## About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

## Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

## Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

## What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: [frontiersin.org/about/contact](https://frontiersin.org/about/contact)

Coronavirus Disease (COVID-19): Psychological, Behavioral, Interpersonal Effects, and Clinical Implications for Health Systems. Lausanne: Frontiers Media SA. doi: 10.3389/978-2-88976-813-4

# Table of Contents

- 12** *Anxiety Status and Influencing Factors of Rural Residents in Hunan During the Coronavirus Disease 2019 Epidemic: A Web-Based Cross-Sectional Survey*  
Yi Zhang, Yi-ping Chen, Jianjian Wang, Yanhong Deng, Dezhen Peng and Liping Zhao
- 19** *Advancing Computerized Cognitive Training for MCI and Alzheimer's Disease in a Pandemic and Post-pandemic World*  
Kaylee A. Bodner, Terry E. Goldberg, D. P. Devanand and P. Murali Doraiswamy
- 24** *Moving Toward Telehealth Surveillance Services for Toddlers at Risk for Autism During the COVID-19 Pandemic*  
Eugenia Conti, Natasha Chericoni, Valeria Costanzo, Roberta Lasala, Alice Mancini, Margherita Prosperi, Raffaella Tancredi, Filippo Muratori, Sara Calderoni and Fabio Apicella
- 31** *Perceived Threat of the Coronavirus and the Role of Trust in Safeguards: A Case Study in Slovakia*  
Martin Kanovsky and Júlia Halamová
- 42** *Fighting Coronavirus One Personality at a Time: Need for Structure, Trait Victimhood, and Adherence to COVID-19 Health Guidelines*  
Yossi Maaravi, Boaz Hameiri and Tamar Gur
- 49** *Does COVID-19 Impact Less on Post-stroke Aphasia? This Is Not the Case*  
Francesca Pisano, Alberto Giachero, Cristian Rugiero, Melanie Calati and Paola Marangolo
- 57** *COVID-19: A Psychosocial Perspective*  
Syed Hassan Raza, Wajiha Haq and Muhammad Sajjad
- 69** *A Narrative Review of Stigma Related to Infectious Disease Outbreaks: What Can Be Learned in the Face of the Covid-19 Pandemic?*  
Fahimeh Saeed, Ronak Mihan, S. Zeinab Mousavi, Renate LEP Reniers, Fatemeh Sadat Bateni, Rosa Alikhani and S. Bentolhoda Mousavi
- 77** *Call for Action to Address Equity and Justice Divide During COVID-19*  
Sonu Bhaskar, Aarushi Rastogi, Koravangattu Valsraj Menon, Beena Kunheri, Sindhu Balakrishnan and Jeremy Howick
- 89** *Psychological Well-Being, Marital Satisfaction, and Parental Burnout in Iranian Parents: The Effect of Home Quarantine During COVID-19 Outbreaks*  
Seyyedeh Fatemeh Mousavi
- 100** *Psychological Symptoms and Behavioral Changes in Children and Adolescents During the Early Phase of COVID-19 Quarantine in Three European Countries*  
Rita Francisco, Marta Pedro, Elisa Delvecchio, Jose Pedro Espada, Alexandra Morales, Claudia Mazzeschi and Mireia Orgilés

- 114** *Anxiety Severity, Perceived Risk of COVID-19 and Individual Functioning in Emerging Adults Facing the Pandemic*  
Alessandro Germani, Livia Buratta, Elisa Delvecchio, Giulia Gizzi and Claudia Mazzeschi
- 123** *Bibliotherapy: Reading OVID During COVID*  
Emmanuel Stip, Linda Östlundh and Karim Abdel Aziz
- 131** *Psychological Typhoon Eye Effect During the COVID-19 Outbreak*  
Guixiang Wang, Yan Zhang, Simiao Xie, Pu Wang, Guanghui Lei, Yueran Bian, Fei Huang, Jingyuan Zhang, Xiaochen Cao, Na Luo, Mingyan Luo and Qiang Xiao
- 142** *Epidemic Rumination and Resilience on College Students' Depressive Symptoms During the COVID-19 Pandemic: The Mediating Role of Fatigue*  
Baojuan Ye, Xiuxiu Zhou, Hohjin Im, Mingfan Liu, Xin Qiang Wang and Qiang Yang
- 152** *COVID-19, Coronavirus, Wuhan Virus, or China Virus? Understanding How to "Do No Harm" When Naming an Infectious Disease*  
Theodore C. Masters-Waage, Nilotpaj Jha and Jochen Reb
- 162** *The Effect of Parent Psychological Distress on Child Hyperactivity/Inattention During the COVID-19 Lockdown: Testing the Mediation of Parent Verbal Hostility and Child Emotional Symptoms*  
Daniela Marchetti, Lilybeth Fontanesi, Serena Di Giandomenico, Cristina Mazza, Paolo Roma and Maria Cristina Verrocchio
- 170** *The Psychological Impact of COVID-19 in Italy: Worry Leads to Protective Behavior, but at the Cost of Anxiety*  
Giulia Prete, Lilybeth Fontanesi, Piero Porcelli and Luca Tommasi
- 177** *A Postcard From Italy: Challenges and Psychosocial Resources of Partners Living With and Without a Chronic Disease During COVID-19 Epidemic*  
Giada Rapelli, Giulia Lopez, Silvia Donato, Ariela Francesca Pagani, Miriam Parise, Anna Bertoni and Raffaella lafrate
- 191** *Organizational Justice, Professional Identification, Empathy, and Meaningful Work During COVID-19 Pandemic: Are They Burnout Protectors in Physicians and Nurses?*  
Isabel Correia and Andreia E. Almeida
- 204** *Burnout Syndrome Among Hospital Healthcare Workers During the COVID-19 Pandemic and Civil War: A Cross-Sectional Study*  
Muhammed Elhadi, Ahmed Msherghi, Moutaz Elgzairi, Ayiman Alhashimi, Ahmad Bouhuwaish, Marwa Biala, Seraj Abuelmeda, Samer Khel, Ala Khaled, Ahmed Alsoufi, Amna Elmabrouk, Fatimah Bin Alshiteewi, Tasneem Ben Hamed, Bushray Alhadi, Sara Alhaddad, Ahmed Elhadi and Ahmed Zaid
- 215** *Depressive Symptoms, Anxiety Disorder, and Suicide Risk During the COVID-19 Pandemic*  
Aurel Pera
- 222** *Perinatal Depression of Exposed Maternal Women in the COVID-19 Pandemic in Wuhan, China*  
Guoqiang Sun, Qi Wang, Ying Lin, Ruyan Li, Lijun Yang, Xian Liu, Min Peng, Hongyan Wang, Xuewen Yang, Wei Ren, Hui Yang and Yao Cheng

- 230** *Children Coping, Contextual Risk and Their Interplay During the COVID-19 Pandemic: A Spanish Case*  
Beatriz Domínguez-Álvarez, Laura López-Romero, Aimé Isdahl-Troye, Jose Antonio Gómez-Fraguela and Estrella Romero
- 244** *Physical and Psychological Impact of the Phase One Lockdown for COVID-19 on Italians*  
Marco Tommasi, Francesca Toro, Simone Arnò, Angelo Carrieri, Marco Maria Conte, Marianna Daria Devastato, Laura Picconi, Maria Rita Sergi and Aristide Saggino
- 256** *The Effect of Concerns About COVID-19 on Anxiety, Stress, Parental Burnout, and Emotion Regulation: The Role of Susceptibility to Digital Emotion Contagion*  
Alena Prikhidko, Haiying Long and Michael G. Wheaton
- 266** *Early Psychiatric Impact of COVID-19 Pandemic on the General Population and Healthcare Workers in Italy: A Preliminary Study*  
Benedetta Demartini, Veronica Nisticò, Armando D'Agostino, Alberto Priori and Orsola Gambini
- 274** *SARS-CoV-2 and Asbestos Exposure: Can Our Experience With Mesothelioma Patients Help Us Understand the Psychological Consequences of COVID-19 and Develop Interventions?*  
Antonella Granieri, Michela Bonafede, Alessandro Marinaccio, Ivano Iavarone, Daniela Marsili and Isabella Giulia Franzoi
- 286** *Assessment of Depression Severity During Coronavirus Disease 2019 Pandemic Among the Palestinian Population: A Growing Concern and an Immediate Consideration*  
Hamzeh Al Zabadi, Thair Alhroub, Noor Yaseen and Maryam Haj-Yahya
- 295** *Does Self-Efficacy and Emotional Control Protect Hospital Staff From COVID-19 Anxiety and PTSD Symptoms? Psychological Functioning of Hospital Staff After the Announcement of COVID-19 Coronavirus Pandemic*  
Monika Bidzan, Ilona Bidzan-Bluma, Aleksandra Szulman-Wardal, Marcus Stueck and Mariola Bidzan
- 304** *Unmasking Reflexivity in HR Managers During the COVID-19 Lockdown in Italy*  
Silvio Carlo Ripamonti, Laura Galuppo, Giulia Provasoli and Angelo Benozzo
- 314** *Is Fear of COVID-19 Contagious? The Effects of Emotion Contagion and Social Media Use on Anxiety in Response to the Coronavirus Pandemic*  
Michael G. Wheaton, Alena Prikhidko and Gabrielle R. Messner
- 323** *The Role of Attitudes, Affect, and Income in Predicting COVID-19 Behavioral Intentions*  
Kelly S. Clemens, John Matkovic, Kate Faasse and Andrew L. Geers
- 330** *Hospital Preparedness, Resilience, and Psychological Burden Among Clinical Nurses in Addressing the COVID-19 Crisis in Riyadh, Saudi Arabia*  
Ejercito Mangawa Balay-odao, Nahed Alquwez, Ergie Pepito Inocian and Raid Salman Alotaibi
- 341** *Mental Health and Coping in the Shadow of the COVID-19 Pandemic: The Israeli Case*  
Mally Shechory Bitton and Avital Laufer

- 351** *Goals and Self-Efficacy Beliefs During the Initial COVID-19 Lockdown: A Mixed Methods Analysis*  
Laura Ritchie, Daniel Cervone and Benjamin T. Sharpe
- 362** *Impact of Coronavirus Disease (COVID-19) Pandemic on Psychological Well-Being of the Pakistani General Population*  
Adeel Ahmed Khan, Fahad Saqib Lodhi, Unaib Rabbani, Zeeshan Ahmed, Saidul Abrar, Saamia Arshad, Saadia Irum and Muhammad Imran Khan
- 372** *COVID-19 Pandemic as the Beginning of a Golden Era for Telepsychiatry in Poland's Healthcare System*  
Łukasz Zadka and Marcin Olajossy

Status and Influencing Factors of  
Rural Residents in Hunan During the  
Coronavirus Disease 2019 Epidemic:  
A Web-Based Cross-Sectional  
Survey. *Front. Psychiatry* 11:564745.  
doi: 10.3389/fpsy.2020.564745

**Objective:** To explore the status quo of anxiety and its influencing factors among rural residents in Hunan Province during the coronavirus disease 2019 epidemic, and to provide an effective basis for prevention of and intervention for anxiety symptoms among rural residents.

**Methods:** Convenience sampling was used. An online questionnaire was distributed to Hunan rural residents through the questionnaire star platform from February 26–29, 2020. The general data and anxiety of Hunan rural residents were investigated, and the data were analyzed using SPSS 18.0.

**Results:** The mean Self-Rating Anxiety Scale score of 179 rural residents in Hunan was  $40.93 \pm 9.36$ . Based on the cutoff criteria, 32 residents had anxiety, including 26 with mild anxiety, five with moderate anxiety, and one with severe anxiety. The detection rate of anxiety was 17.88%. Self-rated health status, level of concern about the epidemic, and self-rated impact of the epidemic on one's life were the factors influencing the anxiety score of rural residents in Hunan ( $P < 0.05$ ).

**Conclusion:** During the coronavirus disease 2019 epidemic, the detection rate of anxiety in rural residents in Hunan was higher than that of the general population in China. The relevant departments should pay attention to the mental health of rural residents and implement targeted mental health prevention and intervention measures during the epidemic situation.

**Keywords:** corona virus disease 2019, rural residents, anxiety, Hunan (South China), COVID-19

## INTRODUCTION

Since December 2019, coronavirus disease 2019 (COVID-19) epidemics have appeared around the world, starting in Wuhan, Hubei Province, China (1). As of October 4, 2020, the total number of confirmed cases worldwide was 34,804,348, with 1,030,738 cumulative associated deaths (2). The total number of confirmed cases in China was 85,470, with 4,634 deaths (3). It has had a considerable impact and caused psychological strain among Chinese people.

Without doubt, the COVID-19 epidemic is a global public health problem that poses a serious threat to the global society, economy, and human health. The cognitive—phenomenological—transactional model proposes that stress is generated through the specific relationship between the individual and the environment. The individual continually recognizes and evaluates stimuli in a stressful environment, and undergoes physical and psychological changes to adapt to the needs of the environment (4). Therefore, in the face of an epidemic, different groups of people will have different levels of anxiety, fear, helplessness, and even impulsive and irritating behaviors (5). Many studies have shown that mental health problems could occur in both medical staff and severe acute respiratory syndrome (SARS) survivors during the SARS epidemic (6–9). Previous studies of Middle East respiratory syndrome also reported similar results (10, 11). Researchers have conducted many surveys on the psychological status of people during the COVID-19 epidemic, but most of them have concentrated on special groups such as patients with COVID-19 (12, 13), medical staff (14–16), or susceptible groups such as the elderly (17), children (18), and students (19). There are few studies on the psychological status of residents, especially rural residents. Rural areas have become extremely challenging for epidemic prevention and control because of various factors such as shortages of medical resources, insufficient public protection capabilities, and population migration caused by the return of migrant workers to their hometown (20). Previous research found that rural residents have poorer mental health compared to urban residents (21), and anxiety is one of the main problems affecting the mental health of rural residents (22). Hubei was the first and most severely affected province in the epidemic. As its neighboring province, Hunan Province is more likely to be exposed to suspected or infected cases than other regions, which increases residents' psychological pressure and anxiety. This study investigated the anxiety status of rural residents in Hunan during the COVID-19 epidemic and analyzed its influencing factors, intending to provide a scientific basis for effective psychological intervention for rural residents in Hunan.

## METHODS

### Study Design and Sample

A cross-sectional study was conducted among rural residents in rural areas of Hunan Province, China, from February 26–29, 2020. The inclusion criteria were as follows: (a) living in the rural areas of Hunan Province during the COVID-19 epidemic; (b) aged 18 years or older; (c) proficient in WeChat and online questionnaires; and (d) were conscious and volunteered for the study. The exclusion criteria were as follows: participants with psychosis or severe mental disorders and inadequate communication ability.

Ethical approval was obtained from the ethics committee of Central South University (No: E202020) before data collection.

### Measures

*Socio-demographic characteristics* were measured using a self-designed questionnaire, including gender, age, occupation,

residence, marital status, relevant knowledge of COVID-19 (understanding relevant knowledge or not, channels of knowledge acquisition), health status (temperature, self-rated health status, history of contact with Wuhan within the previous half month, and history of exposure to potentially infected people), level of concern about the epidemic, and self-rated impact of the epidemic on one's life.

*Anxiety status* was determined using the self-rating anxiety scale (SAS) (23). The scale consists of 20 items and aims to assess respondents' subjective symptoms. Each item was evaluated on a four-point Likert scale ranging from 1 ("little or none of the time") to 4 ("most of the time"), with higher scores indicating higher levels of anxiety. The Cronbach's alpha for the total scale was 0.864, and it has good reliability and validity, and has been widely used in clinical research (24). According to the Chinese norm (25), the standard score has a cutoff value of 50, 50 to 59 represents mild anxiety, 60 to 68 represents moderate anxiety, and 69 points and above represents severe anxiety.

## Statistical Analysis

### Sample Size

We selected 18 possible influencing factors through a literature review. According to the principle that the sample size should be 5 to 10 times the number of independent variables, the estimated minimum sample size was 180; considering a likely attrition rate of 10% and sampling error, the final required sample size was 200.

### Quality Control

This survey used an online questionnaire. The questionnaire could only be submitted after it had been completed and each IP address could only answer once to avoid repeated answers. In addition, real-time background monitoring was performed to ensure data reliability. To prevent possible bias, a uniform guideline was used on the front page of the questionnaire to explain the completion requirements.

### Data Analysis

Data analysis was performed using SPSS 18.0. Results are expressed as mean  $\pm$  standard deviation ( $X \pm S$ ) or number (%). First, descriptive analyses were conducted to describe the demographic characteristics, relevant knowledge of COVID-19, and health status in rural residents in Hunan during the epidemic. Second, *t*-tests and one-way analysis of variance were used to analyze the anxiety levels of residents with different characteristics. Third, a *t*-test was used to compare the anxiety scores between rural residents in Hunan during the epidemic and different populations in different periods. Fourth, hierarchical regression analysis was performed to explore potential factors influencing residents' anxiety in Hunan during the COVID-19 epidemic. *P*-values  $< 0.05$  were considered statistically significant (2-sided tests).

## RESULTS

We collected 200 questionnaires in the rural areas of 45 townships in 15 regions in Hunan Province. After checking each item one by one, a total of 21 questionnaires with high

consistency of answers or answering time of <150 s were excluded, and 179 valid questionnaires were obtained. The response rate of the questionnaire was 89.5%.

As shown in **Table 1**, most participants were living with their spouse or family and only a few lived alone (5.6%). Most participants had relevant knowledge of COVID-19 (93.9%), and official platforms were their main channels for acquiring knowledge (76.5%). Most participants expressed concern about this epidemic (93.9%), and only 3.9% of them self-rated that the epidemic did not affect their lives. Among them, 32 of the 179

participants (17.88%) had anxiety; specifically, 26 participants had mild anxiety, five participants had moderate anxiety, and one participant had severe anxiety.

## Scores of Anxiety Levels of Rural Residents in Hunan During the COVID-19 Epidemic

As shown in **Table 2**, the mean anxiety scores of rural residents in Hunan during the COVID-19 epidemic was  $40.93 \pm 9.36$ , which

\* $P < 0.05$ .

was higher than the rural residents' anxiety scores during the non-epidemic period ( $t = 14.820, P < 0.001$ ), which was also higher than the anxiety scores of healthy Chinese individuals during the non-epidemic period ( $t = 55.098, P < 0.001$ ). However, compared with the anxiety scores of rural residents across China during the epidemic, rural residents in Hunan had lower anxiety scores ( $t = -4.375, P < 0.001$ ). In terms of anxiety detection rate, only the difference between rural residents in Hunan during the epidemic and healthy people before the epidemic was statistically significant ( $\chi^2 = 6.644, P = 0.010$ ).

### Factors Influencing Rural Resident' Anxiety in Hunan During the COVID-19 Epidemic

The results showed that self-rated health status, level of concern about the epidemic, and self-rated impact of the epidemic on one's life had statistically significant effects on anxiety scores ( $P < 0.05$ , as shown in Table 1).

### Hierarchical Regression Analysis of the Influencing Factors of Rural Residents' Anxiety Score in Hunan During the COVID-19 Epidemic

Hierarchical regression analysis was used to analyze whether the gradual addition of self-rated health status, level of concern about the epidemic, and self-rated impact of the epidemic on one's life could improve the model's prediction level of the standard anxiety score.

The final model included three variables: self-rated health status, level of concern about the epidemic, and self-rated impact of the epidemic on one's life, which was statistically significant,

$R^2 = 0.113, F(3, 175) = 7.465 (P < 0.001)$ , adjusted  $R^2 = 0.098$ , which explained 11.3% of the total variation in the anxiety scores of rural residents in Hunan during the COVID-19 epidemic.

Self-rated health status was added into Model 1 and the  $R^2$  value of Model 1 was 0.070,  $F(1, 171) = 13.304 (P < 0.001)$ . After adding level of concern about the epidemic, the  $R^2$  value of Model 2 increased by 0.035,  $F(1, 176) = 6.890 (P < 0.01)$ , which was statistically significant. Based on Model 2 and adding self-rated impact of the epidemic on one's life, the  $R^2$  value of Model 3 increased by 0.009,  $F(1, 175) = 1.678 (P = 0.197 > 0.05)$ , which was not statistically significant. The specific results are shown in Table 3.

## DISCUSSION

### Anxiety Status of Rural Residents in Hunan During the COVID-19 Epidemic

The results of this survey show that the anxiety score of rural residents in Hunan during the COVID-19 epidemic was higher than that of healthy Chinese (26) and rural residents across China (27) during the non-epidemic period. Our research found that the detection rate of anxiety among rural residents in Hunan was 17.88%, while one Turkish study reported that the detection rate of anxiety in people was 45.1% (28) while a study on American adults found a rate of 38.41% (29). The reason for this difference may be that our research was carried out in February, while their research was mainly carried out in April 2020. At this time, COVID-19 was spreading around the world and the epidemic was worsening. Due to the strong contagion, long incubation period, wide spread, and rapid progress of COVID-19, the epidemic seriously threatens

**TABLE 2 |** Comparison of the anxiety level of rural residents in Hunan during the epidemic and different populations in different periods.

	Total number of sample	Mean (SD)	t	P-value	Number of anxiety detected (%)	$\chi^2$	P-value
Anxiety level of residents in different regions during the epidemic			-4.375	<0.001		3.708	0.054
	Rural residents in Hunan Province	179 40.93 ± 9.30			32(17.9)		
	Rural residents across China	1,029 43.99 ± 8.55			398(38.7)		
Anxiety level of rural residents in different periods			14.820	<0.001		0.730	0.393
	During the epidemic	179 40.93 ± 9.30			32(17.9)		
	During non-epidemic period	778 30.56 ± 5.94			119(15.3)		
Anxiety level of rural residents in Hunan Province during the epidemic and healthy people during non-epidemic period			55.098	<0.001		6.644	0.010
	Rural residents in Hunan province during the epidemic	179 40.93 ± 9.30			32(17.9)		
	Healthy people during non-epidemic period	1,158 29.78 ± 10.07			129(11.1)

people's health and safety, and people will inevitably experience negative emotions such as anxiety and fear when facing the epidemic (30). However, it is worth mentioning that because of the specific geographical location of Hunan (near Hubei Province, the province where the epidemic first broke out), before the survey, researchers predicted that rural residents in Hunan Province may have higher levels of anxiety, but our results show that during the COVID-19 epidemic, rural residents' anxiety scores in Hunan were lower than national rural residents' anxiety scores ( $43.99 \pm 8.55$ ), as investigated by Wang (31). This may be related to the fact that the Chinese government immediately locked down Wuhan and the entire Hubei Province after the outbreak of the epidemic to contain the pandemic, so that the epidemic did not break out in large areas in Hunan Province, and the growth rate of the epidemic gradually decreased; thus, most residents in the vicinity of the epidemic became increasingly confident.

