately, social factors (such as work or school schedules) have not been adapted to the sleep-wake cycle, leading to a discrepancy between internal circadian time and external social time constraints. This discrepancy has been named Social Jet Lag (SjL) (Korman et al., 2020).

Social jet lag can be detrimental to health and sleep health in different types of employment, including healthcare workers. As an example, Kang et al. (2020) studied the effect of SjL on sleep quality in nurses; they concluded that overall sleep quality can increase with decreasing day-shift fatigue, decreasing SjL and increasing sleep quality during night shifts.

## Natural Day Light Versus Artificial Light at Night

Environmental cues, mainly nighttime natural darkness, are necessary for normal melatonin synthesis that is essential for biological timekeeping, sleep, and, directly or indirectly, many processes of cells, tissues, and organs. The 24 h Light/Dark cycle of nature conveys crucial temporal cues to the body’s master biological clock (the suprachiasmatic nuclei SCN of the hypothalamus and pineal gland) to achieve internal synchronization of the period and phasing of the Circadian Time Structure CTS (Smolensky et al., 2015).

On the other hand, Artificial Light at Night (ALAN) exposure can disorganize the circadian system, from the level of the molecular clocks that regulate the timing of cellular activities to the level of synchronization between our daily cycles of behavior and the solar day (Potter et al., 2016); ALAN exposure also suppresses melatonin secretion, increases sleep onset latency, and increases alertness, causing circadian misalignment which can cause negative effects on psychological, cardiovascular, and/or metabolic functions (YongMin et al., 2015; Potter et al., 2016).

Throughout the industrialized world, 24 h operations are necessary for public safety and health and are frequently economically advantageous. A subset of shift workers develops shift work disorder (SWD) triggered by circadian misalignment (ICSD-3) (American Academy of Sleep Medicine, 2014). These individuals experience significant negative health consequences and diminished quality of life as a result of shift work (Wickwire et al., 2017).

Some consequences of circadian rhythm and sleep disruption have been described (Potter et al., 2016; Seifalian and Hart, 2019; **Table 1**).

## SLEEP DEPRIVATION, EMOTIONAL REGULATION, AND THE IMMUNE SYSTEM

The immune response protects the organism from substances or organisms that are probably harmful or dangerous. There are many studies that the literature has used to argue the importance of sleep within this immune response and how sleep deprivation influences, in an important way, its regulation (Wilder-Smith et al., 2013; Irwin, 2015).

A first account of this relationship is that during sleep and through its role in the consolidation of long-term memory, such consolidation in the immunological memory is necessary and effective, which occurs during deep slow-wave sleep (stage N3 of sleep), allowing an abstraction of the immune system to remember its action against specific pathogens, in addition to other specific memory threads during the REM state of sleep, which is also related to emotional regulation, which is associated with the decrease of adrenergic loads, which favor immune action (Westermann et al., 2015). It is here where both sleep deprivation and increased responses to stress can alter this process, making the body vulnerable to pathogenic actions, even in the respiratory system, as has been shown in studies that argue that short periods of sleep deprivation are associated with susceptibility to common colds, evidenced and also related to adaptive immunity (Prather and Leung, 2016; Lin et al., 2018).

A second aspect that is important to highlight is that sleep deprivation has a close relationship with two components of our immune response. One such component is innate or non-specific immunity, referring to the defense system with which one is born that forms the first line of defense in the immune response. The other component is related to acquired, adaptive, or specific immunity. It is made up of highly specialized cells and systemic processes that eliminate or avoid the threats of pathogens, generating immune memory and tolerance to the antigens themselves (Wilder-Smith et al., 2013; Irwin, 2015).

### Sleep Deprivation and Adaptive Immunity

When analyzing the adaptive immune response and its relationship with sleep deprivation, the literature has considered that the activity of the hypothalamic-pituitary-adrenal axis is responsible for the distribution of glucocorticoid hormones

through the blood serum, to regulate gene expression in practically every cell in the body. Sleep deprivation causes hormonal activation of leukocyte glucocorticoid receptors, resulting in profound suppression of antiviral gene programs (Wilder-Smith et al., 2013; Irwin, 2015).

Sleep deprivation also gives rise to activation of the sympathetic nervous system (SNS), releasing norepinephrine in primary and secondary lymphoid organs, in all other major organ systems, including our vascular and perivascular tissues, as well as many other peripheral tissues, and stimulates the adrenal glands, also releasing epinephrine. Both neuromediators stimulate leukocytes and adrenergic receptors (e.g., ADRB2) to suppress genetic antiviral (IRG) interferon response (IFN) gene programs, mediated by regulation factors of IRF interferons (Wilder-Smith et al., 2013; Irwin, 2015).

Other studies have linked sleep with the induction of growth hormone release which occurs in the early part of the night. This hormone is involved in improving the proliferation and differentiation of T cells and promoting the activity of type 1 cytokines (Wilder-Smith et al., 2013; Irwin, 2015). According to the above, sleep deprivation reduces the release of growth hormone and suppresses the response of Genetic antiviral interferon (IRG), mediated by IRF regulatory factors, which causes an imbalance in Th1 to Th2 cells, with decreased IFN production in Th1 cells and increased production of interleukin-Th2 cells. 10 (IL-10). This suppression of the adaptive immune response has been hypothesized to contribute to a greater susceptibility to infectious diseases and a lower response to vaccines (Wilder-Smith et al., 2013; Irwin, 2015).

### Sleep Deprivation Innate Immunity

After sleep deprivation, the SNS releases norepinephrine in the primary and secondary lymphoid system and stimulates the adrenal release of epinephrine (Wilder-Smith et al., 2013; Irwin, 2015). Both neuromodulators stimulate ADRB2 leukocyte adrenergic receptors and activate inflammatory systems, which are mediated by nuclear factors (NF)  $\kappa$ B and intrinsic circuits, that in turn are responsible for the detection of microbes through pattern recognition receptors (PRR), among which is the Toll-like-4 receptor (TLR4). This stimulates inflammatory gene expression through NF- $\kappa$ B transcription factors and the production of proinflammatory cytokines, such as interleukin (IL) -6 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (Wilder-Smith et al., 2013; Irwin, 2015).