## Factors Influencing the Anxiety of Rural Residents in Hunan During the COVID-19 Epidemic

### Self-Rated Health Status

Residents who considered themselves to be in poor health had higher anxiety scores than residents who considered their health to be good, and their average anxiety score reached the anxiety cutoff. Metacognition theory posits that self-centered consciousness activities are positive feedback and adjustments to consciousness (32). Therefore, residents who believe they are in good health will be confident in resisting attacks of COVID-19, while residents who believe they are in poor health may think they will be more susceptible to the virus and if they are infected, have no confidence in defeating it, so their anxiety scores would be higher than those who think they are in good health. Studies (33, 34) have shown that emotional therapy has a positive effect on easing the public's negative emotions during the epidemic; therefore, self-positive suggestion may relieve residents' anxiety.

### Level of Concern About the Epidemic

The higher their level of concern about the epidemic, the higher the residents' anxiety score. Studies by Li (35) and Zhang (24) also showed that the degree of concern about the epidemic is a factor influencing anxiety among different groups of people during the COVID-19 epidemic. Several factors are likely to induce anxiety among residents, including the number of confirmed cases and deaths from COVID-19 that continue to rise daily, lack of knowledge of the disease, surrounding people who may have been infected with the virus, and the lack of anti-coronavirus specific drugs (36), among other reasons. Cai (37) believed that during the epidemic, people only know what COVID-19 is but do not know how to control it, which is not sufficient to reduce its effects on their psychological problems. The key is to know how to prevent and control COVID-19. Leung et al. (38) found that publicizing measures for disease prevention and eliminating the spread of rumors can reduce public anxiety. The results of this survey showed that most people acquired relevant knowledge of COVID-19 through an official platform. Therefore, it is necessary to strengthen the dissemination of disease information and prevention measures on official platforms.

### Self-Rated Impact of the Epidemic on One's Life

The greater their self-rated impact of the epidemic on one's life, the higher the residents' anxiety scores. The population density in rural areas is smaller than that in cities or towns, and houses are mostly single-family houses, so rural residents can have a wide range of activities in a relatively safe and isolated environment. Some rural residents usually work in fields or farms and rarely go to densely populated areas, so they feel that the epidemic has little impact on their lives and have low anxiety scores. However, some rural residents need to go to cities to earn a living or need to be in contact with others at work; during the epidemic, their financial and living pressures have greatly increased due to work restrictions, so their anxiety scores are high. For these individuals, it is necessary to actively solve practical problems such as the delayed resumption of work and limited social activities (39).

## LIMITATIONS

Due to the difficulties and limitations in collecting data during the epidemic, random sampling was not conducted in this survey, and the nature of the sample may limit the generalizability of the results. In addition, due to the use of online questionnaires, the survey only included people who can operate WeChat proficiently. Elderly and rural residents who do not use WeChat were not included. Further longitudinal studies should be conducted to better investigate the psychological status of and interventions for rural residents more deeply.

## CONCLUSION

COVID-19 is having a huge impact on the life and the psychology of rural residents in Hunan Province, China. During the epidemic, their anxiety rate was high. This was a particular phenomenon of residents in a specific period; we need to pay enough attention to it and seek positive solutions to deal with it ingeniously. The results showed that self-rated health status, level of concern about the epidemic, and self-rated impact of the epidemic on one's life are the main factors that affect how anxious rural residents are. It is necessary to increase publicity about COVID-19 prevention measures and provide positive psychological guidance to alleviate rural residents' anxiety. Timely announcements about the epidemic, vigorous publicity about epidemic prevention measures, and the support of all sectors of society will give people around the world greater confidence and strength to overcome the epidemic (40).

## INTRODUCTION

Worldwide, some 40 million adults have Alzheimer's disease (AD) (1) and several hundred million may be at elevated risk for AD by virtue of mild cognitive impairment (MCI) and/or silent buildup of cortical AD pathology. There are no pharmacological treatments with more than minimal efficacy for mild AD, and prevention strategies are not established.

The COVID-19 pandemic has transformed mobile health applications and telemedicine from nice to have tools into essential healthcare infrastructure (2–13). We anticipate that this need will be particularly great for the elderly who, due to their greater risk for infection, may avoid medical facilities or be required to self-isolate. These are also the very groups at highest risk for cognitive decline. Further, emerging data suggests COVID-19 may itself be linked with longer-term neurological consequences, including cognitive decline (5).

Definitive data on the utility of cognitive/mental wellness tools during the pandemic awaits the results of ongoing clinical trials (6–10), but there is accumulating preliminary evidence (11). For example, during the COVID-19 pandemic, chatbots employed by hospitals and government agencies fielded millions of queries from concerned patients (3). Digital tools also were deployed to provide psychological self-help to people isolated at home or in retirement centers and nursing homes (2–4). A survey of 1,000 adults done in March 2020 (12) found that 82% were concerned about leaving their home, 78% are avoiding doctor visits unrelated to COVID and 80% would prefer to receive a remote virtual health consultation if given the opportunity. A recent survey of elderly MCI subjects during the pandemic (13) demonstrated potential for cognitive stimulation *via* assistive technology but also found that those living alone had the greatest negative mental effects.

## COMPUTERIZED COGNITIVE TRAINING

Computerized cognitive training (CCT) is one such application of digital health in which individuals can access gamified, engaging, cognitive exercises from their own computers or mobile devices anytime anywhere (14–24). These exercises can be targeted to improve overall cognition or specific domains (such as learning and memory, attention, speed, executive functioning), as well as daily living skills such as financial knowledge or driving performance (14–24). They can potentially be adjusted based on response *via* self-administered cognitive tests, and adherence supervised remotely, as needed, by a physician or psychologist (**Figure 1**).

## CLINICAL TRIALS OF CCT IN AGING AND MCI

While scientific opinion regarding CCT has in the past been divided (15–18), there is now a growing body of evidence (pre-COVID) from pre-clinical and observational research [reviewed in (14, 20–24)] as well as data from large RCTs and meta-analyses to show that certain cognitive training regimens can improve cognitive and functional abilities in older adults (17). For example, the NIH-funded, Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) Trial of 2,832 older people, assigned people to 3 forms of training—memory, reasoning and speed—vs. a control. The memory group showed no benefits. But 5 years after initial training, the reasoning group self-reported fewer daily-living problems, whereas speed-of-processing training resulted in fewer at-fault automobile accidents and a smaller decline in health-related quality of life (21). Further, at 10-year follow up, those on the computerized speed training arm had a 29% reduction in incident dementia rates (22). Likewise, while an initial online study by Owen et al. (18) did not find benefits of CCT in younger adults, a subsequent study of 2,912 older adults by the same group reported that CCT had benefits on both cognition and daily activities (19). A meta-analyses of 52 studies comprising 4,885 cognitively healthy older adults, noted small to moderate beneficial effect sizes for CCT in comparison to control groups in the domains of verbal memory, non-verbal memory, working memory, processing speed, and visuospatial skills (23). This study also found that group-based training was more efficacious than home-based

training—suggesting that future home based CCT may need to be augmented with greater remote supervision and interactions *via* social media (23). A meta-analysis of 18 studies of CCT for MCI ( $N = 690$ ) found small to moderate improvements in global cognition, memory and working memory (20). The largest effect size was on working memory. Whether these improvements result in long-term transfer to clinically meaningful benefits and lowered rates of progression to dementia is not known and require further study (20).

There is also evidence that the effectiveness of CCT in subjects at risk for AD could be improved by supplementing cognitive training with other tools such as physical exercise, diet, vascular risk reduction, neuromodulation or pharmacotherapy. For example, Lenze et al. (25) reported that the addition of a serotonin modulator/stimulator drug, vortioxetine, could improve the efficacy of CCT in MCI. Two studies that examined the effects of combining physical and cognitive training in MCI reported mixed results (24, 26). Singh et al. (24), using a  $2 \times 2$  design, found that CCT improved memory in MCI at 6 months but did not augment the effects of exercise. In contrast, the 40-week population study by Shimada et al. (26) of 945 MCI subjects reported that combined CCT and physical exercise improved memory and non-memory domains, and reduced medial temporal lobe atrophy in amnesic MCI (26). Lastly, the 2-year FINGER randomized controlled trial of 1,260 older adults showed that a multi-domain lifestyle intervention, comprising CCT as one of the components, slowed cognitive decline (27). While the benefits seen in multi-domain intervention studies cannot be attributed solely to CCT, these data, together with data

from monotherapy RCTs, support further development of CCT for cognitive rehabilitation of MCI and early AD.

## ADVANCING CCT AS A DIGITAL BRAIN THERAPEUTIC

The International Medical Device Regulators Forum (IMDRF) for software as a medical device (SaMD) consensus guidelines (28) state that a software intended to treat or prevent a serious disease would have to conduct well-controlled clinical trials to prove efficacy and seek pre-marketing authorization from a regulatory agency. CCT that is marketed for treating MCI or preventing AD would be viewed as a medical device and subject to pre-marketing regulatory oversight. CCT intended for use as a general wellness tool to improve mental speed would likely not be subject to such oversight. Recently, prescription digital therapeutics have been cleared by the US Food and Drug Administration (FDA) for use in substance abuse and sleep disorders, and apps for other diseases are in development (29).

We believe the most efficient regulatory path for CCT is to seek a marketing indication as a prescription digital therapeutic for the symptomatic treatment of MCI or very mild dementia. Such a path would be supported by the large public health threat posed by AD and the urgent need for scalable, low risk, cost-effective, home-based preventive treatments. The small to moderate effect sizes seen in MCI CCT trials to date are likely to be similar to those expected in ongoing anti-amyloid or anti-tau trials. Further, the safety of CCT is superior to most biologics/drugs being studied for MCI and the risk is minimal.

Recent FDA draft guidelines for acceptable outcomes in early AD trials of investigational drugs (30) provide a roadmap for CCT. The FDA guidance categorizes early AD into three stages—Stage 1 (pathological changes but no clinical deficits), Stage 2 (mild cognitive deficits but no measurable functional deficits), and Stage 3 (measurable cognitive and functional deficits). Stages 2 and 3 are analogous to early MCI and late-MCI. The FDA guidance suggests that in Stage 1 one or more biomarkers could serve as a primary basis for accelerated approval with the requirement for a post-approval confirmatory clinical study. In Stage 2, one or more neuropsychological tests (either effect on multiple tests or a large effect on a single test) could serve as the basis for approval. In Stage 3, a single integrated scale that measures both daily function and cognitive effects (e.g., Clinical Dementia Rating Scale) could serve as evidence of efficacy.

CCT manufacturers should seek advice from regulatory agencies and/or utilize the FDA's digital software pre-certification (Pre-Cert) program. In the US, given the lack of a predicate or product code, CCT for MCI would likely be viewed by the FDA as a Class III device (31); however, we believe that a *de-novo* application to request re-classification of CCT as a lower risk Class II device could be successful. If regulatory agencies view the existing studies of CCT in aging and MCI [such as those cited in (14–26)] as supportive, then only a single, methodologically rigorous, relatively short (e.g., 24-week) trial may be needed to gain such an indication. Alternatively a regulatory quality trial could also be conducted in the public interest through a public-private partnership involving one or

more CCT companies or *via* a government grant. For example, our group is currently conducting an 18-month randomized trial of CCT vs. active control in carefully selected MCI patients with clinically meaningful cognitive (ADAS-Cog), functional (FAQ, UPSA), neuronal loss (hippocampal volume) and disease modifying (progression to dementia) outcomes (32).

Given the millions of elderly already doing CCT at home, it would also be insightful to analyze existing large registries to examine real world outcomes consistent with the FDA's total product lifecycle approach (31). Three areas of real world health analytics (RWHA) would be relevant for CCT—(1) patient reported outcomes such as daily activities; (2) user experience analytics such as engagement and compliance; (3) product performance (reliability, privacy, and cybersecurity). Updates on real world performance could be provided quarterly to public and regulators. Databases from large published RCTs (14–26) could be made available for such purpose with data sharing principles similar to the Dementias Platform UK or Alzheimer's Disease Neuroimaging Initiative (14, 33). The Human Cognition Project is one such CCT database that has already yielded useful insights and accessed by several academics (14, 34).

There are numerous CCT programs available on the market as wellness tools but none are currently cleared by regulators as a medical device and hence it is difficult for consumers and clinicians to choose among them. Regulatory clearance would increase trust and allow for greater scaling as a clinician supervised digital therapeutic (**Figure 1**). Future research to clarify the role of augmenting agents, such as off-label medications (e.g., vortioxetine), cholinesterase inhibitors, physical exercise, and other non-pharmacologic interventions, for CCT to achieve maximum efficacy as a cognitive enhancing strategy would also be useful. Future studies could also examine its utility in combination with anti-amyloid or anti-tau agents.

The COVID-19 pandemic has illustrated the demand for digital tools across the entire spectrum of healthcare. Ongoing studies are testing the utility of CCT for elderly subjects during the COVID pandemic (6, 31). For example, the TV-AssistDem a European multicenter randomized controlled trial evaluating a digital technology-based assistive integrated service to provide social connectedness and memory stimulation for MCI has rapidly adapted to the pandemic. Globally, reimbursement and regulatory burdens faced by digital tools before the pandemic have begun to diminish. The optimal features needed post-pandemic are difficult to predict at this time but hybrid models of home-based, tele-medicine and clinical based care will likely become the norm. Companies that integrate digital therapeutics with other modalities (e.g., digital diagnostics, digital pharmacy, live consults *via* tele-medicine) will best provide a seamless experience for consumers. Further, as our figure illustrates, features such as ease of use and ease of trouble shooting minimal supervision or ability to supervise by a caregiver, smooth integration with clinical medical record, remote access to results by doctors and therapists/psychologists for treatment monitoring, real time patient feedback, self-rated outcomes and real world analytics to track progress, and affordability would make it attractive to elderly in a post-pandemic situation. A patient-centered, real world health data sharing platform that can collect and aggregate siloed data sources across multiple health

systems has recently been demonstrated (35). These lessons are highly relevant to optimize CCT as a clinical tool in MCI.

In summary, we believe that it is an important time for the field to advance CCT from a wellness product to a well-integrated, digital brain therapeutic platform *via* an appropriate regulatory pathway to help millions of elderly both during pandemics and in normal times.

Since 2016, the project “Early Bird Diagnostic Protocol for Autism Spectrum Disorders (ASD)” funded by the Italian Ministry of Health has been operative at IRCCS Fondazione Stella Maris (FSM), Pisa (IT), with the main aim of developing early age-specific diagnostic protocols by longitudinally enrolling two different populations at risk for ASD: (i) toddlers with older siblings with ASD (FR) and (ii) toddlers referred by a child psychiatrist or pediatrician for suspected ASD (CR). On January 30, 2020, when the World Health Organization declared the outbreak of coronavirus disease 2019 (COVID-19), 136 patients (85 FR; 51 CR; 93 males; 43 females) had been enrolled in the project with 324 completed time points and 64 still missing. Considering both the huge psychological burden on families with toddlers at risk for ASD during the lockdown and the longitudinal studies reporting the positive “surveillance effect” in terms of a better outcome in at-risk toddlers, our priority has been to maintain regular contact and support to enrolled families. To do this, the research team, being authorized for smart-working research activities, has set up a detailed remote surveillance protocol (RSP). The RSP includes three online interviews and one online video registration of parent–child play. In the current community case study, the authors report the telehealth procedure and discuss possible future directions in developing remote assessment and new evaluation modalities for ecological parent–child play video recordings in at-risk populations. Hopefully, the surveillance protocol will further improve our ability to detect risk and activate early tailored intervention.

**Keywords:** autism spectrum disorders (ASD), coronavirus disease 2019 (COVID-19), public mental health, neurodevelopment, early identification, telehealth

## INTRODUCTION

With an estimated prevalence of one in 87 children aged 7–9 years in Italy (1), autism spectrum disorders (ASD) are increasingly perceived as a public health priority, with a significant individual, familial, and societal burden, both emotional and economic. The phenotypic expression and the detrimental impact of ASD could be mitigated through early identification and intervention prior to the emergence of full-blown symptoms. Current literature, in fact, suggests that (i) it is possible

to detect ASD starting from 14 months of age in at least a certain proportion of children (2); (ii) very young children benefit from early intervention (EI), especially when parents are actively involved in the rehabilitation process (3); and (iii) intervention should be initiated as soon as possible, when signs of ASD risk appear (4). Based on these three assumptions, since 2016 the project “Early Bird Diagnostic Protocol for Autism Spectrum Disorders” (EARLY BIRD; NET-2013-02355263-3) funded by the Italian Ministry of Health has been operative at IRCCS Fondazione Stella Maris (FSM), Pisa (IT), a tertiary-care University hospital that receives patients from all over Italy. This project aimed to develop, through longitudinal clinical monitoring and planned time points, age-specific diagnostic protocols able to detect (i) risk for ASD at 12 months of age; (ii) provisional diagnosis of ASD at 18 months of age; and (iii) stable diagnosis according to the diagnostic criteria of the DSM-5 (5) at 24 months of age. In addition, a clinical follow-up is scheduled at 30 months of age, to confirm the diagnosis or exclude it definitively. Children whose evaluations suggest a diagnosis of autism are referred to their local Child and Adolescent Mental Health Services (CAMHS) for early intervention.

A team of psychologists and child psychiatrists with many years of clinical and research experience in the ASD Unit of the FSM are in charge of the EARLY BIRD surveillance protocol of two different at-risk populations: (i) toddlers with older siblings with ASD (familial risk toddlers: FR), who are vulnerable to ASD and, more broadly, to psychiatric and neurodevelopmental disorders (6, 7) and (ii) toddlers clinically referred (CR) for suspected ASD by a child psychiatrist or pediatrician.

From September 2016 to January 2020, 136 children (85 FR; 51 TR; 93 males; 43 females) were enrolled in the study (see **Table 1**). A total of 106 subjects (FR: 58; CR: 48) have completed the diagnostic protocol, while 30 (FR: 27; CR: 3) are still being monitored. As part of the EARLY BIRD project, we completed 324 time points of the children enrolled, while 64 are still missing (5 at 12 months; 11 at 18 months; 18 at 24 months; 30 at 30 months).

In its original form, the EARLY BIRD surveillance protocol was conceived as a 2-day assessment of cognitive functioning, adaptive functioning, and social and communicative functioning, through standardized tests and interviews [Griffiths Mental Developmental Scales-ER (8), Vineland 2 (9), ADOS-2 (10), ADI-R (11)]. In addition, other information on each child’s development was collected through parental questionnaires and clinical interviews (12–23) (see **Table 2**).

On January 30, 2020, the World Health Organization declared the outbreak of coronavirus disease 2019 (COVID-19) a public health emergency of international concern (24).

Emerging evidence reports the hard situation in which parents have been put during this unpredictable stressful situation, potentially impairing their ability to be supportive caregivers (25). Indeed, parents, especially those with young children, have to suddenly cope with closure of the kindergartens, worries over health and finances, the necessity for quick adaptation to “smart-working” at home, isolation, lack of support from grandparents, and bans on going to parks or other public spaces. Parents of toddlers at risk for ASD are even more exposed to stress,

experimenting with concern that their child might have atypical development can impact family well-being and increase parents’ risk of depression, ruminative thought, anxiety, or other types of psychological distress (26). In addition, stressful factors can interfere with early dyadic interaction between at-risk infants and their caregivers and, ultimately, play a detrimental role in children’s longer-term social functioning and outcome (27). Some interesting suggestions about coping with young children with ASD in “stay at home period” are reported in Narzisi (28).

Coping difficulties may have even greater repercussions in families with infants who have an older sibling already diagnosed with ASD. Indeed, it is reported that caregivers of children with ASD have a higher risk of decreased family cohesion, depression, anxiety, somatic complaints, and burnout in comparison to caregivers of children with other developmental disabilities (29–32).

For all these reasons, our priority has been to maintain regular contact and support the families whose child was being followed in his developmental trajectory by the multidisciplinary team, in order to continue the active surveillance of toddlers at risk for ASD during the COVID-19 crisis. Indeed, a recent review of longitudinal studies on FR toddlers reported that the prospective follow-up strategy improves their developmental outcome, creating a sort of “surveillance effect” through which parents, who have the possibility to talk regularly about their child’s development with clinical experts, can learn new strategies to interact with their high-risk infants, reducing, in turn, their symptom severity (33).

Despite technological tools and facilities (such as smartphones, tablets, PC, and wi-fi connections) spread and used among populations, there is little use for telehealth-based assessments of clinical conditions, including ASD, as recently systematically reviewed in Dahiya et al. (34). Obviously, the final goal consists of reaching the same percentage of success of the “in-person” assessment.

In a recent contribution, Juarez et al. (35) analyzed the accuracy of a remote diagnostic assessment for high-risk infants in the second–third year of life (the diagnosis was later confirmed with an *in-person* visit), using a remote video-analysis of a screening tool—the STAT (36–38). Despite that this diagnostic procedure succeeded in 62% of cases and the procedure was well-accepted by parents, this was still dependent on the “physical” presence of a trained person who could administer the screening tool. On the contrary, Smith et al. (39) validated a novel remote procedure for ASD symptom assessment, where parents were instructed to elicit and record specific target behaviors in different scenarios, comparing it with an *in-person* assessment. Results indicated a high agreement (88.2%) between the two modalities as well as high sensitivity (84.9%) and high specificity (94.4%). Following the same line, Sutantio et al. (40) found a good level of agreement (82%) between parents’ video recording, based on a given specific protocol, in three different home settings and a direct assessment conducted by an expert clinician.

In another study (41), Fusaro and colleagues interestingly examined the potential of applying the ADOS-G (42) protocol to unstructured homemade videos collected via the YouTube platform. They found that the ADOS-G-based video analysis

**TABLE 1** | Number of subjects at each time point (TP) are divided into completed (COM) and planned (PLA) protocol.

	Subjects		Total TP		12 m		18 m		24 m		30 m	
	COM	PLA	COM	PLA	COM	PLA	COM	PLA	COM	PLA	COM	PLA
CR	48	3	106	3	4	0	29	0	41	0	32	3
FR	58	27	218	61	57	5	61	11	55	18	45	27
TOT	106	30	324	64	61	5	90	11	96	18	77	30

CR, Clinical referral; FR, familial risk; TOT, Total.

achieved a classification accuracy of 96.8, 94.1% of sensitivity, and 100% of specificity.

All these studies revealed that parents are capable of collecting appropriate examples of target behaviors of their children, especially when properly guided, and that these homebased procedures might improve the ecological validity of a diagnostic assessment (43). For this reason, we decided to adapt our original surveillance protocol to a remote procedure, aiming firstly to support families during the pandemic period and to provide, when necessary, feedbacks and advice on how to support child development or helping families to create a fast link to the local CAMHS.

Our efforts have been focused on instructing families on how to collect as much meaningful information as possible and to record an appropriate video recording of children’s behavior. For this reason, differently from the previous studies on this topic, we have decided to be virtually present during the video recording, to promptly encourage parents to acquire appropriate examples of target behaviors.

This “perspective” paper describes how the protocol, already in use within the EARLY BIRD project, has been rethought and readjusted to be used remotely following the guidelines of health authorities, local governments and the World Health Organization in the COVID-19 era.

### Remote Surveillance Protocol

The research team consists of three psychologists (V.C., F.A., and N.C.) and two child neurologists and psychiatrists (A.M. and R.T.). Due to the lockdown, all researchers have been authorized to continue activities in smart-working.

The team meets via video conference twice a week to discuss ongoing updates and issues, sharing the documents and materials for the remote surveillance protocol RSP within a shared folder on the cloud.