Homeostasis between the internal and external signals of the brain allow it to regulate inflammatory activity. It can also influence brain activity and alter internal balances, sleep being one of the most affected (Wilder-Smith et al., 2013; Irwin, 2015). Therefore, when sleep dysregulation occurs, it can confer an increased risk of inflammatory factors, resulting in cardiovascular disease, cancer, and emotional disorders (Tobaldini et al., 2013). That is where the relationship of the emotional system appears in this triad and at the same time these factors have been considered mortality factors for the transmission of SARS-CoV-2.

**TABLE 1** | Consequences of the disruption of circadian rhythm.

Disrupted glucose metabolism (reduction in insulin sensitivity, impaired TSH Secretion, and nocturnal cortisol secretion increased after sleep deprivation).

Effects on dietary choices (sleep disruption increases non-homeostatic eating propensity and accentuates increased activity in brain regions involved in reward in response to food stimuli, increased appetite, particularly for energy-dense food).

Limited daylight exposure (many individuals are sheltered from the beneficial effects of natural daytime light on behavior and physiology due to a vitamin D deficiency).

Increased light exposure at night (light exposure shortly after dusk during workdays, delaying sleep onset and shortened sleep duration; this has gotten worse due to the use of electronic devices at bedtime and during the day).

Night workers have higher plasma triacylglycerol, circadian misalignment increases blood pressure (mainly during sleep) and inflammatory markers, reverses cortisol rhythms, and reduces heart rate variability and insulin sensitivity in healthy adults.

Disfunction in the gastrointestinal and cardiovascular system are known to be a risk for colorectal and breast cancer.

Impaired cognitive performance and increased frequency of errors in those suffering from regular sleep disturbance; it includes the cognition of health care workers that are providing treatments and therapy to patients in the hospital.

## Sleep and Emotional Regulation

Sleep deprivation also affects the regulation of emotional processing. This condition makes us more emotionally reactive and more sensitive to stressful stimuli and events. Scientific literature has shown how sleep appears to be essential to our ability to cope with emotional stress in everyday life. However, when daily stress is not properly regulated, it can lead to mental health problems and sleep disorders (Vandekerckhove and Wang, 2017). Not only does emotion impact sleep, but there is also evidence that sleep plays a key role in regulating emotion. Emotional events during waking hours affect physiology, sleep patterns, and even the content of daydreams, and the quality and quantity of sleep influence how we react to events that affect our overall well-being (Bileviciute-Ljungar and Friberg, 2020).

Different investigations have shown how sleep has a modulating action on daily emotions, specifically in the interaction between emotional stress, sleep, and its disturbances. Regular sleep from its homeostasis, circadian presence, and in the respective development of REM—NREM cycles is crucial for general well-being and emotional experience during the day (Vandekerckhove and Wang, 2017). This is observed in the first measure, because our executive functions exert a modulating action on our experience and emotional reaction, evidenced in the correct functioning of our frontal limbic connections, improving when REM sleep is intact. The correct processing of negative experiences also occur during REM sleep, which is important in the consolidation of affective memory and allows emotional stabilization in disorders such as depression (Killgore, 2010; Vandekerckhove and Wang, 2017).

Sleep deprivation alters this regulation and makes the person more reactive in the face of aversive reactions, showing a decrease in mean prefrontal activity and its signals sent to the amygdala, which translates into emotional dysregulation (Minkel et al., 2011; Saghir et al., 2018). Psychophysiological factors such as stress, anxiety, and hyperarousal play an important role in causing sleep disturbances. Furthermore, sleep disturbance predicts later development of mental health, while the development of insomnia predicts psychopathology such as depression or post-traumatic stress disorder after an acutely stressful event (Ironson et al., 1997). This could be what happens in health professionals who are exposed to sleep deprivation due

to long hours of work and also face high levels of stress when they are away from their home and/or when they remain in the medical setting because of the concern of contagion generated by living with family after caring for COVID-19 patients.

This leads us to conclude a bidirectional role of the action of sleep deprivation, either by restriction or fragmentation on stress in the first place and stress on sleep deprivation second. While it is true that stress causes sleep disturbances, sleep deprivation is a high source of psychological and physiological stress (Meerlo et al., 2008; Van Laethem et al., 2015). For a better understanding, the Model of vulnerability and maintenance of the disease, due to sleep deprivation and stress, is shown in **Figure 1**.

One of the main aspects of this regulation is the regulatory action of cortisol, a hormone involved in the control of stress and reactivity against emotions. It seems that the regulatory alteration of the action of melatonin on cortisol, which is one of circadian disturbances, explains said emotional reactivity and an alteration of the circadian cycle due to sleep deprivation or lack of sleep creates said emotional dysregulation (Posadzki et al., 2018; Brignardello-Petersen, 2019; Meng et al., 2020; Shermohammed et al., 2020).

Sleep deprivation has the consequence of inhibiting the previous processes, causing emotional reactivity and chronic stress, which has been related to chronic diseases, similar to those that occurred in the current COVID pandemic, which leads to the conclusion that the alteration in emotional regulation and circadian lag makes the population vulnerable to contracting COVID, or becoming more vulnerable to the consequences of the disease.

## SLEEP ALTERATIONS IN HEALTHCARE WORKERS

As discussed above, the literature data converge with published data on the situation of healthcare workers during the current outbreak of COVID-19, showing that the perceived poor sleep quality and sleep changes appear to be underlying mechanisms in the relationship between shift and work overload, increased susceptibility to infection, and impact on mental health (Brooks et al., 2018; Belingheri et al., 2020b; Pappa et al., 2020).

The first study published by the research group in Wuhan, China, where the pandemic started (Zhang et al., 2020), showed in a sample of 1,563 individuals that 564 participants (34.6%) had insomnia during their work in the hospitals in Wuhan, and that related factors included isolation, psychological concerns about the outbreak of COVID-19 (uncertainty about effective disease control), and being a doctor. Complementary data from Xiao et al. (2020b) with 180 doctors and nurses who treated patients with COVID-19 infection in Wuhan, China, showed that the staff had poor sleep quality and explained that the associated factors were the energy expended for putting on Personal protective equipment (PPE) every day and the disinfection needed for removing these clothes, the continuous work the isolation wards with a high intensity of high-pressure work, and the high mortality rates of patients associated with the infection by COVID-19. These data were replicated by the population, showing high rates of poor sleep quality associated with stress and anxiety in the context of COVID-19 (Huang and Zhao, 2020).