The RSP includes three online interviews and one online video registration of parent–child interaction in a playful setting, for a total of four online sessions. A preliminary telephone call is planned to inform families about the adapted telematic procedure and accept or decline participation. Afterward, caregivers who decide to participate in the remote evaluation fill in written informed consent procedures in compliance with institutional review board standards. Once informed consent has been acquired by the research team, parents are administered the following questionnaires by research assistants.

Detailed instructions on how to prepare the play area for the video recording are also provided. A minimum level of

structure (e.g., in the selection of toys) is required in order to obtain informative video material, sufficiently comparable across children (44, 45).

### First Online Session

The psychologist and the child psychiatrist meet the parents online to record 15 min of parent–child play. Parents are encouraged to resolve any doubts about the setup of the video registration before starting, taking advantage of the researchers’ help. A picture of the setting is taken in order to facilitate the replicability of the video recording at future time points. Researchers follow the recording in “mute option,” intervening only if necessary, to ensure the visibility of both parent and child.

In the days following the first session, the video is viewed and discussed by the researchers, focusing on those behaviors, included in the ADOS-2 Toddler Module (46) diagnostic algorithm, that does not need to be elicited by an adult: overall quality of the social overtures, eye contact, use of gestures to communicate, language level and prosody, play variety, joint attention behaviors, facial expressions, presence of unusual sensory interests, presence of repetitive movements and presence

of restricted and repetitive patterns of behaviors and interests, and presence of other problematic behaviors. At the end of the discussion, a clinical hypothesis on the risk for ASD is made, as a starting point to be further examined during the following two sessions.

### Second Online Session

An anamnestic interview or an anamnestic update is collected. Researchers also discuss with parents any concerns and information that emerged from questionnaires. Parents are asked to report recent auxological parameters (height, weight, and head circumference) as well as other general health status information. Vineland-II interview (9) with one parent is also carried out.

### Third Online Session

The Socio-emotional Bayley III (47) interview is administered to parents along with a non-structured interview focused on age-appropriate behavioral risk signs for ASD or with the ADI-R (48) (in the case of toddlers older than 24 months). Further information on the developmental level of the infant is collected through a non-structured interview based on the developmental milestones of play skills.

After the third session, the clinical-research team meets to discuss the information collected from the interviews and parental questionnaires, in order to decide if the child needs additional assessments to further investigate any causes for concern, which may have arisen. If not, the child will be evaluated again at his next time-point.

### Fourth Online Session

The last session with parents includes feedback on the evaluations and discussion about developmental issues (if present). The appointment for the next time-point is then scheduled. Parents are also asked to compile a questionnaire to collect feedback on the remote procedure they have used including suggestions for improving the service.

If any kind of diagnosis or a consistent risk for ASD is hypothesized at one of the planned time points, the child's parents will be informed. At the same time, the local CAMHS will be contacted in order to start as soon as possible an early treatment tailored to specific strengths and challenges of the child.

A schematic representation of RSP is reported in **Figure 1**.

## CONSIDERATIONS

Lockdown, which is often an unpleasant experience due to isolation, uncertainty about health and economical status with extensive effects on the general population (49), could have even worse consequences in those families with concerns about their child's development, thus forcing health workers to find out alternative remote strategies to keep in touch with them.

Preexisting evidence was already available about remote modality application in the ASD field either in assessment or in rehabilitation programs (34, 50), and during the COVID-19 emergency, the role of remote assistance in children with special needs has been even more stressed (51, 52).

The adaptation of the Autism Surveillance protocol reported here was systematized by the research team within the first few weeks of the Italian lockdown in order to do the following:

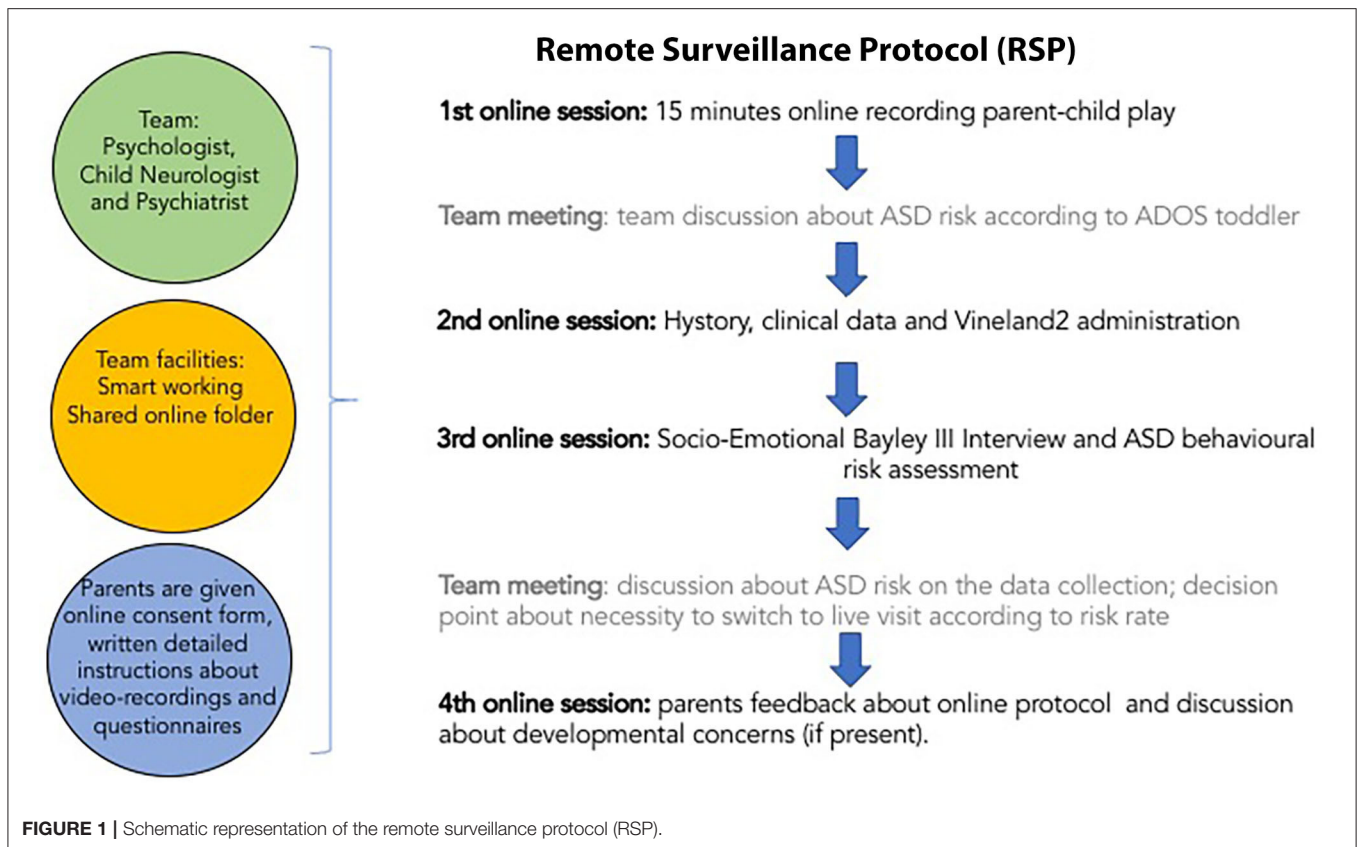

- (1) maintain regular contact and support families involved in the longitudinal surveillance of their FR or CR toddler's development;
- (2) evaluate the feasibility of an online surveillance protocol for toddlers at risk for autism and obtain evaluations at the time-points established by the project; and
- (3) assess the level of compliance and satisfaction on the part of the families with regard to this new telematic protocol.

The current procedure emerged from multiple discussions among professionals with long experience in the field of early typical and atypical development. The main aim was to be able to perform an assessment, which was as structured and standardized as possible. One of the first challenges met was the impossibility to conduct a remote assessment of ASD symptoms and cognitive development using standardized tests such as the ADOS-Toddler and the Griffiths Mental Developmental Scales. To assess the child's spontaneous social behavior, a video depicting the child in interaction with the parent was collected. One of the most debated points regarding the procedure for the video registration was the level of structure. If, on the one hand, we wanted to collect clinically useful information, we did not want to stress parents by asking them to try to elicit particular behaviors (e.g., response to joint attention and imitation skills) as if they were clinicians. For this reason, we chose to ask parents to play with their child as they would naturally, but requested them to provide a specific selection of toys among those available in their house in order to elicit different levels of play and standardize the setting across different children. Despite these limitations, we are convinced that this could represent a way to experiment new procedures, potentially helpful in the future, to reach those patients who have difficulties getting to the hospital as has already been achieved in other countries (53).

Furthermore, the video recordings will also be helpful to assess parent-child interaction in their natural environment (54, 55). In order to obtain information on the children's development, we chose to investigate their level of play skills. For this purpose, we created a dedicated checklist that could be administered to parents during video-conference interviews.

Finally, we encouraged parents to comment on their experience of the telematic adaptation of the procedure and to share their level of satisfaction and perceived efficacy of the different web-platform appointments, highlighting any critical issues and providing suggestions where possible. It will provide researchers with precious feedback that will facilitate future improvements in remote procedures.

The preliminary feedback we have received since the start of the remote surveillance protocol suggests, in the majority of cases, a positive response to our proposal by the families, who have appreciated the possibility to keep in touch with the research team and to share any developmental concerns about their child. In addition, the telehealth procedure we have implemented allows families to avoid traveling to the FSM (they arrive from all over Italy), saving in this way time, money, time off from work,

and potentially stressful experience for both parents and child (e.g., due to travel meltdowns and sensory overload that could occur in the child).

## FUTURE DIRECTIONS

Active surveillance of infants at risk for ASD should continue during COVID-19 social distancing restrictions in order to start an intensive intervention during early sensitive periods (56) for toddlers identified with atypical development. To this aim, we implemented the current protocol intended to provide telehealth assessment in at-risk populations.

We are fully aware that our telehealth assessment is not exhaustive and that the lack of remote standardized tests for ASD diagnosis could limit the ability to detect early risk signs of the disorder, especially with milder cases, leading us to be cautious in our diagnostic conclusions.

Unquestionable advantages of this procedure include (i) better access, especially for families with transportation and childcare challenges; (ii) the possibility of removing job-related absence as well as cost of the travel; and (iii) the opportunity to observe the child in their naturalistic environment and accordingly to provide more family-centered recommendations.

Conversely, extensive use of telehealth certainly needs the following: (i) appropriate knowledge about data security and data protection rules; (II) the use of user-friendly platforms that can be accessible by all caregivers regardless of their technological abilities or economic status; and (iii) the reduction of regulatory

barriers that interfere with reimbursement for services provided via telehealth.

To overcome these difficulties, we used free platforms that are easily downloadable from any online store and do not require payment; we have also created a video tutorial to make downloads for parents. Through the online video registration, we have also avoided the telematic transmission of data by parents, reducing difficulties and risks deriving from this. Moreover, the informed consent contains a detailed section on data protection according to European regulation (GDPR 2016/679 (Prot. 4/2018 PO) and approved by our institutional Data Protection Officer.

In conclusion, in spite of negative health, social, and economic consequences, the current COVID-19 crisis could represent an opportunity to reorganize child mental health care by introducing innovative approaches through telehealth, thus paving the way for broader access and more efficient use of available public resources (57). Future investigations should accurately compare remote surveillance to face-to-face evaluations (e.g., via randomized, controlled trials) in order to shed light on the efficacy, large-scale feasibility, and cost-effectiveness of online procedures, with the final aim of developing evidence-based guidelines for a virtuous coexistence of virtual and in-person assessment (58).

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Pediatric Ethical Committee of Tuscany region at Meyer Children's Hospital. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## AUTHOR CONTRIBUTIONS

NC, VC, AM, RT, and FA conceived and created the protocol. FM supervised all the phases of the study. EC and SC wrote the paper. NC, VC, RL, AM, MP, FM, RT, and FA critically reviewed the manuscript. All authors contributed to the article and approved the submitted version.

In this exploratory research study, we developed an instrument to investigate people's confidence in safeguarding measures [Confidence in Safeguards Scale (CSS)] and we adapted an instrument measuring perceived risk of coronavirus [perceived risk of coronavirus scale (PRCS)] that was originally based on a perceived risk of HIV measure. We then explored the effect of public confidence in safeguarding measures designed to halt the spread of the coronavirus on perceived risk, controlling for related covariates. The sample consisted of  $N = 565$  respondents; 119 were males (21.1%) and 446 were females (78.9%). Mean age was 35.42 (SD = 13.11), range was 18–77 years. We used convenience sampling to gather the data at the end of March 2020 via social media in Slovakia. The CSS showed good reliability levels and a three-factor structure: Confidence in Institutions, Confidence in Personal and Family Behaviors, and Confidence in Others' Behaviors. The PRCS showed good reliability levels and a two-factor structure: Fear of Contraction and Perceived Likelihood of Contraction. Participants with higher levels of Confidence in Others' Behaviors perceived the spread of the coronavirus to be less threatening, both cognitively (less perceived likelihood of contraction) and affectively (less fear of contraction). This finding could be used when designing public health policy and emergency communication. Enhancing confidence in others' behaviors could encourage individual responsibility, social responsibility, and solidarity through social bonds extending beyond the family. In future research we plan to replicate the data collection using the same instruments in different countries so the results are comparable across cultures and can be used to improve emergency communication.

**Keywords:** coronavirus, confidence, risk, safeguards, public health

## INTRODUCTION

The coronavirus outbreak has triggered an unprecedented crisis. No other contagious epidemic (MERS, Ebola, swine flu) has led to such large safeguarding measures in Slovakia. In situations such as this, it is important to gather information on public perceptions of risk, the preparedness of people and institutions, protective behaviors, and trust and confidence in the safeguards so adequate responses can be taken. The public is exposed to a constant flow of information from news channels

and social media, leading to information overload during the public health emergency. There is no doubt the spread of coronavirus is perceived as a threat and a risk. Public and private institutions have implemented many safeguarding measures to tackle the situation. Public confidence in these safeguarding measures is crucial and should help alleviate the perceived risk. However, careful consideration is required: it is crucial to avoid panic, but the public response should not be light-hearted either. The most desirable outcome is a careful balance of worry and just enough fear to change peoples' behavior without the destructive effects of public panic. Risk communication in a public health emergency (Glik, 2007) should be designed whilst bearing in mind its effect on public trust. Carpenter (2010) demonstrated in a meta-analysis that if people perceive a negative health outcome to be severe and think they are susceptible, they are more inclined to perceive the benefits of behaviors that reduce the likelihood of that outcome. Previous research (Rubin et al., 2009) has shown that controlling for personal elements, namely perceptions, trust and anxiety is important: the "recommended changes were associated with perceptions that disease is severe, that the risk of catching it is high risk, that the outbreak will continue for a long time, that the authorities can be trusted, that good information has been provided, that people can control their risk of catching it, and that specific behaviors are effective in reducing the risk." There is a fair amount of literature on risk communication and public trust (see e.g., Prati et al., 2011). It is known that social factors and social trust are crucial here (Phelan and Link, 1995; Kawachi et al., 1999; Hawe and Shiell, 2000; Subramanian, 2002; Kim et al., 2006). There is also research on risk perception and public trust (Weerd et al., 2011). We also have some incidental evidence on public safeguarding measures and social factors in some countries, including Slovakia (Perugini and Vladislavjevic, 2020), that shows that social and economic background (not just perceptions of the coronavirus threat) have an effect on actors' behaviors—for example, socially and economically vulnerable actors with precarious jobs cannot afford to stop working or limit their work hours, especially in countries like Slovakia where state help and/or innovative work solutions are sluggish and inelastic. Actors who have continued to work may have very different attitudes concerning the perceived threat of the coronavirus.

The new Confidence in Safeguards scale (CSS) contains three dimensions (Confidence in Institutions, Confidence in Personal and Family Behaviors, Confidence in Others' Behaviors), and the literature has already provided a rationale for distinguishing between cognitive versus affective risk appraisal in the adapted Perceived Risk of HIV Scale (PRHIV), see Oh et al. (2015). We therefore formulated three hypotheses on the relation between public trust and perceived threat of coronavirus:

- (1) Confidence in behaviors of self/family will positively predict Fear of Contraction—the rationale is that respondents who adapt strict safeguarding measures are more anxious. On the other hand, respondents have more control over their own behavior and the behavior of their family members, and their fear of contraction could positively enhance their behavior and the family's behavior, in turn increasing levels of confidence in self/family behaviors.
- (2) Confidence in others' behaviors will negatively predict both parts of Perceived Risk of Coronavirus—the rationale is that others' behavior lies outside the respondent's control, but it is also true that if others follow the safeguarding measures that could contribute to reducing the risk of infection.
- (3) Confidence in institutions will negatively predict both parts of Perceived Risk of Coronavirus—the rationale is practically the same as in the previous hypothesis: the institutional response is outside the respondent's control and could have an impact on the spread of the coronavirus.

## AIM OF THE STUDY

The coronavirus pandemic is unprecedented. Therefore we have no hypotheses—this research is exploratory and the goal is to describe (rather than explain) some important patterns in perceptions and reasoning during this crisis. Our research goals were to: (1) develop a reliable instrument to investigate people's confidence in the safeguarding measures (both institutional and behavioral); (2) adapt the instrument to measure perceived risk of coronavirus; and (3) to investigate the effect of public confidence in safeguarding measures designed to halt the spread of the coronavirus on perceived risk, controlling for related covariates.

## METHODS

### Setting: Publicly Available Data on the Spread of COVID-19 in Slovakia in March 2020

First of all we present the situation in Slovakia in March 2020, providing information on the spread of the coronavirus, including the rate of testing. For the sake of comparison, data from neighboring countries (Czechia, Poland, Hungary, Austria) is presented as well. Secondly, we list the safeguarding measures implemented by the Slovak authorities during this period (March 2020).

In Slovakia the first positive case of COVID-19 was officially announced on 6 March 2020 (The National Health Information Centre, Extended Statistics, 2020). The daily increase in the numbers testing positive remained very low (under 5) until 11 March. **Figure 1** presents the daily increase in confirmed cases in Slovakia in March 2020 (based on data from The National Health Information Centre, Extended Statistics, 2020). We can see that the cumulative growth curve is linear and does not show exponential growth: the daily increase in numbers is still relatively low (under 50). The total number of confirmed cases in Slovakia had reached 400 by 31 March.

We must also take into account the number of tests performed: the number of tests is relatively low, but Slovakia is capable of conducting the same number of tests on average as its neighbors (recalculated using a log scale per million inhabitants see Roser et al., 2020).

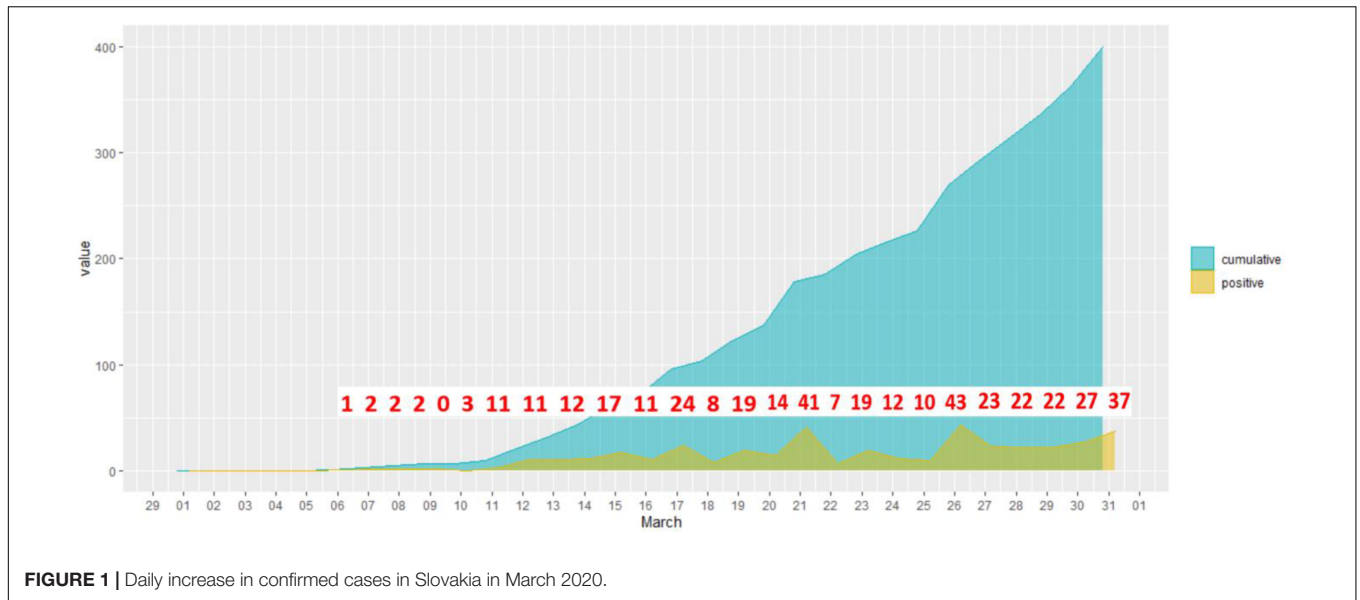

FIGURE 1 | Daily increase in confirmed cases in Slovakia in March 2020.

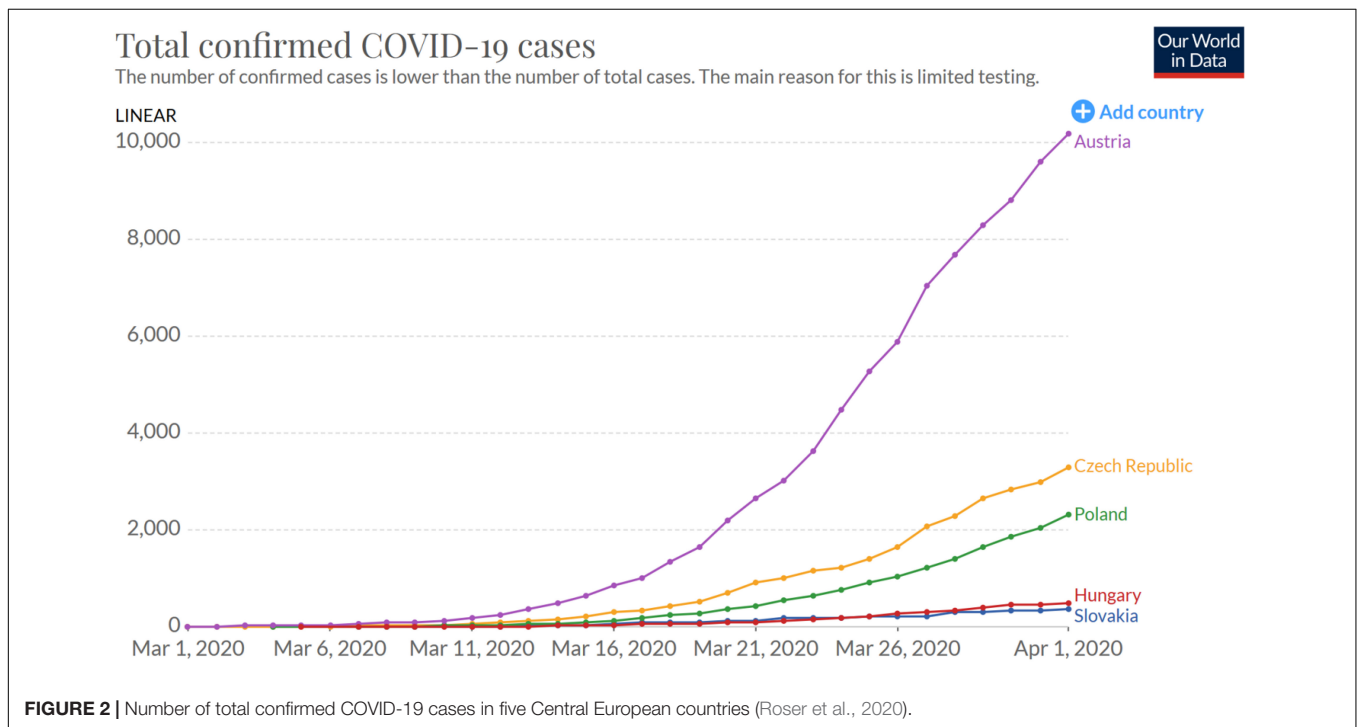

FIGURE 2 | Number of total confirmed COVID-19 cases in five Central European countries (Roser et al., 2020).