Data have shown that health professionals complain of insomnia that causes sleep deprivation and bad sleep quality. However, it is necessary to characterize that insomnia can be a chronic condition by itself, caused by the pandemic context, or a symptom of another sleep disorder. This differential diagnosis is relevant to thinking about cognitive and behavioral recommendations for this group.

It is known that the biological disaster of COVID-19 is a stressful situation, as being infected with a life-threatening physical illness is a traumatic event. Further, being a healthcare worker for patients with a deadly virus and having prolonged contact with them can also lead to symptoms of acute stress. Sleep

and post-traumatic stress disorder (PTSD) are closely related. Literature data showed that the COVID-19 pandemic appears to be a risk factor for sleep disorders and PTSD (Casagrande et al., 2020; Yin et al., 2020). Further, Richards et al. (2020) showed sleep alterations (sleep deprivation, sleep fragmentation, and insomnia) could lead to maladaptive sleep-related compensatory behaviors and cause hyperarousal and anxiety-related disorders like PTSD. Moreover, sleep disorders are core features of PTSD. Therefore, insomnia, associated with another sleep-wake disorder, mental disorder, or medical condition, can only be diagnosed as an independent focus of clinical attention, if these conditions are treated and insomnia persists.

Insomnia disorders are characterized by the complaint of persistent difficulty with sleep initiation, duration, consolidation, or quality that occurs despite adequate opportunity and circumstances for sleep. These symptoms should cause clinically significant impairment in social, occupational, educational, academic, and behavioral functioning; otherwise, they will not be classified as Insomnia Disorder. For the diagnosis of Insomnia Disorder, it is necessary to observe the duration and frequency of complaints. The situational difficulties of sleep due to negative environmental circumstances, such as during the COVID-19 pandemic, should be differentiated. Insomnia may be a symptom of Circadian rhythm sleep-wake disorders shift work type (CRSWD) (International Classification of Diseases—11th revision—ICD-11). The CRSWD are persistent or recurrent disturbances of the sleep-wake cycle due to alterations of the circadian time-keeping system, its entrainment mechanisms, or a misalignment of the endogenous circadian rhythm and the external environment (social demands, work and school

**TABLE 2 |** Behavioral and Cognitive measures for health professionals dealing with sleep problems during COVID-19.

Before work	Operational
<ul style="list-style-type: none"> <li>• Avoid starting work tasks with very high sleep debt.</li> <li>• Track total sleep time compared to hours of sleep with the most drowsiness.</li> <li>• Schedule short naps of maximum 30 min based on this.</li> <li>• Maintain, as much as possible, the same amount of sleep in a workday as in a non-workday. This standard is the one that most favors the immune response.</li> <li>• Assessing the use of more than one sleep period as much as possible reduces the potentially serious consequences of strenuous hours.</li> <li>• Taking a nap if possible when you are sleepy is the most efficient method of countering cognitive errors.</li> <li>• Exposure to bright light before work, particularly blue spectrum light, is alerting.</li> <li>• Limit napping just before work to 30 min to reduce sleep inertia problems.</li> <li>• In free time, try to exercise regularly, but not before bedtime or before naps at work breaks.</li> <li>• Encourage the choice of relaxing activities, including socializing with family, before going to sleep or napping—reading a book using a relaxation technique.</li> <li>• When you sleep at home during the day, educate family members or roommates about sleep and the importance of restful sleep. The family must help protect the health professional's sleep from factors such as neighbors, pets, and delivery people.</li> <li>• Helping techniques also include turning the phone off, turning off the TV, or putting it on a white noise channel, wearing earplugs, darkening the bedroom, wearing eye masks, and sleeping in a cool environment.</li> <li>• The management of luminosity before and after work with dark glasses is necessary to collaborate with the regulation of the circadian cycle.</li> <li>• Food intake involves light meals, at specific times, if possible, and not immediately before the start of sleep, to avoid sleep disturbances due to digestion.</li> </ul>	<ul style="list-style-type: none"> <li>• Try to obtain natural light during the day. If it is not possible, use bright lights at work, but not in the room or place where you sleep at work. The idea is to obtain little light in the place where you sleep to help in the pressure to sleep. Suggesting the use of sleep masks that help to darken the environment to favor sleep is a good strategy.</li> <li>• Social interaction with preventive isolation (teamwork), chewing on snacks, singing, and physical exercise can help maintain alertness.</li> <li>• It is recommended to use short exercise breaks (for example, climbing stairs) of at least 6 min and to work in well-lit spaces.</li> <li>• Finally, avoiding excessive consumption of energy drinks, such as caffeine and stimulant self-medication, should also be considered. Doctors must remember that it is unclear whether these drugs restore executive functions after sleep deprivation and it remains unclear how long you can stay alert to compensate for a lack of sleep.</li> <li>• Unfortunately, some health professionals may be kept away from their family or community due to stigma or fear. This can make a situation much more difficult. If possible, suggest that the health professional remain connected with loved ones, even though digital methods, which is a way to keep in touch. Talk to colleagues or other trusted people for social support and to express stress and other emotions and concerns about the work situation during the day—colleagues may be having similar experiences.</li> <li>• Limit exposure time to COVID-19 news as much as possible so as not to exacerbate anxiety.</li> <li>• Create an outline of personal care activities that the professional likes, when not taking care of patients, such as spending time with friends (virtually) and with family, exercising, or reading a book.</li> <li>• Learning from signs and symptoms—paying attention and differentiating sleepiness, fatigue, fear, feelings of sadness, withdrawal, guilt, anxiety, encouraging them to seek breaks, and asking for professional help. This includes psychological help.</li> <li>• If the health workers identify symptoms related to sleep deprivation, fatigue, errors in performing work-related tasks, inability to concentrate or make decisions, extreme irritability, or strong emotional reactions, should inform colleagues and superiors and take a nap. Even a short nap can help partially reduce these symptoms.</li> </ul>

schedules, or the light-dark environment). The most common complaints are excessive sleepiness or insomnia, or even both (International Classification of Diseases—11th revision—ICD-11; International classification of sleep disorders, 3rd edition.—ICSD-3) (American Academy of Sleep Medicine, 2014).

The CRSWD shift work type is associated with significantly higher odd burnout syndrome and job dissatisfaction (Bagheri Hosseini et al., 2019). Furthermore, the disruption of circadian rhythm may impair immune system function, among other consequences, as mentioned previously (Cuesta et al., 2016).

## BEHAVIORAL AND COGNITIVE RECOMMENDATIONS for SLEEP QUALITY IN HEALTH PROFESSIONALS DURING THE COVID-19 PANDEMIC

Many protective recommendations have been put forward to deal with the SARS-CoV-2 pandemic, but no scientific society around the world (World Health Organization, 2018), including WHO,

has devoted itself to sleep problems, except for the task force of the European CBT-I Academy (Altena et al., 2020).

Researchers from China, the initial epicenter of the pandemic, have discussed social support (size and source of social networks of people helping others, as well as emotional, material, and supportive functions informative—Brugha, 1990) and capital social (social trust, belonging, and social participation—Harpham et al., 2004) as important mediating factors to improve sleep quality (Xiao et al., 2020a) and to help in the sense of self-efficacy by professionals (that refers to individual judgment on the ability to complete a certain behavior or task—Bandura, 1977).

In this sense, it is important to consider the risk and protective factors to suggest behavioral and cognitive recommendations to sleep quality in health professionals during the COVID-19 pandemic, to help with social support, social capital, and a sense of self-efficacy. Factors that negatively affect sleep, in addition to those mentioned above (pandemic stress, work pressure, or irregular or night shift work patterns), include loneliness, negative family environment, technology use, evening light, pre-sleep worry, and the use of caffeine, tobacco, and alcohol. Fear of missing out on family contact and their health and excessive

technology use negatively impact sleep. Persons with comorbid medical, psychiatric, and other sleep disorders such as sleep apnea, and individuals with a strong need for stable hours of sleep, may be at particular risk. Factors that positively affect sleep include social support, good family environments, good sleep hygiene, and physical activity (Altena et al., 2020; Federation Latin-American of Sleep Societies, 2020).

The literature maintains that behavioral and cognitive intervention strategies (Mullins et al., 2014; Aliyu et al., 2018; Marín Agudelo et al., 2019; Almondes, 2020; Altena et al., 2020; Federation Latin-American of Sleep Societies, 2020; Holding et al., 2020) can be applied as preventive measures for health personnel, in addition to the classic norms of sleep hygiene and finding preventive measures before work and operative measures during work (Table 2).

## FINAL CONSIDERATIONS

In order to improve decision-making and reduce the risk of errors at work, it is urgent that the work protocols, with patients with COVID 19, contain measures to improve the sleep of health personnel.

It is important that the recommendations mentioned above are used to reinforce a positive appraisal of the situation with the help of sleep psychologists, avoiding the development of psychopathological conditions and sleep disorders, in order to deal with this situation. It is important to encourage positive coping styles. Coping represents the cognitive and behavioral patterns to manage particular external and/or internal demands appraised as taxing or even exceeding the resources of individuals (Folkman and Lazarus, 1988). In our opinion, three different coping strategies will help the physical and mental health of professionals, since practical behaviors such as emphasizing positive cognitions, understanding sleep alterations and emotional regulation, and getting more information can be associated with fewer mental health problems and sleep problems (Dubey et al., 2020; Guo et al., 2020; Wang et al., 2020): (1) Coping focused on evaluation involves attempts to understand sleep alterations and the cognitive and behavioral variables involved in the context of the COVID-19 pandemic, with information and professional support; (2) Coping focused on problem involves the development of a coping plan, seeking internal resources to find solutions to deal with the situation, and

redefining thoughts to be more positive; (3) Coping focused on emotions involves individual control of emotions and emotional balance, involving efforts to maintain hope when dealing with a stressful situation through emotional regulation, psychoeducation and sleep hygiene techniques, becoming aware, and engaging in pleasurable activities that bring a sense of accomplishment.

Finally, for future post-pandemic phases, it is important to formulate public policies for decisions and actions in the face of sleep disorders.

## CONCLUSION

The occupational field of the health professional during the pandemic brings with it an increase in the workload and a displacement of sleep schedules, causing sleep deprivation and increased stress. Both stress and its deprivation have a bidirectional relationship, intimately linked to the immune system and the regulation of emotions, which creates an increase or presence of sleep disturbances, emotional disturbances, and the appearance of immunological vulnerability.

The literature has reported that these aspects can be prevented through strategies that must be carried out before and after work, in order to mitigate the aforementioned problems and establish better coping strategies both for the COVID 19 pandemic and for problems and contingencies that may arise in the future. The main objective when preparing this document was to present concrete tools that have served in other similar situations and apply them at this time for health professionals. A further aim was to ensure that in future perspectives, faced with similar problems, these tools can be the starting point to improve the quality of life of health professional in times of these crises, which is why this working group meets and this approach is presented for health professionals.

For future consensus and working groups, it remains for us to return to these issues raised and conduct research that will allow us to affirm these recommendations objectively.

Medical Students' Mental Health.  
*Front. Psychiatry* 12:555893.  
doi: 10.3389/fpsy.2021.555893

**Background:** The coronavirus disease—2019 (COVID-19) pandemic has halted in-person medical education worldwide. Limited studies have reported on the mental health status of medical students during this public health emergency. This study aimed to explore the association of personal virus exposure, regional epidemic condition, and social support with medical students' depressive and anxiety symptoms during the COVID-19 outbreak in China.

**Methods:** In February 2020, 5,982 medical students (60.0% females, Mean<sub>age</sub> = 21.7 years, Median<sub>age</sub> = 22 years) completed an online survey consisting of demographics, personal virus exposure, the Patient Health Questionnaire, the Generalized Anxiety Disorder Scale, and the Social Support Rating Scale.

**Results:** The prevalence rates of mild to severe depressive symptoms and anxiety symptoms were 35.2 and 22.8%, respectively. Multivariate linear regression showed that students with low- or medium-level social support had a higher risk of experiencing depressive or anxiety symptoms than those with high-level social support. COVID-19 exposure was positively associated with mild to severe depressive or anxiety symptoms. Respondents living in provinces with 500–1,000 confirmed COVID-19 cases had an increased risk of experiencing mild to severe depressive symptoms compared with those living in provinces with <100 cases. Other related factors were gender and years of training.