If we compare the number of confirmed cases in Slovakia in March to those in neighboring countries, the time series for Slovakia has an almost identical shape to that for Hungary, and similar to that for the Czechia and Poland. The time series for these countries differ markedly from Austria's.

We can now turn our attention to the safeguarding measures adopted in Slovakia by the state authorities. On 9 March all schools and universities were closed, and on 10 March public events were banned. On 13 March all international passenger transport to and from Slovakia was canceled. On 16 March a state of emergency was declared, and all private businesses (except

food shops, health and beauty retailers, pharmacies, and petrol stations) and state offices were closed. On 25 March the wearing of a mask covering the nose and mouth became compulsory in public. On the same day the Slovak parliament passed a “corona law” which permits (among other things) the government to use mobile location data to monitor user location.

We conclude this section by pointing out that Slovakia has a low number of confirmed COVID-19 cases and strict safeguarding measures in place, but this is not exceptional in Central Europe. We would like to stress that this conclusion has nothing to do with the epidemiological situation: we are simply

reviewing the public and published resources that are widely available in Slovakia—our research design focuses on public trust and the perceived threat of coronavirus. The epidemiological situation (i.e., the population ratio of infected people) is unknown and may differ substantively from the number of confirmed cases.

## The Research Sample

The sample consisted of  $N = 565$  respondents; 119 were males (21.1%) and 446 were females (78.9%). Mean age was 35.42 (SD = 13.11), range was 18–77 years. All the participants were Slovak citizens. Data were gathered via social networks between March 27, 2020 and March 31, 2020. We used convenience sampling. Data were collected in accordance with the ethical standards of the institutional and/or national research committee and in accordance with the 1964 Helsinki Declaration and its later amendments or comparable ethical standards.

## Measures

### Perceived Risk of Coronavirus Scale (PRCS)

The PRHIV (Napper et al., 2012) has been adapted. The adaptation is similar to the adaptation for Ebola—the Perceived Vulnerability to Ebola risk scale (PVE; Kim et al., 2016). The scale originally contained 10 items but in the original study the authors excluded two of the items from the scale (Napper et al., 2012). The remaining items were then reformulated using a unified answer format which is more understandable and makes it easier and quicker for participants to complete. We also changed the name of the contagious disease from HIV to coronavirus. For the list of PRC items see **Appendixes 1–3, Supplementary Materials**. The psychometric analysis of the original scale was reproduced in this study, and modified slightly (see “Results” and **Supplementary Materials, Appendixes 1–3**), since the literature has already provided a rationale for distinguishing between cognitive versus affective risk appraisal, see Oh et al., 2015).

### Confidence in Safeguards Scale (CSS)

The CSS contains ten items and was created for this research (see Appendix 2). It contains three dimensions: (1) Confidence in Institutions, (2) Confidence in Personal and Family Behaviors, and (3) Confidence in Others’ Behaviors. We decided to include these three dimensions so three aspects could be distinguished—confidence in personal behavior and family members’ behavior, which is at least partially within the respondent’s control; confidence in others’ behavior, which lies outside the respondent’s control; and confidence in institutional behavior, which also lies outside the respondent’s control but is represented differently. We deliberately avoided mentioning specific safeguarding behaviors (e.g., wearing masks, washing hands, social distancing, and staying at home): respondents could have very different opinions as to which behaviors they consider safe, and the aim was not to measure the prevalence of specific behaviors, but rather the overall confidence of respondents in any safeguarding behaviors: for example, item 4 (“My family members behave with adequate caution in regard to the spread of the coronavirus”) makes no reference to specific behaviors: it measures the respondent’s perception, not the occurrence of specific behaviors. We realize that respondents may have inconsistent opinions

on safe behaviors in both directions (they might be confident the behaviors are safe for no objective reason, or they might consider even very precautionary behaviors as being insufficiently safe). Consequently this instrument is designed to measure confidence only. A psychometric analysis of this new scale was conducted as part of this study (see “Results” and **Supplementary Materials, Appendixes 1–3**).

### Sociodemographic Data–Covariates

We have included the standard set of demographic variables (gender, age, education, size of residential site, number of household members, number of children aged under 18 in the household). Some of these could have a direct effect on perceived threat (women generally display more anxiety than men, see Remes et al., 2016; old people and people living in small villages or towns could be more vulnerable, see Garnier–Crussard et al., 2020; Ranscombe, 2020; Zhang and Schwartz, 2020). Over and above this standard set, two other specific covariates were included: (1) taking any prescribed medication (this factor could influence respondents’ perceptions and behavior), and (2) work attendance (respondents who go out to work could perceive the threat of coronavirus differently). Controlling for these covariates is important because otherwise some or all the structural regression coefficients could produce spurious results—false negatives or false positives (or both).

## DATA ANALYSIS

### Procedure

As far as the data are concerned, after presenting the descriptive statistics, we first investigate the psychometric properties of both scales. We replicate the item-response theory (IRT) approach used in the original PRHIV (Napper et al., 2012) and check its factor structure (the literature has already provided a rationale for distinguishing between cognitive versus affective risk appraisal, see Oh et al., 2015) and reliability. Non-parametric IRT kernel smoothing (Ramsay, 1991, 1997) is used to check the monotonicity of the expected item scores (EIS). We then propose some essential amendments based on the IRT re-analyses of our data. For all the IRT analyses, we use statistical program R, version 3.6.1 (R Core Team, 2019), packages “mirt” (Chalmers, 2012) for the IRT factor models and residuals analyses, and package “KernSmoothIRT” (Mazza et al., 2014) for the IRT kernel smoothing analysis. See **Supplementary Materials, Appendixes 1–3** for all R codes.

The next step is the ESEM (exploratory structural equation modeling, see Asparouhov and Muthén, 2009; Marsh et al., 2011) factor analysis of the new CSS. The ESEM approach combines the confirmatory factor analytical approach (factor structure is specified in advance in target rotation) with the exploratory approach (in target rotation, some small cross-loadings on different factors are allowed, which is more realistic with regards to the data than setting them to zero). This approach is appropriate in our case because we have theoretically justified the factor structure of this instrument (confirmatory approach), but not yet tested it on the data (exploratory approach). Finally

we fit the structural model where the CSS latent factors are predictors of the Perceived Risk of the Coronavirus Scale latent factors, controlling for the covariates: gender, age, education, size of residential site, number of household members, number of children under 18 in household, taking any prescribed medication, and work attendance. See **Figure 1** for this structural model. We then check the fit of this model with the data (Comparative Fit Index CFI and Tucker-Lewis Index TLI should be >0.95 for excellent fit and >0.90 for acceptable fit, and RMSEA index should be <0.050 for excellent fit and <0.080 for acceptable fit, see Hu and Bentler, 1999; Kline, 2005). All ESEM models are fitted in the Mplus program, version 7.4 (Muthén and Muthén, 1998-2017). See Mplus codes in **Supplementary Materials, Appendix 1–3**.

## RESULTS

### Descriptive Statistics

Descriptive statistics for both scales (and covariates) are presented in **Table 1**.

### Psychometric Analysis of the Perceived Risk of Coronavirus Scale (PRCS)

The final version of the original PRHIV (Napper et al., 2012) contains eight items. However, based on their original analyses of the ten items, the authors subsequently dropped two items with suboptimal psychometric properties. The authors checked the unidimensionality and local independence of this instrument and claimed it sufficiently unidimensional based on the RMSEA and GFI fit indices for the one-factor confirmatory factor analysis model (Napper et al., 2012). However, there are serious doubts about this claim: (1) the GFI index is very sensitive to sample size, and its use is discouraged in the relevant psychometric literature (Shevlin and Miles, 1998; Fan and Sivo, 2007); (2) the authors report that the value of RMSEA for the one-factor model is 0.087 and declare that supports use of this model, but this declaration directly contradicts the psychometric recommendations (RMSEA under 0.05 for excellent fit, under 0.08 for acceptable fit, see Bentler, 1990; Hu and Bentler, 1999; Kline, 2005; Chen et al., 2008). Moreover, the 90% confidence interval of the reported RMSEA of 0.087 is 0.078–0.095 (our own calculation based on  $\chi^2(35) = 242$  and  $N = 785$  reported by the authors) which is barely acceptable and so cannot be an indication of good fit.

Following the original procedure in Napper et al. (2012), the PRCS items were modeled using Samejima’s two-parameter polytomous graded response model (GRM) with marginal maximum likelihood estimation, using “mirt” package (Chalmers, 2012) in statistical program R, version 3. 6. 1. (R Core Team, 2019). We do not report the GFI; instead we report the RMSEA (with 90% CI) and SRMSR as recommended in the psychometric literature on goodness of fit for IRT models (Maydeau-Olivares, 2013). The one-factor model had an unacceptable RMSEA (0.116, 90% CI 0.101–0.132) and SRMSR (0.121). An inspection of the residuals (based on G2\* statistics with better properties than a mere inspection of the

residual correlations, see Chen and Thissen, 1997; Houts and Edwards, 2013) showed a distinctive pattern in the signed values of the Cramer phi indices, indicating a second factor (see **Supplementary Materials, Table 1**). Moreover our inspection of the EIS by means of non-parametric IRT kernel smoothing (Ramsay, 1991, 1997; Mazza et al., 2014) clearly indicated that item 4 was a problem (and that item 8, while less problematic, was suboptimal, see **Supplementary Materials, Figure 1**).

Since the literature has already provided a rationale for distinguishing between cognitive versus affective risk appraisal, see Oh et al. (2015), we tried to fit a two-factor EFA model, and

the fit improved substantially (RMSEA = 0.048, 90% CI 0.021–0.078; SRMSR = 0.046). The subsequent inspection of the EIS based on two dimensions showed that the problems with items 4 and 8 had disappeared, see **Supplementary Materials, Figure 2**). The factor loadings of this two-factor model are presented in **Table 2**. Looking at the item content we can see that the items expressing affective content (e.g., worrying, feeling vulnerable) load on the first factor, and items expressing cognitive content (likelihood, chance, thinking) load on the second factor. The correlation between the latent factors is 0.362.

Empirical IRT reliability, based on the weighted likelihood estimates of latent abilities, was 0.83 for the Fear dimension and 0.83 for the Likelihood dimension. Cronbach alpha was 0.75 for the total scale (eight items), 0.72 for the Fear dimension (four items), and 0.71 for the Likelihood dimension (four items). Therefore, we consider the PRCS to be a two-dimensional construct consisting of the Fear of Contraction subscale containing four items, and the Perceived Likelihood of Contraction subscale containing four items. Moreover, the literature has already provided a rationale for distinguishing between cognitive versus affective risk appraisal, which fits nicely with these results (see Oh et al., 2015).

### Psychometric Analysis of the Confidence in Safeguards Scale (CSS)

The CSS was created as a ten-item three-dimensional instrument, containing these three dimensions: Confidence in Institutions, Confidence in Personal and Family Behaviors, and Confidence in Others' Behaviors. The ESEM model was fitted using the WLSMV estimator (weighted least squares mean and variance adjusted method, which performs well with ordinal items, see Beauducel and Herzberg, 2006; Bandalos, 2014) and target rotation specifying the theoretically justified loadings, but

allowing some small cross-loadings at the same time. See **Figure 3**, the CSS model.

The three-factor ESEM model has a good fit with the data:  $\chi^2(18) = 70.88$ , CFI = 0.97, TLI = 0.93, RMSEA = 0.072 (90% CI 0.063–0.080). Factor loadings are shown in **Table 3**.

We can see that both the fit indices and factor loadings support the three-dimensional model of the CSS scale: items expressing confidence in personal and family behaviors predominantly load on the first factor, items assigned to others' behaviors load mostly on the second factor, and items expressing confidence in institutions load mostly on the third factor. The correlations among latent factors are 0.440 (confidence in personal/family behaviors with confidence in others' behaviors), 0.262 (confidence in personal/family behaviors with confidence in institutions), and 0.554 (confidence in others' behaviors with confidence in institutions). All are statistically significant at 0.001. Cronbach alpha for the total scale was 0.75, and for the subscales 0.70 (Confidence in Personal and Family Behaviors), 0.73 (Confidence in Others' Behaviors), and 0.72 (Confidence in Institutions).

### The Final ESEM Structural Model

The final ESEM structural model is presented in **Figure 3** (error variances, disturbances, and covariances are omitted). This model has a good fit with the data:  $\chi^2(239) = 508.88$ , CFI = 0.94, TLI = 0.93, RMSEA = 0.045 (90% CI 0.039–0.050). Regression weights are presented in **Table 4**.

## DISCUSSION

In this exploratory research study we developed an instrument to investigate people's confidence in safeguarding measures (CSS), adapted the instrument measuring the perceived risk of coronavirus (PRCS), and explored the effect of public confidence in safeguarding measures designed to prevent the spread of the coronavirus on perceived risk, controlling for related covariates (gender, age, education, size of site, number of household members, number of children under 18 in household, taking any prescribed medication, and work attendance).

The three-factor ESEM model for the CSS had a good fit with the data, confirming a three-dimensional structure: Confidence in Institutions, Confidence in Personal/Family Behaviors, and Confidence in Others' Behaviors. In addition the correlations among the three latent factors were statistically significant. The Cronbach alpha for the scale was adequate at 0.75. The CSS showed good psychometric properties and the expected factor structure and consequently the CSS can be used to reliably measure confidence in safeguards to prevent the spread of Coronavirus at three levels: personal and family, other people, and institutions. Admittedly, the three items of the "Self/Family" factor are mixed—two of them are formulated such that they express the person's own behavior, and one item is formulated such that it expresses the behavior of family members. This is probably the reason this "family" item has a moderate cross-loading on the "Others" factor. Item 1 ("I have enough information.") is passive, and could be amended to "I try to get

8. My fellow workers behave with adequate caution in regard to the spread of the coronavirus.	0.128	<b>0.583</b>	-0.016
9. Banks and financial services are prepared for the spread of the coronavirus.	-0.011	0.095	<b>0.539</b>
10. Overall, people in my country behave with adequate caution in regard to the spread of the coronavirus.	-0.029	<b>0.454</b>	0.209

Factor loadings specified in target rotation are presented in bold.

up-to-date information about the spread of the coronavirus.” In the same vein, Item 4 could be amended to “As a family, we all behave with adequate caution.” This formulation refers to both the person’s own behavior and the behavior of family members. We recognize that including the family item along with items referring to the person’s own behavior introduces an element of confounding here, but we assume that many respondents will have a tightly knit family life (reinforced during the pandemic, for good or for worse), and having only individualistic and institutional items (i.e., omitting the family item) would be too restrictive. On the one hand, one can far more easily avoid interactions with non-family others than interactions with family members, and on the other hand, people have more influence on the behavior of family members than on the behavior of non-family others. At the height of the pandemic, families were often the centre of social life, and arguably “family members”

and non-family others are not equivalents. Therefore merging the self and family precautions is to an important extent necessary: removing the family item from the “self” factor and including it in the “others” factor would probably distort the situation. In future research it would probably be worth considering a four-dimensional construct: Self, Family, Others, and Institutions—but adding the family item to the others factor would probably be too restrictive.

The PRCS was adapted from the PRHIV (Napper et al., 2012). Although Napper et al. (2012) claim the scale is unidimensional, their reported results (RMSEA value and confidence interval) do not support this. Similarly, our PRCS results show that the scale has two factors, not one. The two factors represent Fear of Contraction (e.g., worrying, feeling vulnerable, picturing self, and recurrent thoughts) and Perceived Likelihood of Contraction (e.g., likelihood, chance, thinking, and gut feeling) which

**TABLE 4** | Regression weights from the final ESEM structural model.

*Bold = Statistically significant coefficients are presented in bold. SD value = standardized value.*

correlated together at the level of 0.362. Concerning reliability, the scale showed good reliability coefficients (Cronbach alpha was 0.75 for the total scale, for Fear of Contraction it was 0.72, and for Perceived Likelihood of Contraction it was 0.71. This two-dimensional structure makes sense in interpretational terms: we can easily assume different patterns of responses—one respondent could perceive a high risk cognitively, but still express either high affective concern or low affective concern; while another respondent could perceive a low risk cognitively, but still feel either high affective concern, or low affective concern. Without considering these two different patterns, we could obtain distorted results.

Now we will discuss the hypotheses we formulated in the introduction:

- (1) Confidence in behaviors of self/family will positively predict Fear of Contraction: this hypothesis has been confirmed. Confidence in personal and family behaviors predicts fear of contraction and is statistically significant and positive, but it does not predict the perceived likelihood of contraction. Respondents who are more confident about their own and their family's precautionary behaviors are more scared of becoming infected: they affectively perceive the coronavirus to be a threat, but not cognitively. It could be that some form of circular causality is at work here: their fear of contracting the coronavirus could in turn boost their precautionary behaviors, but not enough to alleviate their cognitive perception of this threat. It is likely that worrying about contagion motivates more precautionary behaviors.

From a clinical psychology perspective it makes perfect sense that this does not alleviate worries about contagion because the precautions act as “safety behaviors.” These offer short-term relief from worry but in the long run confirm and thereby maintain the worry beliefs. This is inflated even more if confidence in others' behaviors is low, as we cannot control others' behaviors to the extent we can control our own behavior. This is in line with models of generalized anxiety disorder (Lissek et al., 2014; Stein and Sareen, 2015), because it shows so clearly why the processes underlying generalized anxiety disorder can be adaptive depending on the context. These results suggest that this mechanism is probably one that policy should exploit.

- (2) Confidence in others' behaviors will negatively predict both parts of Perceived Risk of Coronavirus: this hypothesis has been confirmed as well because confidence in others' behaviors predicts both fear of contraction and perceived likelihood of contraction and is statistically significant and negative: the more confidence people have in the precautionary behaviors of others, the less of a threat they consider the spread of the coronavirus, both affectively and cognitively. People who worry about becoming infected will escalate their safeguarding behaviors. At the same time, people who think others are not doing the same as them will become even more worried. A side effect of this is that people will also perceive that the likelihood of contraction is higher if others are not following the safeguards (after all, “all the others” constitutes a much bigger proportion of the population endangering them than just “me and my

family”). We should also clarify that the PCRS “cognitive” factor (perceived likelihood of contraction) assesses the perceived likelihood of contracting the coronavirus, and not necessarily cognitive appraisals of the fear of the negative consequences of becoming infected (this comes under the “affective” factor, fear of contraction). People in Slovakia who have confidence in others’ safeguarding behaviors (but not in their own and their family’s safeguarding behaviors) consider the coronavirus to be less of a threat. Respondents probably also take into account the fact that social factors are predominantly behind the spread of the coronavirus. This trust in social solidarity is very promising and should be reinforced as much as possible, providing it is strongly connected to the actual mechanisms of coronavirus infection—the best protection is to monitor and avoid people who ignore safeguarding measures. The fact that confidence in others’ behavior is more predictive than confidence in self/family behavior seems to be related to the way the contagion spreads and the anti-contagion measures.

- (3) Confidence in institutions will negatively predict both parts of Perceived Risk of Coronavirus—this hypothesis has not been confirmed. In general the Slovak respondents display low confidence in institutions and their preparedness for the coronavirus pandemic (see **Table 1**), and there is no statistically significant relationship between confidence in institutions and perceived threat of the coronavirus.

As far as the covariates are concerned, there is no statistically significant relationship between education level and number of children in the household and Fear of Contraction or Perceived Likelihood of Contraction. Taking medication significantly and positively predicts both fear of contraction and perceived likelihood of contraction: people taking medication think the spread of coronavirus is more of a threat, which comes as no surprise. Respondents who go out to work (versus those staying at home) show a significant and positive relationship with the perceived likelihood of contraction (cognitive awareness of being at a higher risk), but they do not show a significant relation to fear of contraction. Women (compared with men) display significantly more anxiety (there is a statistically significant and positive relation with fear of contraction), but there is no significant gender difference in relation to the perceived likelihood of contraction, which is again in accordance with previous research (Remes et al., 2016). Respondents living in small sites display more fear of contraction, but less perceived likelihood of contraction (or, to put it the other way around, respondents living in larger sites perceive the coronavirus as less threatening). This finding might seem to run counter to the facts because almost all the main confirmed outbreaks of coronavirus infection in Slovakia and in other countries are located in large cities, but incidental evidence shows that rural areas may be uniquely vulnerable due to the older age structure of many rural communities, the higher prevalence of chronic illnesses, and relative lack of health care facilities and services (Ranscombe, 2020; Zhang and Schwartz, 2020). The same strange pattern of reasoning is valid for age: older respondents think (cognitively

that they are less likely to be infected even though statistically older people are at a higher risk of becoming seriously ill with the coronavirus (Garnier—Crussard et al., 2020). And finally, the more members a household has, the less the coronavirus is affectively perceived to be a threat. This is probably the dual effect of consolation from family members on the one hand, and the psychological effect of loneliness on the other.

## Limitations of the Study

The first limitation consists in the fact that the sample is not representative for the Slovak population: educated respondents, women, and inhabitants of larger sites are overrepresented. Therefore, our results cannot be generalized to the Slovak population.

The second limitation is that we had neither the opportunity nor the time to adopt the proper procedures for validating and piloting our measures: according to psychometric standards, we should have collected the first set of data, then conduct detailed psychometric analyses, and only after inspecting the psychometric properties of our instruments and making the necessary adjustments, should we have begun the second wave of data collection. However, it would be extremely difficult to follow this procedure in the ongoing coronavirus crisis: it would require weeks and the situation is changing so rapidly that the prospective piloting sample could end up measuring very different perceptions from the reference sample collected after several weeks. We therefore decided to collect the data at the end of March 2020 with the aim of obtaining explorative insights instead of developing a more accurate instrument.

There is one more limitation: we cannot offer an adequate explanation for our outcomes—we lack background information about the respondents’ psychological characteristics, social background and networks, biographical histories, and so on. We are therefore unable to explain the significant variability and patterns observed in their responses. Further research is required to achieve this. This could be done using comparative research to replicate the data collection using the same instruments in different countries as soon as possible and comparing the results.

## CONCLUSION

Social trust (Subramanian, 2002; Kim et al., 2006) and other social conditions (Phelan and Link, 1995; Kawachi et al., 1999; Hawe and Shiell, 2000) are very important factors that strongly affect behaviors during any public health emergency, and the current coronavirus pandemic crisis is no exception. Our research indicates that Slovak respondents with higher levels of confidence in others’ behaviors perceived the spread of the coronavirus to be less threatening, both cognitively (perceived likelihood of contraction) and affectively (fear of contraction). Confidence in institutions and confidence in personal and family behaviors had no such effect. This finding should be considered when formulating public health policy and emergency communication to boost and enhance this effect—confidence in others’ behaviors could promote responsible attitudes: if others stick to the safeguarding measures, actors will consider their

own behavior to be meaningful, in accordance with the social situation and their social reputation. However, confidence in others' behaviors might reduce risk perception, and when trust in others' behaviors is too high, actors may reconsider adhering to the safeguarding measures. The impact of social pressure and social reputation implied by the conformist adherence to the safeguarding measures will probably prevail: for example, recent results from Japan (Nakayachi et al., 2020) show that people conformed to social norms by wearing masks and at the same time felt relief from anxiety when wearing masks. Our findings (and other evidence) suggest that decision makers responsible for public health should consider social motivations when implementing public strategies to combat the COVID-19 pandemic.

Following the outbreak of the COVID-19 pandemic, authorities have issued several guidelines to curb the pandemic's disastrous effects. However, measures' effectiveness is dependent upon people's adherence to them. Therefore, it is crucial to understand the potential factors that explain guideline adherence. In the present brief research report, we investigated need for structure and trait victimhood, i.e., the tendency to feel like a victim, and their effect on fear of the pandemic, which in turn, predicted guideline adherence. Furthermore, the association between fear and guideline adherence was shaped by participants' global self-efficacy: higher levels of self-efficacy predicted more guideline adherence regardless of fear levels. The present findings may be relevant to health messaging endeavors aiming to improve compliance with guidelines.

## INTRODUCTION

In late 2019, the first cases of COVID-19 were reported in Wuhan, China (Guan et al., 2020). In just a few months this virus had spread across the globe, infected millions, killed hundreds of thousands and caused trillions of dollars in damages to the world economy (Ayittey et al., 2020). Consequently, the World Health Organization (WHO) declared COVID-19 a pandemic and announced a global emergency (Sohrabi et al., 2020). Health authorities and governments globally have responded by issuing numerous guidelines (Lau et al., 2020), the most common of which were: isolation, quarantine, and social distancing (Wilder-Smith and Freedman, 2020). Guidelines for personal measures included sterilizing surfaces, wearing masks, washing hands, etc. (Zhou et al., 2020).

The success of such efforts relies on adherence to these measures. Since some people who are able to adhere to the guidelines, do so, while others do not, adherence is possibly affected by various personal factors. For example, Zhong et al. (2020) have recently demonstrated that adherence to preventive measures depended on people's differential knowledge and attitudes toward COVID-19. Other possible explanations might include solution aversion (Campbell and Kay, 2014), resistance to scientific information (Hornsey and Fielding, 2017), and—as shown regarding COVID-19—even political orientation (Pennycook et al., 2020).

One critical category of personal factors that has been repeatedly shown to affect health-related behaviors and specifically adherence to health guidelines is personality (e.g., Christensen and Smith, 1995). Some notable examples are the lack of adherence of impulsive patients to asthma control guidelines (Axelsson et al., 2009) and of patients suffering from anxiety to multiple sclerosis

disease-modifying therapies (Bruce et al., 2010). More relevant to the current article, Bogg and Milad (2020) have recently shown that adherence to COVID-19 guidelines was positively related to the personality trait of conscientiousness.

## THE PRESENT STUDY

In the current brief research report, we focus on two personality traits: mental rigidity (e.g., Webster and Kruglanski, 1994), and victimhood (Gabay et al., 2020a,b). As detailed, these traits are highly relevant due to the specific psychological characteristics of pandemic: uncertainty (Eichenberger et al., 2020) and fear (Ren et al., 2020).

### Mental Rigidity and Stressful Events

Mental rigidity received different names (such as need for closure, need for structure, tolerance of ambiguity, certainty orientation), each with its' own theoretical focus and variations (e.g., Webster and Kruglanski, 1994; Bar-Tal et al., 1997; Leone et al., 1999; Muluk and Sumaktoyo, 2010). Mental rigidity is the desire to reduce ambiguity through category-based processing and receive answers on given topics (Webster and Kruglanski, 1994). It leads to seeking simplified, one-sided information while disregarding more complex aspects of the situation (Sharifi, 2019), and psychological maladjustment to new situations (Kashima et al., 2017). This trait is of high relevance to stressful or uncertain circumstances, such as war, natural disasters, or disease (Kruglanski et al., 2002). Given the uncertainty around COVID-19 as a new virus with unprecedented spread, no vaccine, and dramatic consequences and measures, people high in mental rigidity may be more fearful than others (Webster and Kruglanski, 1994). Moreover, increased fear (Ren et al., 2020) should result in a greater tendency to follow health instructions, which may be perceived as a means to reduce uncertainty (Kruglanski et al., 2006). Mental rigidity was also related to reduced risk taking in various domains (Schumpe et al., 2017). A study conducted in the US during the COVID-19 pandemic revealed that anxiety related behavior patterns (e.g., stockpiling food) of mentally rigid people were greatly affected in such times of crisis (Brizi and Biraglia, 2020).

### Victimhood and Dealing With Life's Misfortunes

Trait victimhood is defined as "an ongoing feeling that the self is a victim ... generalized across many relationships, such that victimization becomes a central part of the individual's identity..." (Gabay et al., 2020a, p. 361). Victimhood fundamentally affects emotions, cognitions, and behaviors (Gabay et al., 2020b). Particularly relevant to this research, Gabay et al. (2020b) found that individuals with high levels of trait victimhood were more likely to interpret ambiguous situations as threatening through a black-and-white prism (Gabay et al., 2020b; see also Schori-Eyal et al., 2017). We argue that this recently introduced personality trait may offer a simple, yet powerful, measure of individual differences when facing hardships and misfortunes. Specifically, this trait is relevant to the behavioral guidelines of the pandemic since individuals high in victimhood are hyper-vigilant, neurotic, and susceptible to threat, which should increase their level of

fear. Such fear may lead to a greater tendency to follow health instructions (Ren et al., 2020). Nevertheless, the actual ability to follow the instructions, or lack thereof, can be captured by the concept of self-efficacy.

### Self-Efficacy and Adherence to Medical Instructions

The construct of self-efficacy was introduced by Bandura (1986) who defined it as "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances" (p. 391). Self-efficacy beliefs determine how people feel, think, motivate themselves and behave. Though self-efficacy was mainly conceptualized as domain-specific, scholars have also suggested global self-efficacy (GSE) to describe people's global belief in their ability to cope with different challenges or uncertainties (Schwarzer et al., 1999). Bandura (1997) treated self-efficacy as the main factor in performance, postulating that motivation is affected by self-efficacy via goals selection. However, some argued that motivation, rather than self-efficacy, is central in determining future performance (Vancouver et al., 2001), and yet others postulated that the effect of self-efficacy varies along different levels of performance (Gur and Bar-Tal, under review).

We argue that GSE is relevant to the current endeavor as it captures one's perceived competence to effectively cope with challenging and stressful situations (Schwarzer et al., 1999; Judge and Bono, 2001). Indeed, self-efficacy was shown relevant to coping with health and medical situations. Specifically, past research has described how GSE affects adherence to medical instructions and health guidelines across various settings, ranging from dietary adherence (Warziski et al., 2008), to HIV medication adherence (Wolf et al., 2007). Since increased fear was found to motivate adaptive danger control actions (Witte and Allen, 2000), in the case of COVID-19, fear may represent one's strength of motivation to adhere to health guidelines. Therefore, we predicted that it may interact with GSE in affecting adherence to guidelines. Thus, we hypothesized that while fear should mediate the relationship between mental rigidity and trait victimhood and adherence to COVID-19 health guidelines, GSE would moderate the extent to which fear would in fact translate into actual adherence.

To summarize, the current research focuses on the relationship between mental rigidity, operationalized using the Need for Structure (NFS) scale, and trait victimhood, and adherence to COVID-19 health guidelines. This is based on previous research showing that mentally rigid individuals tend to be more fearful (Webster and Kruglanski, 1994), and that high trait victimhood individuals tend to mistrust others (Gabay et al., 2020b), which may also increase fear in the context of a pandemic. We hypothesized that mental rigidity and trait victimhood would be positively related to COVID-19 guideline adherence, and that fear would mediate these associations. Additionally, we hypothesized that GSE would moderate the extent to which fear would lead to guideline adherence, such that high- (vs. low-) GSE individuals would adhere more to the guidelines.

## METHOD

### Sample and Procedure

Three hundred and fifty four Israelis (48.6% women;  $M_{\text{age}} = 41.71$ ,  $SD = 16.02$ ) reported their mental rigidity (NFS), trait victimhood, GSE, fear of the coronavirus (COVID fear) and adherence to Israel's health department regulations regarding protection from the virus. Participants were recruited through an Israeli survey company (Midgam Project)<sup>1</sup>, responded electronically via the internet and were paid for their participation in the study. The data was collected from March 22nd until March 23rd, 3 days after emergency regulations were initiated in Israel (on March 19th) and 2 days after the first documented COVID-19 death in Israel (on March 20th)<sup>2</sup>. The study was reviewed and approved by the Interdisciplinary Center Herzliya Institutional Review Board (see ethics statement). All subjects provided informed consent to participate in the study. To protect the respondents' privacy, the survey was conducted anonymously.

### Measures

The presentation order of all scales and statements within them were randomized and all used a 7-point Likert-type scale ranging from "strongly disagree" (1) to "strongly agree" (7). We used the NFS scale to assess mental rigidity, since it has a short, validated, 11-item Hebrew version (Bar-Tal et al., 1997;  $\alpha = 0.82$ ). The *Trait victimhood* scale used an abridged version, consisting of nine statements ( $\alpha = 0.82$ ), of the scale developed by Gabay et al. (2020b). *COVID fear* was assessed by five statements, two of which (i.e., "I am very worried about being infected or infecting others that are close to me" and "I am afraid of corona disease") were adapted from a fear of cancer scale (Vrinten et al., 2015). We developed the three remaining statements for the purposes of the current research. They refer to a unique aspect of epidemics vs. other disease, i.e., the risk to oneself, to one's closest environment, and to the society in general ( $\alpha = 0.71$ ). The GSE scale used a modified version of Zeidner et al. (1993) Hebrew GSE 10-item scale (Weber et al., 2013;  $\alpha = 0.91$ ). *Guideline adherence* was assessed using two items we developed for the current study (i.e., "I make sure to wash my hands more often than I did before the coronavirus outbreak"; and "Since the coronavirus outbreak, I have been very careful to follow instructions (stay at home, reduce contact with people as much as possible, sneeze and cough into my elbow or tissue paper)";  $r = 0.43$ ,  $p < 0.001$ )<sup>3</sup>.

<sup>1</sup>We have chosen to use computerized questionnaire via a web based panel since past research indicated that online samples provide similar results to face-to-face samples, however, online samples tend to be more diverse (Casler et al., 2013). Midgam Project web panel was chosen as it includes over 50,000 panellists aged 17 years and older in Israel. It is one of the biggest panels in Israel, allowing its clients a representative sample of the population. It is highly regarded and used extensively for academic research and political surveys. Other variables (irrelevant to the current analysis) also collected in this survey will be published in a separate paper.

<sup>2</sup>On March 19th the Israeli government issued a stay-at-home order, limiting travel and work, except for essential needs such as getting food, medicines and medical or essential services, assistance to others in need, religious reasons, demonstration, blood donations and solitary sports.

<sup>3</sup>We omitted an additional item from this scale (i.e., "Adhering to the public guidelines is pointless, since we have no control over the disease's outbreak."), since

## RESULTS

For all variable means, SDs and correlations see **Table 1**. We tested our hypothesized moderated mediation path model, reasoning that our independent variables, i.e., NFS and trait victimhood, would lead to COVID fear, which in turn would lead to more guideline adherence; and that the association between COVID fear and guideline adherence would be moderated by GSE. We conducted a path analysis using Hayes's (2018) PROCESS (Model 14) bootstrapping command with 5,000 iterations controlling for participants age and gender<sup>4</sup>. Given that the PROCESS add-on cannot estimate a moderated mediation model with two parallel independent variables, we ran two models separately<sup>5</sup>: (1) indirect effect of NFS on guideline adherence through COVID fear, moderated by GSE, controlling for trait victimhood; and (2) the same model with trait victimhood as the independent variable, controlling for NFS.

Both models with either NFS or trait victimhood as the independent variables yielded similar pattern of results. Specifically, both NFS and trait victimhood's total effects on guideline adherence (see **Table 1**) were no longer significant when the mediator, COVID fear, and its interaction with GSE were introduced into the models ( $\beta = 0.04$ ,  $SE = 0.05$ ,  $p = 0.428$ , 95% CI [-0.06, 0.15], and  $\beta = 0.06$ ,  $SE = 0.05$ ,  $p = 0.266$ , 95% CI [-0.04, 0.16], respectively). Guideline adherence was predicted by COVID fear ( $\beta = 0.45$ ,  $SE = 0.05$ ,  $p < 0.001$ , 95% CI [0.35, 0.55]) and by the COVID fear X GSE interaction ( $\beta = -0.16$ ,  $SE = 0.05$ ,  $p = 0.001$ , 95% CI [-0.25, -0.06]; see **Figure 1**).

To probe the interaction, we used simple slope analysis (Aiken and West, 1991). GSE was fixed at 1 SD below the mean, corresponding to low-GSE participants, and 1 SD above the mean, corresponding to high-GSE participants. Conditional effects showed that for low-GSE participants, COVID fear significantly predicted guideline adherence ( $\beta = 0.61$ ,  $SE = 0.08$ ,  $p < 0.001$ , 95% CI [0.45, 0.76]); while for high-GSE participants the effect of COVID fear on guideline adherence was still significant, but considerably smaller ( $\beta = 0.29$ ,  $SE = 0.06$ ,  $p < 0.001$ , 95% CI [0.17, 0.42])<sup>6</sup>.

Finally, the COVID fear X GSE interaction yielded a significant indirect effect via COVID fear for low-GSE

we realized that it did not directly address guideline adherence, and it also reduced the reliability of the scale.

<sup>4</sup>Since the study was cross-sectional, we controlled for age and gender to eliminate potential alternative explanations. The same pattern of results appears when not controlling for participants' age and gender.

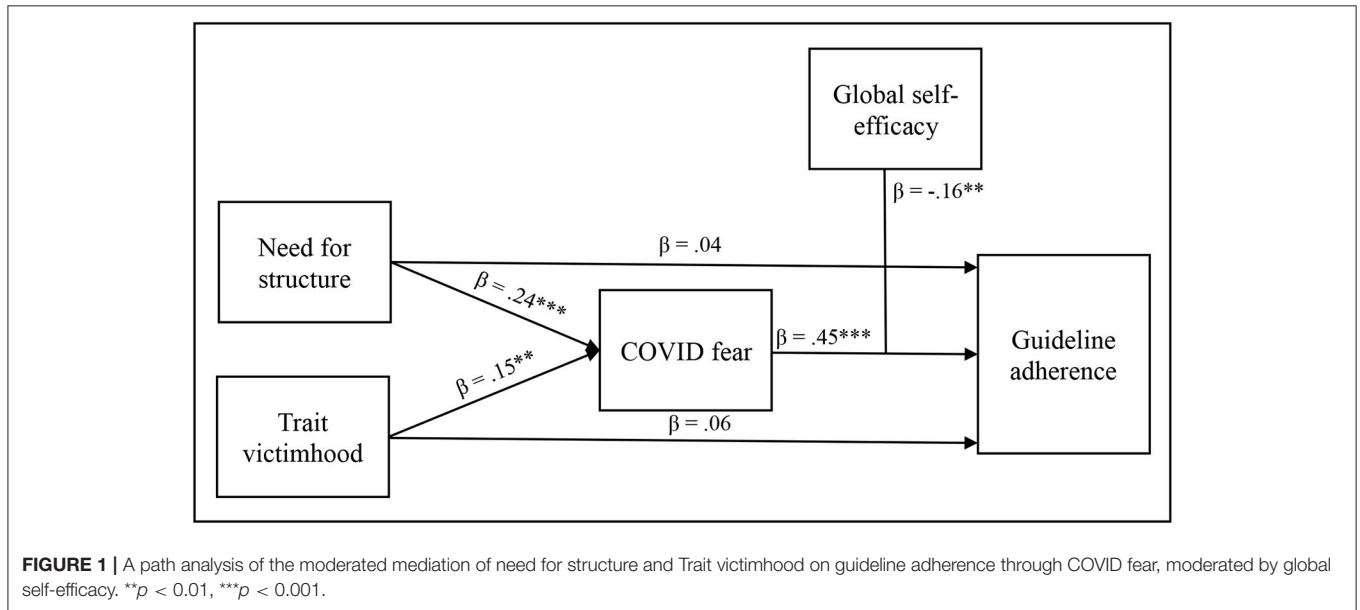

<sup>5</sup>The two conducted PROCESS analyses represent one hierarchical regression, in which need for structure and trait victimhood are in the first step; COVID fear, general self-efficacy and the interaction between them are in the second step; and guideline adherence is the result variable. To receive the indirect effects for both IVs, we used the PROCESS add on. However, due to a technical limitation, the PROCESS add-on can calculate the indirect effect for only one IV at a time. To overcome this limitation, we conducted two analyses: in the first, trait-victimhood was the IV while need-for-structure was controlled for; and in the second need-for-structure was the IV while trait-victimhood was controlled for.

<sup>6</sup>Examining the interaction between COVID fear and GSE with COVID fear fixed at 1 SD below and above the mean indicated that for low fear participants GSE significantly predicted guideline adherence ( $\beta = 0.39$ ,  $SE = 0.07$ ,  $p < 0.001$ , 95% CI [0.26, 0.52]); but not for high fear participants ( $\beta = 0.08$ ,  $SE = 0.07$ ,  $p = 0.274$ , 95% CI [-0.06, 0.22]).

**TABLE 1** | Means, SDs and correlations of all variables.

	Mean (SD)	1	2	3	4	5	6	7
Guideline adherence	5.99 (1.03)	–						
COVID fear	4.92 (1.13)	0.44***	–					
Need for structure	4.88 (0.88)	0.20***	0.30***	–				
Trait victimhood	4.54 (0.99)	0.20***	0.25***	0.39***	–			
Global self-efficacy	5.33 (0.85)	0.25***	0.01	–0.06	0.14**	–		
Age	41.71 (16.02)	0.06	0.10	–0.04	0.003	0.01	–	
Gender (1 = M, 2 = F)	–	0.13*	0.09	0.15**	0.09	0.04	0.02	–

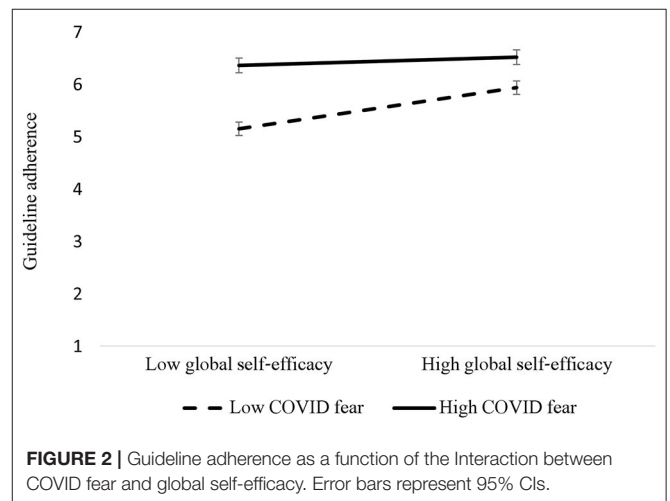

\* $p < 0.05$ , \*\* $p < 0.01$ , \*\*\* $p < 0.001$ .

participants in both the NFS and trait victimhood models ( $\beta = 0.15$ ,  $SE = 0.04$ , 95% CI [0.07, 0.22], and ( $\beta = 0.09$ ,  $SE = 0.04$ , 95% CI [0.02, 0.17], respectively). The indirect effect via COVID fear was still significant for high-GSE participants in both the NFS and trait victimhood models ( $\beta = 0.07$ ,  $SE = 0.02$ , 95% CI [0.03, 0.12], and  $\beta = 0.04$ ,  $SE = 0.02$ , 95% CI [0.01, 0.08], respectively), but considerably smaller, yielding both moderated mediation models to be significant ( $index = -0.04$ ,  $SE = 0.02$ , 95% CI [-0.07, -0.01], and  $index = -0.02$ ,  $SE = 0.01$ , 95% CI [-0.05, -0.002], respectively; see Figure 2).

**DISCUSSION**

In the current brief research report, we suggested that adherence to authorities COVID-19 health guidelines is associated with mental rigidity, operationalized as NFS, and trait victimhood. Our model suggests that these traits may be associated with guideline adherence through an indirect effect of fear of the pandemic. However, the extent to which fear predicted guideline adherence was moderated by GSE, such that for low-GSE, the extent to

which participants feared the pandemic had a significantly bigger effect on guideline adherence, compared to the high-GSE participants.

Adherence to the COVID-19 health guidelines is dependent upon various factors. In some cases, adherence to guidelines issued by the authorities is predominately dependent upon the ability to do so, such as those considered emergency workers. Some cannot afford not to work if they do not get paid sick leave. And in other cases, people cannot properly practice social distancing if they live in densely populated neighborhoods (e.g., Bouie, 2020). For those who *are* able to adhere to the guidelines, we argue and show evidence that specific personality traits may be important factors affecting adherence.

Considering mental rigidity, we argue that a pandemic of such magnitude involves great uncertainty and fear for those high in mental rigidity, and thus following the guidelines might reduce this uncertainty (Kruglanski et al., 2006). Regarding trait victimhood, people high in this tendency may be fearful of the pandemic, due to their general tendency to be vigilant to potential harm. This, in turn, should lead to more adherence to hand washing and practicing social distancing due to high-victimhood individuals' self-reliance in protecting themselves, as well as their perceptions of moral superiority (Gabay et al., 2020a,b).

Interestingly, while victimhood has mostly been shown to lead to negative consequences, especially in the realm of interpersonal and intergroup relations (e.g., Gabay et al., 2020a; Vollhardt, 2020), the current research suggests it might also have positive outcomes for the individual and possibly for the community. Furthermore, unexpectedly, we found that trait victimhood was positively associated with GSE. Although trait victimhood should be distinguished from actual experienced victimization, which is characterized perception of powerlessness, this finding is interesting and should be examined in future studies.