**Conclusions:** Some medical students suffered from a poor psychological status during the COVID-19 outbreak. Low social support was a stronger factor related to poor mental status compared with COVID-19 exposure or the provincial epidemic condition. Thus, we suggest that colleges or universities provide social support and mental health screening.

**Keywords:** depression, anxiety, COVID-19, medical students, exposure, social support

## INTRODUCTION

Newly emerging infectious diseases are black swan incidents that are challenging for global healthcare systems. National capacities for coping with public health emergencies rely heavily on healthcare human resource preparedness. It is questionable whether mass news coverage, potential exposure to coronavirus disease—2019 (COVID-19), and possible suspended education (1, 2) can impact medical students. Medical students have multiple identities, such as future healthcare workers, young adults, and common citizens. Their emotions and psychological suffering during this outbreak may provide important information toward preparing human resources for further health emergencies.

Meta-analyses showed that, on normal days, the prevalence rates of depression and anxiety among all medical students were approximately 27% (3–5) and 30% (6), respectively. The risk factors were being female, receiving 1st year undergraduate or postgraduate education, and poor psychological support (5, 7, 8).

The COVID-19 pandemic has influenced the mental health status of college or university students. A meta-analysis showed that approximately one-third of college or university students had depressive or anxiety symptoms (9). Different testing procedures, dates, scales, or the cutoff points of scales may result in varied prevalence rates (9), such as 12% in Greece ( $N = 1,104$ ) (10) and nearly half in France ( $N = 619$ ) (11). An online survey conducted among 11,787 Chinese college students in February 2020 showed that the prevalence rates of depressive [the Patient Health Questionnaire—nine-item (PHQ-9)  $\geq 5$ ] and anxiety [the seven-item Generalized Anxiety Disorder Scale (GAD-7)  $\geq 5$ ] symptoms were 25.9 and 17.8%, respectively (12). This study also found that traveling to or living in the outbreak “hotspot” area was associated with a higher risk of depressive and anxiety symptoms (12). Another survey from Guangdong Province in China found that the rate of depressive symptoms among college students was 7% ( $N = 361,969$ , PHQ-9  $\geq 10$ ) (13).

Some studies have focused on the mental health status of medical students during epidemic outbreaks. Previous studies reported that medical students had increased anxious feelings after the severe acute respiratory syndrome (SARS) (14) and the Middle East respiratory syndrome coronavirus (MERS) outbreaks (15). Furthermore, varied prevalence rates of poor mental health status were reported in different areas after the COVID-19 outbreak. In February 2020, 25.3% of Chinese medical students ( $N = 933$ ) were reported to have depressive symptoms (PHQ-9  $\geq 5$ ) and 17.1% of them were with anxiety symptoms (GAD-7  $\geq 5$ ) (16). A small-scale survey ( $N = 217$ ) conducted in a Chinese university in February 2020 found that 37% of medical students had a serious mental illness [the Kessler 6 Psychological Distress Scale (K6)  $\geq 12$ ] (17). A comparative study found that 1,442 Chinese health professional students (including 764 medical students) experienced increased distress (K6  $\geq 5$ , 26.6%) and acute stress in February 2020 compared with that in the pre-pandemic in October 2019 (18). In addition, nearly half of the medical students in the United Arab Emirates had mild to severe anxiety symptoms ( $N = 1,485$ , GAD-7  $\geq 5$ ) in March 2020 (19). During the initial

period of the COVID-19 pandemic, 49.9% of 425 Bangladeshi medical students reported anxiety and 69.9% of them were with depressive symptoms through an online survey using the Hospital Anxiety and Depression Scale (20). A survey conducted in the United States ( $N = 741$ ) also showed that COVID-19 disrupted medical education and clinical training and that medical students experienced moderate stress and anxiety, which was measured using one Likert item (2). In Pakistan, approximately one in five final-year medical students ( $N = 2,661$ ) felt bored or nervous about the closure of their institutes because of the COVID-19 pandemic in June 2020 (21).

All of these studies among medical students did not explore the association between the severity of viral exposure and mental health. Additionally, mental health during a crisis is often related to social support (22). The government enforced “physical distancing” aimed at infection control, such as the transition from classroom learning to virtual learning, which may result in personal isolation (23). However, previous research has poorly studied the possible effect of social support on medical students’ mental health during epidemic outbreaks. Studies during the COVID-19 pandemic showed that low-level social support was associated with a higher risk of mild to severe depressive or anxiety symptoms among Chinese college students (24), Chinese adolescents (25), and British pregnant women (26). More perceived social support was associated with a decreased risk of sleep disturbance and suicidal ideation among the Taiwanese population (27).

Thus, this study aimed to explore whether personal virus exposure, regional epidemic condition, and social support were associated with medical students’ depressive and anxiety symptoms during the period of the fast-spreading COVID-19 outbreak in China. It would inform medical educators and health policymakers to take measures in order to make young health workforce or students mentally well-prepared for public emergencies.

## METHOD

This cross-sectional survey enrolled respondents between February 11, 2020 and February 18, 2020. The retrospective design collected information on the period from the fast outbreak at the end of January 2020 to the stable epidemic in the middle of February 2020. After the COVID-19 outbreak in China at the end of 2019, more than 30,000 health workers from other provinces were deployed to the frontlines to fight against the virus in Hubei Province (28). Due to high hospital-associated transmission risks (29), as of February 14, 2020, 1,716 health workers were diagnosed with COVID-19 because of hospital-acquired infections, and eight of them died (30).

We distributed online questionnaires through messaging and social media apps (WeChat and QQ) to medical school staff and students. Students’ participation was anonymous and voluntary. They completed the questionnaires on the Wenjuanxing survey platform (<https://www.wjx.cn/>). All subjects were informed of an introduction to the study and provided online informed consent before starting the survey. They did not receive any reward.

Epidemic condition data were from the official daily briefings of the Health Commission of China or provincial health commissions (31).

The Institutional Review Board of Beijing HuiLongGuan Hospital approved this study.

## Participants

Medical students were defined as full-time undergraduate or graduate students majoring in clinical medicine. According to the medical practice policy in China, only those studying clinical medicine could be qualified to register to practice (modern medicine) in the future. After a 5-year undergraduate medical education program, medical students can schedule their National Medical Practitioner Examination the following year. After they pass the exam, acquire practice licenses, and complete 2 years of standardized residency training programs, they can finally seek registration to practice medicine.