In terms of possible implications of the current research, due to the great importance of pandemic related messages, they should be perfected to lead to favorable results. In today's world, in which so many messages are imparted via social networks, social marketers trying to promote more COVID-19 related guideline adherence can enhance their messages' effectiveness using tailored, or personalized messaging (e.g., Hirsh et al., 2012; Halperin and Schori-Eyal, 2020). Indeed, the literature on attitude change has long established that the effectiveness of a message is not only based on the message itself, but also on the message source, the medium, and the characteristics of the message recipient (Hovland et al., 1953; Greenwald, 1968). Yet, while most research has focused on the different messages used (e.g., Maaravi et al., 2011), differential characteristics of recipients may also influence the results of the persuasion attempt. The current research provides preliminary indications that individuals with high levels of mental rigidity and/or trait victimhood, might be more susceptible to messages that describe the risk of the COVID-19 pandemic, which might increase their compliance with the guidelines. Interestingly, we found that age, which has played a pivotal role in the deadliness of the pandemic (e.g., Remuzzi and Remuzzi, 2020), as well as with guideline

adherence (Bogg and Milad, 2020), was neither significantly correlated with COVID fear nor with guideline adherence. This suggests that perhaps messaging that does not rely on emphasizing the potential risk could resonate more with older message recipients.

At this point, it should also be noted that the hypothesized independent variables in our model are personality traits, which in theory should precede and predict a response to a current event. Yet, the current research is correlational, and we cannot draw any firm conclusions regarding the causal relationships between the variables. Future research should attempt to establish causality by, for example, priming of a sense of victimhood (e.g., Baumeister et al., 1990) and then exploring its effects on fear and guideline adherence.

## CONCLUSION

In conclusion, the current report has pointed to the possible role mental rigidity, trait victimhood, and GSE play in fearing the COVID-19 pandemic, as well as in adhering to the guidelines issued by the authorities. Our model suggested that mental rigidity and trait victimhood both predicted fear of COVID-19, which in turn translated into more guideline adherence. High levels of fear yielded high levels of guideline adherence. However, when fear was not particularly high, participants' GSE was also associated with more guideline adherence. We argue that the current research may contribute to our understanding of how personality traits shape responses to adversities, as well as to the development of more effective messaging to promote message recipients' compliance with guidelines issued by the authorities.

## DATA AVAILABILITY STATEMENT

The data that support the findings of this study are openly available at [https://osf.io/rqbxu/?view\\_only=11b5049cb83943deaf87d01c448b2540](https://osf.io/rqbxu/?view_only=11b5049cb83943deaf87d01c448b2540).

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Institutional Review Board, IDC Herzliya Adelson School of Entrepreneurship (IRB # YMCD19003). All subjects provided informed consent to participate in the study. To protect the respondents' privacy, the survey was conducted anonymously. All procedures were in accordance with the Declaration of Helsinki.

Does COVID-19 Impact Less on  
Post-stroke Aphasia? This Is Not  
the Case. *Front. Psychol.* 11:564717.  
doi: 10.3389/fpsyg.2020.564717

**Background:** The coronavirus disease 2019 (COVID-19) pandemic has greatly affected people's mental health resulting in severe psychological consequences. One of the leading causes of long-term disability worldwide is aphasia. The language changes experienced by a person with aphasia (PWA) often have a sudden and long-lasting negative impact on social interaction, quality of life, and emotional wellbeing. The main aim of this study was to investigate the impact of COVID-19 on the different psychosocial dimensions which affect PWA.

**Methods:** This retrospective study included 73 PWA and 81 elderly matched controls. All patients were in the chronic phase. They were all discharged from rehabilitation services, which left them with different degrees of language deficits (i.e., severe vs. mild vs. moderate). All participants were administered the hospital anxiety and depression scale (HADS) through an online survey. PWA also took part in the stroke and aphasia quality of life scale questionnaire (SAQOL-39).

**Results:** Although the comparison between two different time points [one month before (T0) and one month after the lockdown (T1)] led to a significant increase in depression and anxiety symptoms in both groups (PWA vs. control), lower rates of depression and anxiety were found in PWA compared to the healthy group. Significant deterioration was also present in PWA in the communication and psychosocial scales of the SAQOL-39 test, which correlated with the observed changes in the psychological domains. Interestingly, the results were not significantly influenced by the degree of aphasia severity. Similarly, in both groups, none of the demographic variables (gender, age, and educational level) significantly affected the scores in the different subscales.

**Conclusions:** This evidence which, at first glance, seems to suggest that PWA have been partially spared from the impact of COVID-19, actually masks a dramatic situation that has always characterized this population. Indeed, given that PWA already live in a state of social isolation and emotional instability, these conditions might have, paradoxically, limited the effects of the coronavirus. However, as our results showed a deterioration in the emotional state and communication skills of our patients, possible solutions are discussed in order to prevent further decline of their cognitive abilities.

**Keywords:** COVID-19, aphasia (language), stroke, depression, anxiety, psychosocial well being

## INTRODUCTION

First identified in China in late 2019, the coronavirus disease 2019 (COVID-19) emergency has become a global pandemic, spreading all over the world within a short period of time, including Italy (Şencan and Kuzi, 2020; World Health Organization [WHO], 2020). On March 8, 2020, the Italian Government implemented extraordinary measures to limit viral transmission, restricting movement in all regions of Italy using stay-at-home orders and lockdowns, limiting physical contact between people with the months-long suspension of commercial, educational, and social activities (Soraci et al., 2020). Given the unknown causes of the infection, the poor knowledge of its transmission, the unpredictability of the duration, and the high risk of mortality, the outbreak of COVID-19 led to severe physical and psychological consequences for people's health (Brooks et al., 2020; Kang et al., 2020; Li et al., 2020; Moccia et al., 2020). Indeed, all over the world people are still mostly affected by negative emotions (i.e., depressive symptoms, anxiety, high stress levels, confusion, post-traumatic stress disorders, and insomnia) and negative cognitive assessment for self-protection (i.e., feelings of helplessness and fear of falling sick or dying), breaking the balance of daily activities, and decreasing the perception of wellbeing (Brooks et al., 2020; Kang et al., 2020; Li et al., 2020; Moccia et al., 2020). The work of Santini and collaborators (Santini et al., 2020) also reported a strong correlation between social isolation and high rates of anxiety and depression in both healthy young and older adults.

Since COVID-19 has resulted in serious negative psychological consequences in different populations, we wonder whether coronavirus has also dramatically affected people with brain damage, and, in particular, persons with post-stroke aphasia (PWA).

As is well known, stroke is one of the leading causes of long-term disability worldwide (Feigin et al., 2015). After a stroke, survivors can experience a wide range of difficulties, among them aphasia, which is one of the most serious socially disabling consequences. Aphasia, the loss of ability to produce and/or to understand language, manifests itself in about one-third of left brain-damaged people (30% of acute vs. 10–20% of chronic stroke patients, Ali et al., 2015). The aphasic symptoms are heterogeneous, varying in terms of severity and degree of involvement across the modalities of language, including the expression and comprehension of speech, reading, and writing. Variation in the severity of expressive impairments, for example, may range from the patient's occasional inability to find the correct word to telegraphic and very reduced speech output. Thus, PWA experience frustration and depression since their exclusion from language-dependent activities has strong implications for many aspects of their emotional condition and social status. Indeed, the language changes experienced by PWA often have sudden and long-lasting negative impacts on friendships, social engagements, quality of life, and psychological wellbeing (Engelter et al., 2006; Spaccavento et al., 2014; Mattioli, 2019). Less curiosity and less emotional stability with anxiety and depression, distress, social exclusion, and loss of autonomy are frequently reported symptoms in aphasic people (Kouwenhoven

et al., 2011; Ayerbe et al., 2014; Hackett and Pickles, 2014; Feigin et al., 2015; Robinson and Jorge, 2016; Mitchell et al., 2017; Kirkevold et al., 2018; Torres-Prioris et al., 2019). In particular, regardless of the degree of language impairment, the patient tends to isolate him/herself and to have less intrinsic motivation in taking part in language rehabilitation programs since he/she feels oppressed by negative feelings (Cott et al., 2007; Woodman et al., 2014; Foley et al., 2019; Hjelle et al., 2019). Accordingly, several studies have already pointed out that PWA have a quality of life worse than non-aphasic patients (Spaccavento et al., 2014; Wray and Clarke, 2017; Kirkevold et al., 2018; Hjelle et al., 2019).

Considering that COVID-19 has dramatically maximized the risk of social isolation and associated depression, in the present study, we wanted to investigate if the psychosocial difficulties experienced by PWA would have worsened due to coronavirus. Indeed, language problems limit the use of digital media (i.e., cellular and/or social networks) in order to maintain social contact. Thus, aphasic patients could not even rely on these social means, as other stroke or healthy people do, to compensate for the lack of social interaction imposed by the coronavirus.

As far as we know, to date, no study has explored the effects of COVID-19 on patients with chronic post-stroke aphasia.

In this exploratory retrospective study, we investigated the psychological impact of the COVID-19 outbreak on a group of chronic PWA matched with a control group of elderly participants by comparing their psychological state one month before (T0) to one month after lockdown.

## DESIGN AND PARTICIPANTS

The study design was an interview-based psychometric study. Seventy-three patients with post-stroke aphasia were recruited from two different speech and language therapy (SLT) service providers in Italy, one in Rome and the other in Turin.

All patients were already discharged from rehabilitation services before the COVID-19 emergency. They were all native Italian speakers with right premorbid manual dominance, affected by a single left hemispheric stroke occurring at least one year prior to experimentation. They were all cared for by a caregiver and lived at home before the stroke. No patients presented a history of severe cognitive decline, mental health problems, alcohol or drug abuse, head injury, or tumoral lesions. None of the participants had received structured language therapy for at least 6 months before the time of inclusion in the study in order to prevent confounding therapy effects. A group of 81 age- and education-matched elderly individuals were also recruited to serve as normal controls. They were all retired from work and they mostly stayed at home.

Persons with post-stroke aphasia had a mean age of 64.52 years ( $SD \pm 9.85$ ), 41 (56%) were male and 32 (44%) were female. The mean educational level was 11.88 ( $SD \pm 3.85$ ). For the control group, the mean age was 68.11 years ( $SD \pm 10.08$ ), 38 (47%) were male and 43 (53%) were female. The mean educational level was 11.27 ( $SD \pm 4.07$ ). The two groups did not significantly differ in age, educational level, and gender from each other. According to their age, all participants were subdivided into three groups: (1)

40–55 years (12 PWA, 11 controls), (2) 55–70 years (36 PWA, 34 controls), and (3) 70–85 years (25 PWA, 36 controls). According to the educational level, three different groups were identified: (1) 5–8 years (26 PWA, 37 controls), (2) 8–13 years (30 PWA, 26 controls), and (3) 13–17 years (17 PWA, 18 controls).

## Ethical Approval

An ethical review and approval were not required for the study on human participants in accordance with the local legislation, institutional requirements, and the legislation governing the psychologist profession (L.56/89). Written informed consent to participate in the study was provided by the patients.

## Procedure and Outcome Measurements

We used the Esame del Linguaggio II (Ciurli et al., 1996) and the Aachen Aphasia Test (AAT, Luzzatti et al., 1996) to screen for aphasia. According to their AAT score (Luzzatti et al., 1996), all patients were divided into three groups: 30 with severe/global aphasia (13 males and 17 females; age  $65.07 \pm 10.21$ ; education level  $10.60 \pm 3.64$ , AAT score: 1–3); 28 with moderate aphasia (18 males and 10 females; age  $63.75 \pm 8.36$ ; education level  $13.11 \pm 3.98$ ; AAT score: 4–5), and 15 with mild aphasia (10 males and 5 females; age  $64.87 \pm 12.08$ ; education level  $12.13 \pm 3.40$ ; AAT score: 6–7). Both the groups (PWA vs. control) were first contacted via telephone or e-mail, and those patients who gave their informed consent to the study were invited to take part in the survey. The online survey took around 20 min to be completed. The questionnaires were administered online to healthy people through forums and social network communities. In order to ensure that PWA could be assisted during the survey, the questionnaires were administered to the patients through Skype, a telecommunication platform specialized in providing video-chat and voice calls. The survey was anonymous and data confidentiality was assured. Depressive symptoms and anxiety were measured through the hospital anxiety and depression scale (HADS). Both the subscales consist of seven items scored on a 4-point Likert scale (0–3), yielding a maximum score of 21. A cut-off score =8 was established to indicate pathological symptoms of depression or anxiety (Aben et al., 2002; Bjelland et al., 2002). The HADS scales have good internal consistency, good to excellent sensitivity and specificity, and good to very good concurrent validity (Aben et al., 2002; Bjelland et al., 2002). We used the stroke and aphasia quality of life scale (SAQOL-39), an interview-administered self-report scale to measure general dimensions of stroke-specific, health-related quality of life. The SAQOL-39 was validated for use in people with and without aphasia (Hilari et al., 2003, 2009). The questionnaire was comprised of 39 items grouped into 4 subdomains: physical, psychosocial, communication, and energy, which are the most affected areas in post-stroke patients (Parr et al., 1997; Duncan et al., 1999; Williams et al., 1999). The SAQOL has two response formats, both based on a 5-point scale: 1-could not do it at all to 5-no trouble at all and 1-definitely yes to 5-definitely no. Overall, subdomain scores can range from 1 to 5. The overall SAQOL score is calculated by adding across the items and dividing by the number of items; subdomain scores are calculated in the same way. Higher scores indicate a higher quality of life.

The questionnaire has high validity and reliability in aphasic individuals and it is sensitive to changes (Hilari et al., 2003, 2009). Each questionnaire included two protocols, which were administered in a counterbalanced order across the groups. For each protocol, the questions were the same but they compared the psychological state of each participant between two distinct time periods: one month before (T0) and one month after the lockdown (T1).

## Data Analyses

All statistical analyses were conducted with IBM SPSS Statistics 22 software. For each group (PWA vs. control), paired *t*-tests were calculated on the mean score differences between the two time points: pre (T0)- and during (T1) COVID-19 in the different questionnaires. Two separate mixed ANOVAs were also performed for each subscale (anxiety vs. depression) of the HADS questionnaire with group as the between-subjects variable (PWA vs. control) and time as the within-subjects variable (T1 vs. T0). The primary analysis was the group-by-time interaction. The values of  $p < 0.05$  were considered statistically significant. In both groups, correlational analyses (Pearson's *r*-coefficient) were also conducted on the mean score differences among the different subscales between the two time points (T1 vs. T0).

To evaluate the impact of aphasia severity on the PWA's responses in the different questionnaires, separate mixed model ANOVAs were also performed. We also analyzed the influence of gender, age, and educational level on the results collected in the two groups through two samples *t*-test comparisons (gender), the Kruskal–Wallis test (age), and a mixed-model ANOVA (educational level).

For each variable, in order to evaluate its statistical power, the values of the effect size were entered using the partial  $\eta^2$  index and the observed power index which SPSS software automatically associates with the ANOVA.

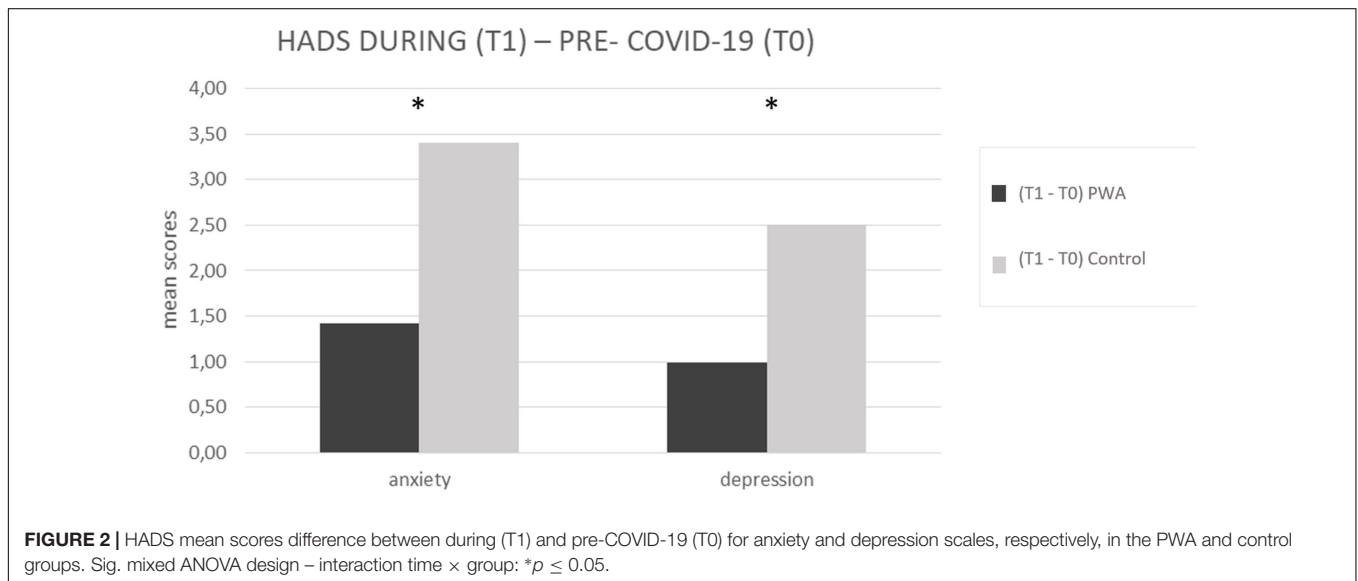

Our sample size was determined with the G\*Power 3.1.9.2 software (Faul et al., 2009). It was calculated that a sample size of at least 54 subjects per group was required to obtain an expected effect size of  $d = 0.51$  (at 80% power;  $\alpha = 0.05$ ). Therefore, our samples were considered large enough to generalize the results to the reference population.

## RESULTS

### Anxiety and Depression Scales

In both groups, the prevalence of depressive symptoms and anxiety increased significantly between T0 (pre) and T1 (during COVID-19) (PWA: T0 5 vs. T1 = 6,  $p = 0.000$  and T0 5 vs. T1 = 7,  $p = 0.000$ , respectively, for depression and anxiety; controls: T0 3 vs. T1 = 6  $p = 0.000$  and T0 4 vs. T1 = 8,  $p = 0.000$ , respectively, for depression and anxiety) (see **Figure 1**) as revealed by the paired *t*-tests.

The mixed ANOVA design performed on the anxiety levels of the HADS questionnaire revealed a significant effect of time (T1 vs. T0) [ $F(1,152) = 107.5$ ,  $p < 0.001$ , partial  $\eta^2 = 0.414$ , and observed power = 1.000] and no significant effect of group (PWA vs. control) [ $F(1,152) = 0.046$ ,  $p = 0.831$ , partial  $\eta^2 = 0.000$ , and

observed power = 0.055]. The interaction time  $\times$  group was also significant [ $F(1,152) = 18.1, p < 0.001$ , partial  $\eta^2 = 0.106$ , and observed power = 0.988] showing that the anxiety levels were greater in the control group than in the PWA (T1–T0 controls = 4 vs. T1–T0 PWA = 2,  $p < 0.001$ ) resulting above the cut-off score (Aben et al., 2002; Bjelland et al., 2002) (see **Figure 2**).

The mixed ANOVA design performed on the depression levels of the HADS questionnaire revealed a significant effect of time (T1 vs. T0) [ $F(1,152) = 73.8, p < 0.001$ , partial  $\eta^2 = 0.327$ , and observed power = 1.000] and a significant effect of group [ $F(1,152) = 4.5, p = 0.035$ , partial  $\eta^2 = 0.029$ , and observed power = 0.562]. The interaction time $\times$ group was also significant [ $F(1,152) = 13.9, p < 0.001$ , partial  $\eta^2 = 0.84$ , and observed power = 0.960] showing that the depression levels were greater in the control group than in the PWA (T1–T0 controls = 3 vs. T1–T0 PWA = 1,  $p < 0.001$ ) (see **Figure 2**).

### SAQOL-39 Scale

In the PWA group, the difference between the two time points (T1–T0) revealed that COVID-19 significantly impacted on the SAQOL-39 total score and, specifically on the communication and psychosocial domain. Indeed, the mean score was significantly lower at T1 than at T0, showing a significant deterioration of the performance in both areas (communication: T0 2,29 vs. T1 2,20 and  $P = 0.019$ ; psychosocial: T0 3,07 vs. T1 2,85 and  $P = 0.001$ ) (see **Figure 3**).

### Correlational Analyses

In both groups (PWA vs. control), the analyses (Pearson's *r*-coefficient) performed on the mean percentage difference between the two time points (T1 vs. T0) revealed positive correlations ( $p \geq 0.05$ ) among the anxiety and depression scales

**FIGURE 3 |** SAQOL-39 mean scores (pre- and during COVID-19) in the PWA group. Sig. two tailed paired *t*-tests: \* $p \leq 0.05$ . Legend: globalqol, mean score in SAQOL-39 total score; physical, mean score in physical scale; communication, mean score in communication scale; psychosocial, mean score in psychosocial scale; energy, mean score in energy scale.

(HADS) and the different subdomains of the SAQOL-39 scale. Only the psychosocial and the communication subdomains of the SAQOL-39 test were not correlated to each other.

### Influence of Aphasia Severity, Gender, Age, and Educational Level

Three separate mixed model ANOVAs performed with aphasia severity (severe – moderate – mild), as a between-subject factor, and time (T0–T1), as a within-subject factor, revealed that the detected changes between the two time points in the level of depression and anxiety of PWA and in the two subdomains of the SAQOL-39 questionnaire (communication and psychosocial area) were not significantly affected by the degree of aphasia severity. Similarly, when the variables, gender, age, and educational level were investigated, none of these factors significantly affected the scores in the different subscales.

However, the *post hoc* comparison between the three groups (severe vs. moderate vs. mild), showed that the severe group had a higher degree of anxiety and depression and worse performance in the different subscales of the SAQOL-39 questionnaire than the other two groups (moderate and mild), which differed from each other only in the communication scale (see **Table 1**).

## DISCUSSION

The main aim of the present study was to investigate the impact of the COVID-19 outbreak on different psychosocial dimensions, such as depression, anxiety, communication, and social isolation in persons with chronic post-stroke aphasia (PWA). A group of elderly matched controls also took part in the study. For the purpose of our work, it is necessary to highlight that all patients were already discharged from rehabilitation services before COVID-19 and they all lived at home with a caregiver.

**TABLE 1 |** Bonferroni *post hoc* comparisons between the three aphasic groups (severe vs. moderate vs. mild).

Variable	Groups comparison	<i>p</i> -value
Hads-anxiety scale	Severe vs. moderate	0.001
	Severe vs. mild	0.015
Hads-depression scale	Severe vs. moderate	0.008
	Severe vs. mild	0.041
SAQOL-39 – total score	Severe vs. moderate	0.000
	Severe vs. mild	0.000
SAQOL-39 – physical	Severe vs. moderate	0.000
	Severe vs. mild	0.000
SAQOL-39 – communication	Severe vs. moderate	0.014
	Severe vs. mild	0.000
	Moderate vs. mild	0.000
SAQOL-39 – psychosocial	Severe vs. moderate	0.010
	Severe vs. mild	0.000
SAQOL-39 – energy	Severe vs. moderate	0.009
	Severe vs. mild	0.006

Overall, results indicated that during the COVID-19 pandemic, both groups (PWA vs. control) scored significantly higher on the anxiety and depression subscales of the HADS questionnaire compared to the pre-COVID-19 condition. Moreover, although before the pandemic, the control group performed in the normal range with respect to the aphasic population, during the coronavirus, they reached significantly higher levels in both subscales, which even exceeded the cut-off score of the anxiety scale.