We included medical students who were 18–35 years old and who finished all the questionnaires. Then, we excluded those who were living abroad or completed the questionnaires in <3 min.

## Measurement

Possible personal COVID-19 exposure was identified if the person was diagnosed with COVID-19, if the person's family members or close contacts were diagnosed with COVID-19, or if the person was under involuntary isolated care or observation.

The provincial epidemic condition was converted from the cumulative confirmed COVID-19 cases in the respondent's present residential province on the day before the answering day. It was categorized into four levels: "1–100," "100–499," "500–999," and "1,000 and above."

Depressive symptoms within the past 14 days were screened using the nine-item PHQ-9, with each of the nine DSM-IV criteria scored on a scale from 0 "not at all" to 3 "nearly every day" (32). The score ranges for symptom severity are 0–4 for minimal, 5–9 for mild, 10–14 for moderate, and 15–27 for severe (32). The scale was validated in Chinese university students with a clinically significant cutoff point of 10 (33). The majority of studies among medical students or students' mental health during the COVID-19 pandemic only presented results on mild to severe depressive symptoms using five as the cutoff point (3, 9, 12, 16, 34). For a better comparison with previous research and policy attention for subclinical symptoms, we used two cutoff points, namely a PHQ score  $\geq 5$  for mild to severe depressive symptoms and a PHQ score  $\geq 10$  for moderate to severe depressive symptoms. The Cronbach's  $\alpha$  in the present study was 0.87.

Anxiety symptoms within 14 days were screened using the seven-item GAD-7, with items rated from 0 "not at all" to 3 "nearly every day" (35). The score ranges for symptom severity are 0–4 for minimal, 5–9 for mild, 10–14 for moderate, and 15–21 for severe. The clinical cutoff point at 10 was validated in China (36). Some studies on college students during the COVID-19 pandemic used five as a cutoff point for mild to severe anxiety symptoms (12, 16, 25). In our study, the result of the GAD score  $\geq 5$  for mild to severe anxiety symptoms and the GAD score  $\geq 10$  for moderate to severe anxiety symptoms were presented. The Cronbach's  $\alpha$  in this study was 0.92.

Social support was assessed using the Social Support Rating Scale (SSRS), which measured subjective social support, objective social support, and support utility (37). The total score was categorized into three levels ("low," "medium," and "high") using terciles as cutoff points because its distribution was skewed (38). The Cronbach's  $\alpha$  in the present study was 0.95.

Recent emotions were collected using a multiple-choice question: "Please choose one or more words to describe your emotions toward the COVID-19 outbreak within the past seven days." The seven emotion words were: "terrified," "pessimistic," "numb (detached)," "nervous," "helpless," "calm," and "angry."

Demographics included age, gender, years of training, and residence area (rural/urban). The 3 years of training subgroups were: undergraduates (years 1–3), undergraduates (years 4–5), and graduate students. In the Chinese 5-year medical curriculum, the preclinical phase included 3 or more years of education on medical concepts and science. Students usually start clinical education or internship at teaching hospitals once a week during their 4th year. In the 5th year, they engaged in full-time clinical rotations. Medical graduate students should complete residency training programs during their graduate education.

## Power

We used a sample size calculation for the logistic regression (39). According to previous research on the prevalence of depressive symptoms among medical students or college students (3, 9), we set  $P_{x=0} = 0.27$ ,  $P_{x=1} = 0.40$ . Then, we assumed a detectable odds ratio (OR) of 1.2,  $\alpha = 0.05$ , power = 0.8. Thus, the sample size would be 4,890.

## Statistical Analysis

The chi-squared test and Mann–Whitney rank-sum test examined differences in the rates of symptoms or emotions by the four ordered provincial epidemic conditions. Multivariable logistic regression tested the associations of COVID-19 exposure factors and social supports with depressive symptoms or anxiety symptoms, controlling for age, gender, years of training, and residence area. We presented the regression results for mild to severe depressive symptoms, moderate to severe depressive symptoms, mild to severe anxiety symptoms, and moderate to severe anxiety symptoms, respectively.

The software for statistical analysis was Stata 15.0 for Windows (StataCorp, College Station, TX, USA). Statistical significance was set at  $P < 0.05$ .

## RESULTS

### Demographics

In total, 5,982 medical students participated the survey and finished all questions. The median age was 22 years [interquartile range (IQR) = 3, range = 18–35, mean = 21.7, standard deviation (SD) = 2.5], and 60.0% were female. The students came from all provincial regions of China except for Macau (Table 1). The majority (69.3%) were first to 3rd year undergraduates, approximately one in five were 4 and 5th year undergraduates, and the other were graduate students. Among them, 63.0% lived in rural areas.

<sup>c</sup>Provincial confirmed COVID-19 cases 1 day prior to the answering day. Data were from health commissions.

<sup>d</sup>The levels of social support were converted from the total scores for Social Support Rating Scales with terciles as cut points.

Results statistically significant at  $p < 0.05$  level are in bold.

## Epidemiological or Clinical Characteristics

The median scores for PHQ-9 was 3 (IQR = 6, range = 0–27) and that for GAD-7 was 1 (IQR = 4, range = 0–21). Approximately one-third (35.2%) of the respondents had mild to severe depressive symptoms, and one in 10 (9.8%) had moderate to severe depressive symptoms (**Table 1**). More than one-fifth of patients (22.8%) had mild to severe anxiety symptoms. Only 4.2% of patients had moderate to severe anxiety symptoms. The Cohen's *d* of both the PHQ score and the GAD score between with and without personal exposure was 0.18.

Nearly one in ten (9.2%) respondents were at possible risk due to personal exposure to COVID-19 (**Table 1**), and 26 of them reported that they or their family members were infected. Those with COVID-19 exposure had an elevated severity of depressive [ $\chi^2_{(3)} = 18.35, P < 0.001$ ] and anxiety [ $\chi^2_{(3)} = 21.89, P < 0.001$ ] symptoms than those without COVID-19 exposure.

Two in five (40.7%) respondents living in provinces with 500–999 confirmed cases had mild to severe depression, which was higher than that of others [1,000 and above confirmed cases, 37.8%; 100–499 cases, 35.0%; 1–100 cases, 30.1%;  $\chi^2_{(9)} = 17.67, P = 0.039$ ] (**Table 1**).

The highest rate of mild to severe anxiety symptoms was also among respondents in provinces with 500–999 confirmed cases (28.2%), followed by those in provinces with over 1,000 provincial cases (24.9%), 100–499 cases (22.5%), and 1–100 cases (20.0%). However, the association between provincial epidemic condition and anxiety symptoms was insignificant [ $\chi^2_{(9)} = 13, P = 0.162$ ].

The median score for social support was 36 (IQR = 9, range = 11–60). Increased social support was associated with a decreased severity of depressive [ $\chi^2_{(6)} = 350.62, P < 0.001$ ] and anxiety [ $\chi^2_{(3)} = 174.83, P < 0.001$ ] symptoms.

## Emotions Within 7 Days

Approximately three-fourths (72.5%) of the respondents stated that they felt calm about the COVID-19 outbreak within 7 days, and nearly half (47.7%) reported that they felt nervous. Approximately one in five reported that they felt angry (20.2%) or terrified (18.3%). Helpless, numb, and pessimistic emotions were experienced by 12.6, 10.7, and 8.1% of the respondents, respectively.

Respondents living in a severe provincial epidemic condition reported more numbness (detached feelings) about the outbreak ( $z = 2.71, P = 0.007$ ): <100 cumulative COVID-19 cases, 14.7%, 100–499, 11.1%, 500–999, 10.6%, and 1,000 and above, 8.2%. Other emotions did not vary significantly between the different provincial epidemic conditions (all  $P > 0.05$ ).

## Related Factors for Depressive Symptoms

Logistic regression (**Table 2**, model 1) showed that the risk factors for mild to severe depressive symptoms were low-level social support [adjusted odds ratio (AOR) = 3.19, 95% CI = 2.77–3.67] or medium-level social support (AOR = 1.53, 95% CI = 1.33–1.76), female gender (AOR = 1.48, 95% CI = 1.32–1.65), 500–999 provincial confirmed cases (AOR = 1.50, 95% CI = 1.08–2.08), and COVID-19 exposure (AOR = 1.33, 95% CI = 1.11–1.61). 4 or 5th year undergraduates reported fewer depressive

symptoms (AOR = 0.81, 95% CI = 0.69–0.95) compared with other undergraduates. Residence areas (urban/rural) were not associated with depressive symptoms. No interaction effect was observed in the model.

Moreover, when the analysis was repeated using moderate to severe depressive symptoms as the dependent variable, the odds ratio of COVID-19 exposure or provincial epidemic condition was insignificant ( $P > 0.05$ ; **Table 2**, model 2). The effect of low-level social support (AOR = 4.89, 95% CI = 3.78–6.33), medium-level social support (AOR = 1.98, 95% CI = 1.50–2.62), and female gender (AOR = 1.47, 95% CI = 1.22–1.77) remained significant.

## Related Factors for Anxiety Symptoms

Female gender (AOR = 1.36, 95% CI = 1.20–1.55), living in rural areas (AOR = 1.14, 95% CI = 1.00–1.30), possible COVID-19 exposure (AOR = 1.40, 95% CI = 1.15–1.71), and medium-level (AOR = 1.62, 95% CI = 1.37–1.92) or low-level (AOR = 2.78, 95% CI = 2.37–3.27) social support were associated with an elevated risk of mild to severe anxiety symptoms (**Table 3**, model 1). Fourth or Fifth year undergraduates (AOR = 0.79, 95% CI = 0.65–0.95) had lower anxiety symptom rates than 1st to 3rd year undergraduates. No significant relationship was found between the provincial epidemic condition and anxiety symptoms ( $P > 0.05$ ). However, the interaction effect was not statistically significant.

Furthermore, possible COVID-19 exposure and the provincial epidemic condition were not associated with an elevated risk of moderate to severe anxiety symptoms (all  $P > 0.05$ ; **Table 3**, model 2). Low-level social support (AOR = 3.45, 95% CI = 2.40–4.95), medium-level social support (AOR = 1.64, 95% CI = 1.10–2.44), and female gender (AOR = 1.35, 95% CI = 1.03–1.76) increased the risk of these symptoms.

## DISCUSSION

This large-scale survey demonstrated that most of the medical students had good mental status and calm feelings. Furthermore, mild depressive symptoms and anxiety symptoms were relatively common. Possible exposure to COVID-19 and provincial epidemic spread were associated with a slightly increased risk of poor mental health, while low social support was a more relevant factor.

The prevalence rates of mild to severe depressive (35%) and anxiety (23%) symptoms in our study were higher than those in another survey of Chinese medical students (25.3% for depressive symptoms and 17.1% for anxiety symptoms) that was conducted during a similar period using the same scales and cutoff points (16). Both studies used convenience sampling, but our sample size was much larger. The rates of depressive and anxiety symptoms in the medical students in our study were higher than those reported in a Chinese college student survey (25.9% for depressive symptoms and 17.8% for anxiety symptoms) in February 2020, which used the same cutoff points for the same scales (12). In addition, the rates in our study were also higher than the rates among Chinese medical students on normal days: 29% for depressive symptoms and 21% for anxiety symptoms

(40). The small number of elevated mental problems may have occurred because the COVID-19 outbreak happened during the Spring Festival, the most important family gathering for Chinese people. Most students were at home rather than at universities or medical settings, meaning that they had more family support and lower occupational infection risk. The low prevalence rate of anxiety may be related to the decisive governance of the Chinese central government, social mobilization, mass official health education, and timely news updates from official media (41).