Thus, in line with several recently published studies, our work confirms that the COVID-19 emergency has dramatically affected the emotional state of the healthy population leading to an increase of depressive and anxiety symptoms (Brooks et al., 2020; Kang et al., 2020; Li et al., 2020; Moccia et al., 2020;

Santini et al., 2020). It has already been suggested that the distorted perception of risk with fear and uncertainty experienced during the COVID-19 outbreak, along with the separation from loved ones and the limitations on freedom, have made a strong impact on mental health with an increase of negative emotions (Brooks et al., 2020). Accordingly, our healthy group reported emotional distress, low mood with depression, and anxiety. However, surprisingly, lower rates of depression and anxiety were found in PWA compared to the control group. These results, which, at first glance, may seem positive, actually mask a dramatic situation which affects aphasic people. Indeed, as stated in the Introduction, the anxiety and the depressive symptoms associated with poor social functioning, low quality of life, and poor functional abilities are frequently reported conditions in aphasic stroke survivors in the long term (Aström, 1996; Robinson, 1997; D'Alisa et al., 2005; Hilari et al., 2012; Jeong et al., 2012; Campbell Burton et al., 2013; Tang et al., 2013; Eccles et al., 2017). Normally, negative emotions are more pervasive in aphasic people than in healthy subjects, since their exclusion from language-dependent activities dramatically impacts their emotional wellbeing and social life (Engelter et al., 2006; Spaccavento et al., 2014; Baker et al., 2018; Mattioli, 2019; Pompon et al., 2019). In particular, as already stated, the patient tends to isolate his/herself and to have less intrinsic motivation in taking part in social relationships since he/she feels oppressed by negative symptoms (Cott et al., 2007; Woodman et al., 2014; Foley et al., 2019; Hjelle et al., 2019).

Thus, given that aphasic people already live in a state of social isolation, the virus had a paradoxically greater psychological impact on the control group (Spaccavento et al., 2014; Kirkevold et al., 2018). However, it is worth noting that the levels of anxiety and depression during COVID-19 have worsened in the aphasic population too. More importantly, since we also found a deterioration of their performance on the communication and psychosocial scales of the SAQOL-39 questionnaire which was positively correlated with their emotional status, we cannot exclude the possibility that these patients, already discharged from rehabilitation services, manifested a relapse on their communication skills due to the worsening of their psychological symptoms. Given these results, we believe that we must take into serious consideration not only the risks of COVID-19 on healthy people but also its impact on a population that is no longer benefiting from rehabilitation services. In fact, unlike what is often suggested by the literature (Thomas and Lincoln, 2008; Hilari and Byng, 2009; Hilari et al., 2012), we found no specific influence of aphasia severity with respect to the changes observed in anxiety, depression, communication, and psychosocial wellbeing. In other words, although there is a general agreement that aphasia severity correlates with patient performance (Thomas and Lincoln, 2008; Hilari and Byng, 2009; Hilari et al., 2012), in our study, the highest levels of anxiety and depression and the lowest rates in the communicative and psychosocial scales were independent of aphasia severity. Thus, COVID-19 had equally affected our three selected groups of aphasics. Similarly, no influences were found among the different demographic variables taken into consideration (educational level, age, and gender).

Given the current dramatic impact of COVID-19 on clinical services, although our aphasic population was already discharged from rehabilitation, our results point to the urgency of implementing new strategies and possible interventions for them. A very recent study (Bersano and Pantoni, 2020) also confirmed this need for acute stroke patients who, due to COVID-19, suffered from a shortage of services and delays in time-dependent treatments and diagnostic work-up. In order to circumscribe the consequences of the COVID-19 pandemic, one possible strategy might be to set up tele-rehabilitation and home-based services, which have been already successfully implemented for aphasia rehabilitation (Zhou et al., 2018; Gerber et al., 2019; Chang and Boudier-Revéret, 2020) and to focus on specific rehabilitation programs which allow the patients, who are no longer followed-up in therapy, to keep training their communication skills, and avoiding further deterioration. This would not add excessive costs to the healthcare system since it could be easily supported by the patients' families.

Before concluding, it is worth noting that one possible limitation of our study is that our aphasic population was not entirely representative of the stroke population. Thus, our results do not allow for an advance in any final conclusion regarding the impact of COVID-19 on post-stroke people in general. However, since we strongly believe that one of the most serious socially disabling consequences after stroke is aphasia which does not offer the opportunity, as in other post-stroke syndromes, to communicate remotely, our results point to the urgency of taking into serious consideration the dramatic impact that COVID-19 has had on these patients.

In conclusion, since global attention is currently focused on clinical populations who, prior to COVID-19 were followed-up in rehabilitation services, our results point to the need of also considering the already discharged patients. For this population, we recommend they access home-based remote services in order to promote adaptive behaviors, reduce negative feelings, and prevent further deterioration of their cognitive performances.

## DATA AVAILABILITY STATEMENT

The data will be available upon request.

## ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation, institutional requirements and the legislation governing the psychologist profession (L.56/89). Written informed consent to participate in the study was provided by the patients.

## AUTHOR CONTRIBUTIONS

FP and PM designed the research and wrote the manuscript. FP, CR, and MC performed the research. MC, CR, and AG analyzed the data. PM and AG edited the manuscript. All authors contributed to the article and approved the submitted version.

# COVID-19: A Psychosocial Perspective

Syed Hassan Raza<sup>1\*</sup>, Wajiha Haq<sup>2</sup> and Muhammad Sajjad<sup>3</sup>

<sup>1</sup> School of Economics, Quaid-i-Azam University, Islamabad, Pakistan, <sup>2</sup> Department of Economics, School of Social Sciences and Humanities, National University of Sciences and Technology, Islamabad, Pakistan, <sup>3</sup> School of Energy and Environment, City University of Hong Kong, Kowloon, Hong Kong

The World Health Organization declares coronavirus disease 2019 (COVID-19) as a pandemic, and The World Economic Forum argues that the COVID-19-induced global lockdown is the biggest psychological experiment. This study is an attempt to empirically evaluate the possible adverse psychosocial effects caused by COVID-19-related lockdown, if any. To do so, a cross-sectional study is conducted based on a comprehensive online survey using snowball sampling to analyze the level of social and psychological impacts (i.e., stress, belief in stakeholders, fear of losing job, and life satisfaction) during the early stage of the outbreak in Pakistan. The questionnaire is filled out by the residents in Pakistan including working professionals and students (sample size is 428). We find that the development of stress due to COVID-19-induced lockdown is particularly because of mood swings. Additionally, a higher prevalence of stress in the children of highly educated mothers is evident (95% confidence). To assess the belief in stakeholders, we focus gender, demographics, and education. It is observed that parental education and age significantly affect the belief in several stakeholders (i.e., government, media, religious clerics, and family). The lockdown-induced fear of losing job is lower in female and male children whose fathers are graduates. Lastly, we observe that food storage and “no fear of losing job” significantly increases the odds of life satisfaction. These findings have important implications in the context of social insurance, parental education, and policy related to COVID-19 at various levels. This study further facilitates to understand the factors that might affect the mental health and life satisfaction of people during such pandemics.

**Keywords:** public health, psychology, stress, COVID-19, well-being

## INTRODUCTION

The world is facing one of the most dangerous challenges in our lifetime due to the outbreak of the novel coronavirus (COVID-19), which has now spread to almost every country (211 countries and territories to be specific) on the global map (Pettersson et al., 2020). The effects caused by COVID-19 apart from adverse health are becoming eminent in different dimensions such as social, psychological, and economic. COVID-19 affected the first patient in late November 2019, and the World Health Organization (WHO) declared the phenomena as a Public Health Emergency of (international concern)

in January 2020 (World Health Organization [WHO], 2020). COVID-19, also known as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), is a major outbreak after SARS-CoV-1, which spread in the year 2002. As of 18th April 2020, about 1.5 million people have been confirmed to be affected by COVID-19 and more than 1,00,000 are dead due to this global outbreak. As an optimal solution, WHO has advised a quarantine policy to limit the spread of the virus, and now more than one-third of the global population is under some form of isolation (Kaplan et al., 2020).

COVID-19 outbreak has changed the current living arrangement via social isolation, fear of human-to-human transmission, and closure of educational as well as business institutes. This situation could very well lead to severe psychological impacts on societies (Fardin, 2020), which is well evident as the consequences of previous outbreaks such as the recent Ebola (Van Bortel et al., 2016) and Middle East respiratory syndrome coronavirus (MERS-CoV) (Al-Rabiaah et al., 2020). The outbreak of Ebola in Guinea, Liberia, and Sierra Leone adversely affected the quality of life and led to social, psychological, and economic breakdown (Van Bortel et al., 2016). Fear and anxiety in the patients of COVID-19 have already been observed (Xu et al., 2020). Belief in governments during the flu pandemic has been found significantly associated with gender, whereas income, age, education, and people living in urban and rural areas were found to have no effect on belief in the government that they will do actions to benefit the community. Gender, education, and income were found to be correlates of belief in the family (Paek et al., 2008). Life satisfaction during COVID-19 was also tested during pandemic (Satici et al., 2020; Zacher and Rudolph, 2020). Another study investigated that age, income, and gender are significant correlates of life satisfaction during COVID-19 in Germany. However, the effect of education on life satisfaction during COVID-19 pandemic was found insignificant (Zacher and Rudolph, 2020). Similarly, the existing literature in the field of epidemiology has well recognized the impact of diseases on the behavior and psychology of individuals (Cherif et al., 2016; Pellmar et al., 2020).

Humans, known as social animals, living in social clusters might suffer not only from COVID-19 itself but through the isolation as well. Theorists define the perceived social isolation as physical separation from others and tested this phenomenon for having any psychological consequences. They found that social isolation can result in negative emotions (e.g., anger, sadness, and low mood), decreased levels of arousal in extroverts, and those who prefer to stay around individuals and even decline in cognitive abilities (e.g., problem solving and decision making; Cacioppo and Hawkey, 2009). Consequently, overwhelming feelings of isolation or the feeling of loss of social relations have been shown to have implications for the decline in trust in relations and belief, alongside a buildup of worsening immune functioning, disruptions in sleep, and laziness, which lead to weight gain and stress (Cacioppo et al., 2002). These theories have also been used with regard to studying how social disconnection can lead to the emergence of stress, fear, suicidal ideation, and risks of early mortality (Holt-Lunstad et al., 2010). Therefore, the need to have social connection is a core human characteristic

and, if violated, can bring many consequences including mood swings, stress, fear, and decline in belief and trust on family or other relations. Human beings cannot remain isolated for longer periods, as it results in the development of fear, stress, distrust, depression, and associated negative feelings. The outbreaks are known for disturbing societal psychology (Van Bortel et al., 2016; Lee et al., 2018; Al-Rabiaah et al., 2020; Fardin, 2020). Wang et al. (2020) evaluated the psychological responses to analyze the impact of COVID-19 on psychology. However, the evidence on the psychological impacts of COVID-19 and the consequent social-distancing-induced isolation is scarce, as it has roughly been 4 months since the pandemic started around December in China. The need for studying the psychological outcome of COVID-19 is pivotal particularly in low-income countries where the Happiness Index is substantially low and people are struggling to improve their living standards (United Nations, 2020). This study will evaluate the psychological impacts (positive/negative) of COVID-19 that can eventually help in making corrective decisions and resource allocation to support societal life satisfaction taking the public perception into account.

In connection to this, we assess the psychological influences of COVID-19-induced lockdown, if any, from different perspectives in Pakistan, a developing country in Asia. Pakistan is geographically located between two epicenters of the COVID-19 outbreak—China and Iran (Saqlain et al., 2020)—making it suitable to study the psychological impacts of this current outbreak. This study is an initial effort to document the varied psychological effects in connection to COVID-19-related social-distancing and lockdown situation. As of April 18th, 2020, Pakistan has 7,516 confirmed cases of COVID-19, and the country is practicing a lockdown situation from the last 4 weeks including the closure of public/private business centers and educational institutions along with a very limited market activity. Pakistan first took measures on February 28, 2020 by closing the borders with Iran followed by China suspecting departure of affected people. Schools were closed nationwide on March 1st, 2020. After 2 months of complete lockdown, the country shifted to a partial lockdown.

The main aim of this study is to stimulate theoretical perspectives and novel investigations on how the COVID-19-induced quarantine is psychologically affecting the public. To do so, we first identify the presence of stress and fear in the respondents due to COVID-19 and then evaluate different associated factors such as the belief of individuals in major stakeholders such as family, government, media, and religious clerics toward COVID-19 response and the education of respondents and their parents. The COVID-19 pandemic did not only spread disease but was also supplemented with the lockdown as well. As the observed lockdown is first of its nature in the current century and the disease is novel, it is important to analyze the psychological effects on people. The study is novel due to nature of the problem and is one of the initial attempts, particularly in Pakistan. The study has analyzed different demographic and sociological factors affecting stress, trust, and belief of people during the lockdown. The fear of job loss and life satisfaction was also analyzed during lockdown. The findings from this study would progressively

further the understanding regarding the psychological impacts of such pandemics providing policy-related implications, which can ensure effective public health-relevant management. Hence, this study has not only practical implications for current times but will also advance the theory for further research.

## MATERIALS AND METHODS

The overall workflow of the study consists of five main steps: questionnaire design → pilot survey → revising the questionnaire for the nature of questions and clarity → final survey → impact analysis. To begin with, previous surveys are comprehensively reviewed (Leung et al., 2003; Leung et al., 2009; Rubin et al., 2010; Wang et al., 2020), and the most relevant questions are selected to design the final questionnaire. Questions on demographic, socioeconomic, and psychological aspects during the COVID-19 outbreak are the key constituents of the questionnaire. For example, respondents are asked about their gender, age, education, occupation, living arrangement, household size, and the education of their parents. Additionally, we emphasize asking about fear, stress, mood swings, laziness, belief, and trust in different associated actors (i.e., government, family, and media). The variables are operationally defined and asked particularly in the context of COVID-19-induced lockdown. The variable of “fear” includes fear of losing job due to lockdown, fear of being diagnosed with COVID-19, and fear that a family member will be diagnosed with COVID-19 leading to some social stigmatization. In order to assess the “belief” in social and government institutions, respondents are asked how well they believe that their family, government (i.e., federal, provincial, and local), medical services providers, and religious clerics responded to COVID-19 pandemic. It is noted that the questions are asked for each category separately. The “trust” variable is measured by how well the respondent trusts the organizations in the context of COVID-19 pandemic response. The Likert scale is used to measure the fear, belief, trust, stress, mood swings, and laziness as a consequence of COVID-19-induced lockdown. Belief was measured on Likert scale of 5 ranging from “poor” to “very good.” The five-category Likert scale of life satisfaction ranges from “very unsatisfied” to “very satisfied.” We present the distribution of mood of swings in **Figure 1A**, food storage in **Figure 1B**, believe in media in **Figure 1C**, believe in religious clerics in **Figure 1D**, believe in family in **Figure 1E**, and social discrimination in **Figure 1F**. Stress was measured using the 4-point Likert scale ranging from “not at all” to “often” based on the Depression Anxiety Stress Scale (DASS) (Lovibond and Lovibond, 1995).

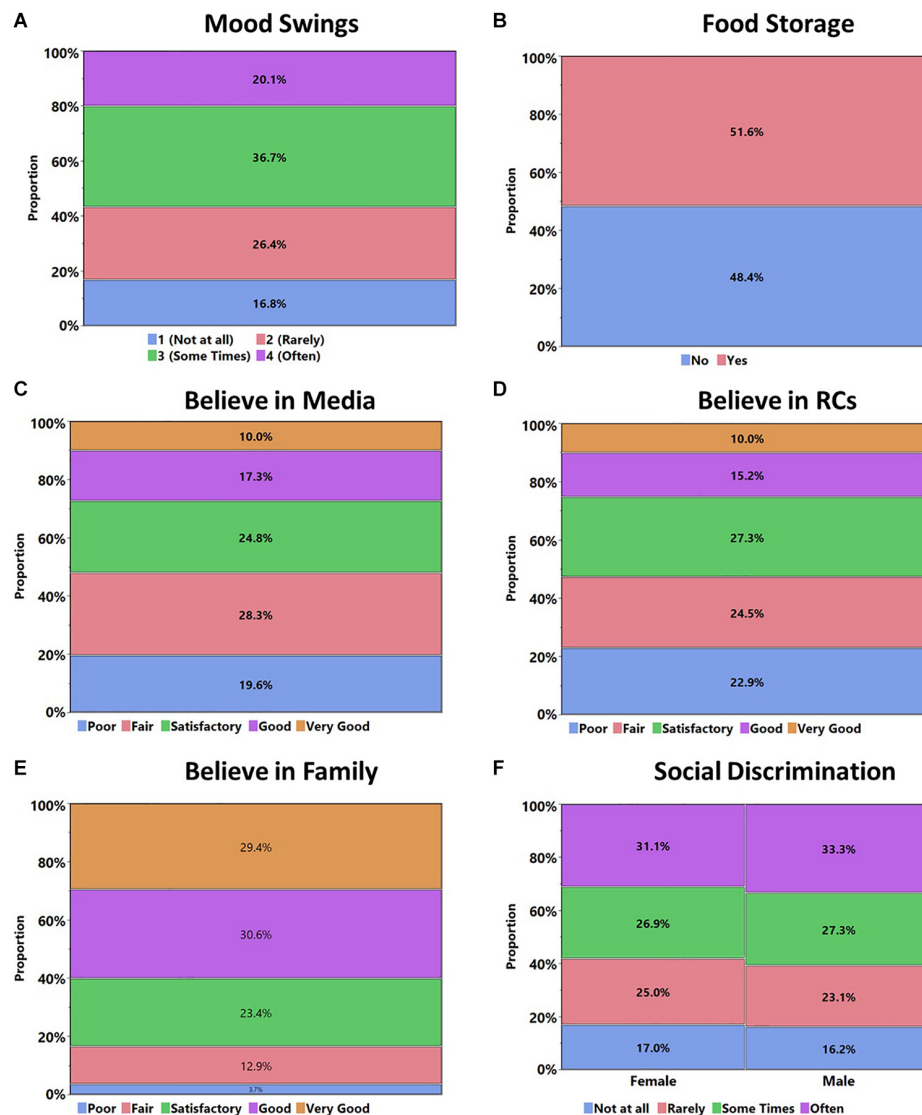

Similar to many other countries, the government of Pakistan has restricted gatherings, and staying at home is advised to reduce the human interactions during this pandemic. The country is experiencing a lockdown situation from the last 4 weeks. Therefore, the respondents are also asked whether they have stored food due to lockdown or not. In addition, respondents are asked whether they think the relief package of PKR 12,000 by the federal government is sufficient or not. It is noted that the responses to these questions are dichotomous.

We use the questionnaire-based cross-sectional survey across Pakistan to evaluate the psychological response during this pandemic of COVID-19, if any. Assuring the safety of respondents and keeping the paradigm in mind, the best possible way in this current situation is the online surveying approach to collect the data (Wang et al., 2020). Using a snowball sampling strategy, an anonymous online questionnaire is floated among individuals. It is initially floated among the residents of Islamabad Capital Territory (ICT), Pakistan, including working professionals and students. They were further encouraged to pass it on to others. In addition to this, we approach people residing in all the provinces in Pakistan, electronically, and ask them to float the questionnaire further so that we can cover a wider area. The data are collected during the last week of March and first week of April 2020, and we receive 560 responses in total. After data cleaning for incomplete responses and randomly selecting a balanced mix of male and female respondents, we are left with 428 responses, which are used in further analysis. Simple random sample may lead to a sample that does not truly reflect the population makeup. The sample may over- or underrepresent a demographic such as gender. Stratified techniques are used to overcome this problem. According to this technique, pools according to categories are formed from which the subsample is randomly selected to better represent the population (Pérez Salamero González et al., 2016). It is important to note that our sample of 428 observations is enough for generalization with a 5% margin of error at 95% confidence as per the sample size calculation criteria discussed in Krejcie and Morgan (1970). Hence, we are confident to say that the survey data are stable, and it is appropriate to use the data for further analyses procedures (DeVellis, 1991; Wu et al., 2020).

To analyze the association between different COVID-19-related outcomes (i.e., stress, trust, belief, fear of job loss, and life satisfaction) with potential explanatory factors (**Table 1**), we use the multivariate logistic regression because the dependent variables in our analysis are categorical. The general equation is as follows:

$$\theta(Y = k|X = x_{mi}) = \text{logit}\delta(x) = \ln \left[ \frac{\delta(x)}{1 - \delta(x)} \right] = \beta_{0k} + \beta_{1k}x_{1i} + \beta_{2k}x_{2i} + \beta_{3k}x_{3i} + \dots + \beta_{nk}x_{ni}$$

where “Y” is a vector for dependant variable having k outcomes, and “X” is a vector for independent variables. The number of observations is given by “i,” and “m” denotes the number of independent variables. The detail on independent and dependent variables is provided in **Table 1**. We have only reported significant variables in the results from the models, whereas, for the rest of the variables in the model, please refer to **Table 1**. The Benjamini–Hochberg procedure (Thissen et al., 2002) has been used to get the adjusted *p*-values to reduce the chance of false positive results (type 1 error). The omitted variable test has also been used to check the omitted variable bias and model misspecification following Papke and Wooldridge (1996). The insignificant *p*-value shows that the model is correctly specified. In addition, while using the logistic regression, the test of parallel line assumptions has also been carried out. The significant test

**FIGURE 1 |** Frequency distribution of key indicators of respondents.

shows that the assumption of parallel lines for the usage of ordinal analysis has been violated. In addition, the model fit has further been carried out. In this study, we use JMP Pro. Software, a comprehensive suite of computer programs for statistical analysis from the SAS Institute, United States of America<sup>1</sup>.

## RESULTS

Pakistan has a relatively young population, which is also reflected from the responses as the mean age of the respondents is 25 years ranging between 18 and 55 years. The descriptive analysis shows that around 77% of the respondents are single and the rest are married. In the context of the working population, we observe

that 32% of the respondents are currently working and 48% hold a graduation degree in the sample ( $n = 428$ ). The overall respondents are widespread across the country belonging to 50 distinct districts. Most of the respondents (89.5%) are living with family, which might be due to strong family bonding and the concept of social insurance in Pakistan. Besides, we observe that ~55% of respondents are having a household size of three to six people, and ~35% of respondents have more than six people, reflecting a relatively higher household size in Pakistan. In general, the education of respondents' fathers is higher than their mothers (**Figure 2**). For example, the proportion of "undermatriculation"—the lowest level of education in the survey—for mothers is ~31% as compared to 14% for fathers. Similarly, the proportion of "postgraduation and above" for fathers is higher than that for mothers (~25 and ~14%, respectively). Therefore, it becomes interesting to

Father's education	✓	✓	✓	✓	✓	X

**FIGURE 2** | Frequency distribution of parental education of respondents.

explore the role of parents' education in developing stress-related outcomes, especially when people are spending a lot of time with their families under the lockdown situation. From the life satisfaction perspective, it is even more compelling to document the role of parental education in "overall life satisfaction." In short, we compile a diverse group of respondents of different ages, living in distinct areas, with different household size, and having different family backgrounds.