COVID-19 exposure increased the likelihood of mild to severe depressive or anxiety symptoms more than the provincial epidemic condition. Being an infected person or with family caregivers fighting against a communicable disease means directly facing death, loss, care-seeking, and even financial issues (42). These life events may be more related to poor mental health than provincial epidemic conditions. When the number

of provincial confirmed cases of COVID-19 was between 500 and 1,000, the medical students expressed more depressive symptoms. The initial rapid COVID-19 outbreak required people in their respective regions to quickly adjust their minds and lifestyle and adapt to the “new normal.” Therefore, we found that the association between the depression rate and the severity of the provincial epidemic condition was not linear but like an inverted “U” even after being adjusted for personal virus exposure and other factors. Furthermore, it is surprising that the relationship between provincial epidemic conditions and anxiety symptoms was insignificant. Another study among Chinese college students showed that confirmed COVID-19 cases in the current residence area were not associated with depressive (PHQ  $\geq 5$ ) or anxiety (GAD  $\geq 5$ ) symptoms (12). However, their study only presented crude odds ratios rather than ratios adjusted for demographics and social support. Then, it is important

to note that, when using different cutoff points of scales, the epidemic-related factors were not related to moderate to severe depressive or anxiety symptoms. In other words, the impact of the epidemic may only increase mild mental problems in this sample. The elevated symptom severity might be a normal sadness and disturbance response to an unprecedented health crisis (43). Major depressive disorder or general anxiety disorder may be a result of an interaction between genetic factors and lifetime environmental conditions rather than COVID-related factors. Another study found that, compared to people without mental disorders, those with the greatest mental disorder burden had decreased depressive symptoms and worries during the COVID-19 pandemic (43). Pandemic exposure may only be a relatively small stressor for those with poor mental health pre-pandemic. In addition, students living in difficult provincial epidemic conditions expressed more numbness. This feeling seems to be one of the acute stress symptoms caused by the epidemic.

Compared with the epidemic-related factors, factors associated with poor mental health on normal days showed more potent effects. The risk of depressive or anxiety symptoms for medical students with low-level social support was approximately

three times more than those with high-level social support. This result is similar to previous findings among medical students under normal conditions (44). In addition, the association between social support and poor mental health status is consistent with studies conducted among other populations during the COVID-19 pandemic (24–26). Poor mental health status among female medical students was also reported by other studies after COVID-19 (16, 18, 19) or the MERS outbreak (15), while this gender difference was not significant on normal days (40). The lower risk of depression among fourth and fifth year students is consistent with a previous meta-analysis (5). Comparatively, preclinical undergraduates had more curricula to complete and less knowledge about medicine. Some graduate students needed to be engaged and immersed in the clinical environment because of healthcare workforce shortage, and some of them also had to conduct research tasks in their labs.

The findings of this study highlight the importance of improving the social support of medical students. Physical distancing, as a method to avoid virus transmission, also reduces social activities that keep people mentally healthy. Universities and colleges can provide online psychological support, hotline

services, or online courses about psychological preparations for disasters or public crises. When students return to teaching hospitals, they should ensure students' occupational safety, provide supervision, and fully train them on COVID-19. In addition, it is necessary to screen the epidemiological history and mental health status of some high-risk medical students when they return to medical schools or teaching hospitals. Female students, those with low social support, or those who have experienced negative life events associated with the COVID-19 pandemic should receive assistance through possible referrals when the results of screens are positive. Considering our finding that the depressive and anxiety symptoms were generally mild, self-help methods and mental health education programs would also be helpful. Some students had negative feelings, such as anger and hopelessness; thus, emotional expression or management may be important. Furthermore, resilience training (45) can be integrated into medical education to help students become more competent in future health emergency challenges. More infection treatment experience or training may also increase their self-efficacy and intention to provide services or care for patients infected with a newly discovered virus (46).

## Strengths and Limitations

The most significant strength of this study is that, to our knowledge, it is the largest survey on the mental health of medical students at a very unique and important window of time during an emerging communicable disease. Using data from a large country with a strong "lockdown" policy made it possible to explore the association between regional epidemic severity and mental status in a "natural trial." Then, we differentiated personal virus exposure as a "small" environment and provincial epidemic condition as a "large" environment to test their independent impacts. Furthermore, matching personal data with official provincial epidemic data also minimized reporting bias. Finally, this study not only identified the negative mental effects of the outbreak (e.g., depression and anxiety) but also demonstrated the students' positive feelings, such as calmness, providing a complete picture of their experience.

However, there are several limitations. Firstly, the recruitment of participants was conducted through convenience sampling. We could not give a response rate or weigh this sample to increase the representativeness because statistics on national medical students (only majoring in clinical medicine) were not available. The total number of students in medical schools, including students majoring in nursing, pharmacy, or basic medical science, was ~3 million (47). In addition, the infected or virus-exposed medical students may not want to participate in this survey; therefore, the generalization of the rates of depression and anxiety was limited. Secondly, this study did not collect the locations of the medical schools. While most of the students were at home because of the winter vacation, the epidemic condition where their colleges or universities were located could also impact them, for example, through postponement of the return to medical school or a high risk of virus exposure in

teaching hospitals. Thirdly, we did not collect information about their socio-economic status and parents' education level, which may have confounded the results. Finally, an online survey cannot validate the respondents' identities, and self-reports may accompany information bias despite an anonymous data collection process.

In conclusion, nearly one in three Chinese medical students had mild to severe depressive symptoms during the COVID-19 outbreak. Over one-fifth of the patients had mild to severe anxiety symptoms. The risk of depressive or anxiety symptoms for medical students with low social support was higher than those with medium- or high-level social support. COVID-19 exposure increased the risk of depressive and anxiety symptoms. Initial rapid increase in provincial confirmed COVID-19 cases was positively related to mild to severe depressive symptoms. However, COVID-19 exposure and the severity of provincial epidemic conditions were not associated with moderate to severe depressive or anxiety symptoms. Correlates for poor mental status on normal days, such as low social support, female gender, and classification of pre-clerkship or graduates, should be highlighted. Some high-risk medical students need more social support.

## DATA AVAILABILITY STATEMENT

The datasets presented in this article are not readily available because of ongoing analyses. Requests to access the datasets should be directed to chenjx1110@163.com.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Institutional Review Board of Beijing HuiLongGuan Hospital. All subjects were informed of an introduction to the study and provided online informed consent before starting the survey.

## AUTHOR CONTRIBUTIONS

JC and YT conceptualized and designed the study. XY, LG, SZ, MQ, and LZ acquired the data. YY analyzed and interpreted the data. YY and JC drafted the manuscript. YT, XY, LG, SZ, MQ, and LZ critically revised the manuscript for important intellectual content. All authors gave final approval of the version and agreed to be accountable for all aspects of the work in ensuring questions related to the accuracy or integrity.

## FUNDING

This study received funding from the Capital Foundation of Medicine Research and Development (grant no. 2018-3-2132) and the Special Foundation of Beijing Municipal Science & Technology Commission, China (grant no. Z171100001017001).