### Socioeconomic Factors

It is observed that ~51% of the respondents have stored food during this lockdown (Figure 1B). Most of those respondents have a family size of four to six people (56%) and more than six household sizes (45%). This seems legitimate that respondents with larger household sizes tend to store food during emergencies such as COVID-19, as the duration of the current lockdown is not clear at the moment. More than 50% of the respondents said that quarantine, staying at home, and social distancing

have affected their lives to some extent. In addition, ~70% think that working from home has not increased their workload. Respondents are also asked which challenge Pakistan is facing currently. Around 61% of respondents think that COVID-19 is the biggest challenge right now. On the other hand, 32% consider the economic crisis as the biggest challenge. Respondents were also asked about the existence of pandemic response policy. Around 37% of people think that Pakistan has a pandemic response policy, which, in fact, does not exist. This represents a false public perception toward government measures to deal with current and future pandemics such as COVID-19, which could potentially lead to ineffective/non-serious precautions to tackle the pandemics. Among those who think that Pakistan has a pandemic response policy, ~50% are graduates. The proportion of the respondents who think the response policy exists is larger for female (41%) than for male respondents (33%). Similarly, a reasonable proportion of the respondents (~32%) think that if they tested positive for COVID-19, they will face social

discrimination often. Among these respondents, the proportion of male is slightly larger than the female respondents, ~33% as compared to ~31%, respectively (Figure 1F). A major reason behind this larger male proportion might be that men in Pakistan have more leverage to go outside as compared to women.

## COVID-19-Related Stress

Stress is the most evident outcome of any outbreak (Al-Rabiaah et al., 2020; Wang et al., 2020). Stylized facts from this study reveal that approximately 38% of the respondents are stressed “sometimes,” and 22% of them are stressed “often” in the context of lockdown related to COVID-19 (Figure 3). As mentioned earlier, Pakistan is under lockdown situation from the last 4 weeks with a clear government advisory to stay at home and avoid all sorts of gatherings. In this regard, we evaluate the association of stress with the age of the respondent, parental education, household size, and mood swings. The results show that stress is being affected by age, parent’s education, and mood swings due to the lockdown (Table 2). It is noted that the results are only presented for the statistically significant factors at a 95% confidence level. If the respondent is not having mood swings at all, he/she has a higher probability that he/she might not experience stress at all. Therefore, a demonstration of mood swings might have become a source of elaboration of stress, and similarly, having mood swings “often” increases the odds of experiencing stress “often.” Likewise, experiencing mood swings “rarely” increases the odds of having stress “rarely.” It is evident from the results that if the mother has secondary school certification (matriculation) as compared to intermediate, then they have higher odds of having “no stress due to lockdown at all.” But if the mothers of respondents are “postgraduate or above” as compared to “intermediate,” then they have lower odds of having stress “rarely.” This situation indicates that the respondents having highly educated mothers have higher odds of having stress “often.” Highly educated mothers can sense the severity of the situation and unintentionally transfer it to children, which might result in higher stress. Furthermore, if the overall life satisfaction is “good” and “satisfactory,” the respondents have higher odds of relatively less stress (i.e., odds of having stress “rarely” and “sometimes” are higher as compared to “often” simultaneously). This result is self-explanatory that if life satisfaction is high, then the probability of having stress “often” is low.

## Belief in Response to COVID-19

### Belief in Family

Belief is measured on a scale of “poor,” “fair,” “satisfactory,” “good,” and “very good.” The results show that the respondent’s age along with parent’s education are significant factors to affect the respondents belief in response to COVID-19 outbreak by his/her family (Table 3). We further find that increasing age or elderly people have lesser odds of having “poor” belief in the family’s response to COVID-19 as compared to “very good.” If the respondent’s fathers have “postgraduation or above” education as compared to intermediate, they have lower odds of having “fair” belief in the family as compared to “very good.” On the contrary, if mothers have “postgraduation or above” education as compared to intermediate, they have

lower odds of having “satisfactory” belief in the family as compared to “very good.” In short, the respondents with highly educated parents have a strong belief that their family has responded well to COVID-19 outbreak. Conclusively, elderly people and respondents whose parents have “postgraduation or above” have a higher belief in the family’s response to COVID-19.

### Belief in Media

The odds of female respondents are lower for having “poor” belief as compared to “very good.” It implies that female respondents have a higher belief in the media’s response as compared to male respondents (Table 4). This brings an interesting insight regarding the female individual’s reliability over media for the response to COVID-19. Thereafter, we document that elderly people also have lower belief in the media’s “poor” response in the context of COVID-19 as compared to “very good.” This implies that they are satisfied with the media’s reporting and role in making people aware of COVID-19 situations, or in other words, they believe that media somehow fulfilled their responsibility toward COVID-19 communication. If the mother’s education is “under matriculation” (secondary school certification), the odds are higher for having “poor” belief in media. The same trend follows for “fair” belief. Whereas, if the mother’s education is “postgraduation or above” as compared to “intermediate,” then the odds of having “fair” belief as compared to “good” are lower. The respondents having highly educated mothers have a higher probability of having a “very good” belief in the media’s response to this current pandemic. Therefore, we observe the acceptance of media with higher attainment of mothers’ education. Additionally, the media’s role is questionable as well; one can argue the inability of media to form a better opinion among the mothers with lower educational attainment.

### Belief in Religious Clerics

Our results show that as one grows older, the odds increase for having “fair” and “satisfactory” belief in religious clerics as compared to odds of “very good” (Table 5). Similarly, the

respondents whose mother’s education is “postgraduation or above” have higher odds of having “fair” and “good” belief than “very good.” Thus, the belief in religious clerics for their response to the pandemic is significantly influenced by the age of the respondents and their mother’s education (95%

confidence). Respondents having highly educated mothers and elderly have lesser belief in religious clerics. This is interesting to observe that the odds of having higher belief in religious clerics are linked with mother’s education instead of that with the father in Pakistan. This is due to the fact that mothers

usually spend more time with the family, and educated mothers are more likely to educate their children at an early age about religion and importance of different stakeholders. On the other hand, majority of the fathers remain engaged in the labor market or daily life routines out of their homes. Therefore, they usually have less time to spend with the family to discuss the importance or the role of religious clerics during such pandemics. In the past, Pakistan has experienced SARS,

MERS, H1N1 flu, and dengue (Khan et al., 2008; Hakim et al., 2011; Aamir et al., 2012; Saqib et al., 2017). In the history of Pakistan, religious clerics have not been active in case of any endemic and have not played a pivotal role in spreading awareness about the outbreaks of different diseases or taking any necessary measure. This might have led to a situation where the educated group has lesser belief in religious clerics.

## Fear of Losing Job in Response to COVID-19

The results show that the working female respondents (81%) have no fear of losing job. Among those who are working, the respondents with higher education [i.e., graduates (38%) and postgraduates (50%)] have no fear of losing job. Since our reference category in this case is “Yes,” the respondents whose father’s education is “matriculation” as compared to “intermediate” have lower odds of “no of fear of losing job” (Table 6). In contrary, we observe that the respondents whose father’s education is “graduation” as compared to “intermediate” have higher odds of “no fear of losing job.” This signifies that the role of a father’s education cannot be undermined in terms of psychological consequences during such pandemics.

Our findings ascertained that people with lower educational attainment are more susceptible to this economic insecurity as a consequence of COVID-19 that they will be laid off, whereas we do not observe such estimates for women or people with higher educational attainment. It is noted that the model used for fear is simple logistic instead of the multivariate logistic model due to the nature of responses.

## COVID-19 and the Public Perception Toward the Life Satisfaction

Human life satisfaction is a broad concept representing how well people meet their emotional, environmental, spiritual, social, physical, and economic needs. It also includes individuals’ own judgment about their own life and society (Levy and Guttman,

**TABLE 6** | Logistic-regression-based results for fear of losing job due to COVID-19-induced lockdown/quarantine.

1975; Levy and Sabbagh, 2008; Jowell and Eva, 2009). The results from the descriptive analysis show that around 38% of the respondents remain neutral about their life satisfaction. Around 57% of male and 43% of female respondents are satisfied with their life during this pandemic. Among those people who have responded “very satisfied” even in this pandemic, 37% have postgraduate education. Thus, the perception about the life satisfaction of female and highly educated individuals even in this pandemic seems not to be much influenced. Higher educational attainment is linked with higher premium or security for long-term success in the labor market. This might be the potential reason that a larger proportion of people with higher education is satisfied even during this emergency.

**Table 7** shows that female, as compared to male, respondents have higher odds of having “not satisfied life” in this pandemic as compared to “very satisfied life.” If people have no fear of losing job, the odds of “not at all satisfied” are lower as compared to “very satisfied.” “No fear of losing job” has lower odds of being “not at all satisfied” and “little satisfied” as compared to “very satisfied” with life. In Pakistan, the job market is not precipitating except for low-/daily wage workers. That is why having fear of losing job has not influenced the perception of individuals about life satisfaction. Additionally, the respondents have higher odds of “satisfied” as compared to “very satisfied” when they have no food storage. In Pakistan, people are hoarding food, and thus, having food storage might increase the satisfaction level and assure life sustainability.

## CONCLUSION

In connection to WHO’s considerations about the psychological impacts of COVID-19 pandemic, this study is considered an initial effort to provide a thorough evaluation of the possible impacts of COVID-19-induced lockdown on public psychology—in Pakistan. For this purpose, an online survey is conducted, with a 5% margin of error (95% confidence), and several statistical approaches are employed to analyze different factors and to establish on how people might have been psychologically affected by the current COVID-19-induced isolation. Based on the initial results presented here, it can be argued that the outbreak has posttraumatic effects on public psychology. The results show that parental education is a significant factor associated with the stress level among the respondents during this quarantine situation. Respondents of older age and having parents with higher education have a higher belief in their family during COVID-19 outbreak. People have a lesser belief in “response by religious clerics.” Highly educated people have a high probability of having no fear of losing job. Women have a higher probability of less satisfaction with their life during this pandemic. This outbreak has affected the life satisfaction of society and caused stress.

This study indicates that the role of parental education during such pandemics cannot be undermined especially the role of father’s education. Therefore, the policy-making institutions must focus on spending more on the current generations’

education to cope with such challenges in the future. This will further remove the economic insecurity in the people of Pakistan, as we document higher odds in fear of losing jobs among less-educated people. Moreover, higher education, less fear of losing jobs, and no stress will contribute positively toward the life satisfaction in the people, which is ideal not only to have a happy population but also to have highly productive labor. Lastly, Pakistan is a religious country where religious clerics are the stakeholder in every major decision making. Thus, the government must mobilize all the resources to convince religious clerics to take up the responsibility and contribute more in terms of educating people regarding such psychological consequences in the wake of pandemics such as COVID-19.

The governments need to focus on the mental health of societies, as they might get more stressed with prolonged lockdown situation, carrying minimal out-of-house activity, and having “fear of losing job” (e.g., among the less educated such as daily wagers). To cope with this situation, counselors and psychologists can also play an important role through providing their voluntary services for the life satisfaction of society during this pressing time of global emergency. The study is important in the context of psychological interventions to improve future pandemic response in a more resilient way.

The authors do acknowledge the intrinsic limitations of the current study at this point. First of all, due to the lockdown situation, we had to rely on the online surveying approach, which might have some issues (i.e., inability to reach challenging population such as elderly population and people with no educational background). However, online surveys are a robust and cost-effective means to systematically gather the data from a wider range of audiences. It not only increases the response rate but also saves time, which is a critical aspect of the current situation. A further in-person survey or mix-method approach can be used to survey the same questions once the lockdown is over to check the sensitivity of the online survey, if any. Furthermore, we do not, particularly, emphasize the socioeconomic conditions of the respondents, which could help in evaluating the correlation of outcomes to tailor necessary interventions. Lastly, although the global time period for COVID-19 is roughly 4 months, the pandemic surged in Pakistan in March 2020. This implies that the study is performed in an early outbreak situation and is only focused on Pakistan. Follow-up large-scale studies could progressively help to assess progression of psychological manifestations. However, this might have to wait until the imminent threat of COVID-19 subsides.

Infectious disease pandemics are associated with social consequences and stigma that are noticeably similar in various health conditions, health systems, and cultures. Stigma impacts health-related outcomes, not only as a barrier to receiving the timely diagnosis and appropriate treatment but also as an important variable that increases mental health issues such as anxiety and depression. The COVID-19 outbreak has been associated with stigma too. Studying similarities as well as differences in the features of stigma observed in each outbreak can provide us with the knowledge and deeper understanding of the situation, which is necessary for approaching the issue comprehensively. The stigma needs to be addressed rigorously by professionals and health care providers as well as authorities. Here, we narratively review stigma due to some well-known infectious diseases and how it parallels to the current COVID-19 situation. After discussing its effects on both individuals and societies, we provide solutions to manage this important issue.

**Keywords:** corona virus disease (COVID-19), stigma & discrimination, health consequence, pandemics, mental health, public health

## INTRODUCTION

The Covid-19 pandemic is progressively known as a social problem rather than just an infectious disease. There are diseases that not only burden the medical system but also by provoking social stigma, lay an increased tension on each individual. Contagious diseases such as acquired immunodeficiency syndrome (AIDS), Ebola, some types of severe Influenza such as H1N1 and COVID-19 are among those (1–3). They seem to be mysterious due to a lack of sufficient knowledge about them and being lethal (4, 5). Nowadays, many people suffering from COVID-19 are challenged doubly, both by the disease and by the stigma associated with it.

Stigma has been defined as an identifying mark of disgrace or one defining characteristic that is related to a particular context, quality, or person. It is a deleterious label that makes the stigmatized person or group feel secluded from mainstream society (6, 7). Labeling can further develop into pigeonholing and stereotype formation, therefore leading to discrimination and status loss (8). In the case of stigma related to infectious diseases, stigmatization, blaming others, and discrimination are exacerbated by fear of illness. It is not always done consciously and might serve several means.

Firstly, in the face of an unfamiliar or intolerable adverse situation (here, lack of knowledge about the source of infection and protective measures) or an unknown hazard (insufficient scientific understanding about the infection source), stigmatization can temporarily bring feelings of security even if it is not a real or a permanent one. This is done by distancing from the source of the threat (here infected people), through dividing people into “them” and “us.” The underlying thought is: we are not them, we do not possess the same risk factors, so we are not in danger (1). Individuals may be the victims of persistent discriminatory behavior and prejudice in such situations. Secondly, attributing a familiar cause—even if it is not a real or relevant one—changes an unknown situation to a more recognized one. Finding a culprit for a disease changes a mysterious and scary disease into a more tangible and controllable one. The anger caused by the disease can be directed toward the attributed source and by reducing the feeling of responsibility for spreading the disease, it can temporarily reduce anxiety. In the case of infectious disease outbreaks, scapegoating and projecting negative emotions onto a group of people, attributing the cause of their illness to their irresponsibility or their poor morals or even their prior health conditions are some examples (1, 4, 5).

Stigma has several features. Self-stigma happens when the stigma is internalized, so it affects attitudes, emotions, and even beliefs of individuals and forms the behavior of the people who are stigmatized (9). Internalized stigma can induce the feeling of inferiority and rage turned inward (10). Stigma interferes with the process of diagnosis and treatment by disrupting social communication, individual identity, and the sense of free will (11). People who feel stigmatized are susceptible to avoiding certain behaviors that they feel might increase stigma; in the case of COVID-19 that can be getting tested, because a positive test can be the label they consider stigmatizing. Consequently, by preventing social adjustment and healthy adaptive behaviors, stigmatization can exacerbate physical health problems (10). People who have internalized stigma, are less likely to follow health guidelines provided to control infections (e.g., wearing face covering, keeping distance from others and not mixing with other households), have less tendency to undergo diagnostic tests or comply with test-and-trace systems, and even are reluctant to receive necessary treatments (11, 12). Stigma, therefore, can be a barrier to effective prevention and control mechanisms and can affect, not only the stigmatized group, but also a wide range of people, including patients, families, friends, and the whole community.

Perceived stigma is another important facet of stigma; that is, how much people expect stigma from society and even health care providers. In most infectious diseases, perceived stigma is high and is associated with health-related outcomes (13, 14). Even the decision of whether to seek help from traditional healers or the conventional health care system is related to perceived stigma (15, 16). Literature suggests that in many cultures such as Africans and Asians, stigma is associated with approaching traditional healers as a first step (16, 17). This will further complicate the situation by delaying accurate diagnosis and treatment. Perceived stigma not only discourages infected

individuals from accessing needed health care services (18) but it also affects health care professionals themselves (3, 19). In the case of COVID-19, for instance, stigma has highly influenced health care workers' performance by increasing fatigue, burnout, and decreasing satisfaction. Perceived stigma and discrimination also affect health care providers' sense of self-efficacy, and increase psychological distress and somatic symptoms (3).

Although there are arguments suggesting that the stigma related to the disease might have some evolutionary functions, that is, avoiding the source of infection, and staying safe by distancing from people who are infected with the disease (20), the costs of stigmatization almost always outweigh the hypothetical benefits (1, 10). There seems to be a delicate line separating stigmatization from necessary infection prevention measures that encourage social distancing and avoiding the source of contamination. Avoiding the source of hazard prudently can reduce the hazard but stigmatization has a component of moral judgment about an individual, a group of people, or a place (21). People and infection must not get conflated. Avoiding the source of infection and disease must clearly get distinguished from the whole character of an individual, their ethnicity, cultural, religious and socioeconomic background, and place of living; otherwise, the consequences can be serious as will be discussed below.

Stigma is a pressing issue and its consequences are noticeably similar in various health conditions, health systems, and cultures (22, 23). Here, we evaluate stigma related to some well-known infectious diseases and how it parallels to the current COVID-19 situation. Then, we review its effects on both individuals and societies and how disease-related fear and impulsive measures can be generalized and projected to irrelevant features such as ethnic background or the place of living. Consequences of stigma on public health and individuals' life as well as some solutions are provided.

## STIGMA IN PREVIOUS EPIDEMICS AND PANDEMICS

Throughout history, human beings have been exposed to dangerous diseases that have forced them to modify their behavior to adapt to new conditions. The WHO has defined a pandemic as “a worldwide spread of a new disease” (24). From the 19th century's smallpox to the 21st century's COVID-19, epidemics and pandemics have always been associated with stigma and severe social consequences (25–27). Dealing with several outbreaks delivers a wealth of knowledge on what the consequences of stigmatization are in society and how to deal with them effectively. Despite similarities, each infectious disease outbreak, such as plague, tuberculosis, syphilis, HIV, and hepatitis have represented different features of stigma that should be addressed to plan preventing or eliminating stigma measures scientifically (1, 10, 28). These differences could explain why we struggle with stigma so much, even though we have been through pandemics before.

Stigma exists in a variety of cultures and its consequences are markedly parallel in various health conditions, health systems,

and cultures (22). In almost all pandemics, minorities [whether due to ethnicity (5), sexual orientation (11), gender identity (29), or place of living (2)] are at the highest risk of stigmatization. Both fears of exposure to illness and fear of dissimilarity (here people who we think are different) result in stigma (2, 21, 30). In all outbreaks, insufficient knowledge about the prognosis and outcomes, how long it could take until a cure is found and no availability of an effective treatment option or vaccine for prevention, are the main sources of fear (26). There are, however, differences in the features of stigmatization in each pandemic that can color our understanding of stigma. These differences present important areas of investigation and can be categorized as below:

### Risk Appraisal

The difference in estimated risk and related response is related to stigma (21, 23). Even when estimated risk is low, stigmatization happens. There are, for example, several reports of Americans stigmatizing Africans and their neighborhoods during the Ebola outbreak in West Africa despite the risk to Americans being declared low (2, 21). Sending conflicting messages from media has been suggested to play a role in this (21). In the Covid-19 pandemic, the risk is high for almost all countries. This can increase fear which can result in increased stigmatization toward people who are assumed to be infected. By distortions of hazard appraisal, social stigma can lead to anxiety and panic in society and can even affect the distribution of resources by authorities (23, 31). For example, government regulated distribution of personal protective equipment (PPE) as well as its shortages gave high levels of conflict and uncertainty as hospitals were prioritized whereas people working in care homes had to work under close contact with those affected but without proper PPE available to them.

### Transmission Way

Respiratory viruses are more contagious than other well-known stigmatizing diseases and there is less control on its spreading; therefore, the social reactions can be dissimilar. Fear of a global pandemic combined with scenarios of economic breakdowns and shortages can exacerbate fear driven reactions along with stigma in these cases (5, 19, 23).

### Lethality

Lethality of a disease is one of the factors that causes stigmatization. On the other hand, most of these viruses are less lethal than some sexually transmitted diseases (STDs) such as HIV. The contagion of Covid-19 is much higher, which introduces new challenges. In the case of COVID-19, people opposing the measures to stop the rate of infection state that COVID-19 is about as lethal as the flu. However, with COVID-19 being much more contagious, death rates soar if nothing is being done.

### Difference in the Population Who Are at Risk

Prejudice and established social norms are associated with stigma (1, 4). For example, in STDs such as HIV, homosexual men have been (and continue to be although to a lesser

extent) stigmatized, which contributed to less funding on research and delaying treatment in the 1980s (1, 30). In respiratory viruses such as MERS and Covid-19, the main at-risk groups are the elderly, people with immune deficiencies, and individuals suffering from cardiopulmonary illnesses (19). These groups often face different forms of stigma that will be discussed later.

## RISK FACTORS AND VULNERABLE GROUPS

### Ethnic Background and Place of Living

Established social hierarchies and some biases in attitudes regarding ethnic minorities and immigrants predispose them to risk of stigmatization (2, 4, 5). Phenotypic features such as the color of the skin and even the accent of speech can be a source of stigmatization (2). When an association of the disease takes place with a particular ethnic background or even a place of living or origin, it might shape a metonymy that completely associates the disease with that particular group or place. For instance, in the nineteenth century, after several smallpox epidemics in Chinatown in San Francisco, the metonymy of the infection and the region took place (25). This association caused severe racialism and xenophobia during that period. During H1N1 epidemics in the US, the Mexicans and immigrants from South America were considered the main population that contributed to spreading the disease and therefore faced severe stigma (5). Currently, as COVID-19 started in Wuhan, associating it with the originating place (China) resulted in labels such as “Chinese Virus” or “Wu Flu.” One study found that there has been a prominent rise in application of the terms “Chinese virus” or “China virus” on Twitter in the USA (32). This goes strongly against the recommendations of the World Health Organization (WHO), who recommends avoiding the use of geographic locations for naming a disease as a practical way to minimize its unnecessary negative impact. Reports of people with Asian phenotype who have been victims of racist attacks on several occasions is proof of stigma and discrimination that could have been avoided (32, 33). Naming diseases such as “swine influenza” and Middle Eastern Respiratory Syndrome (MERS) has been harmful due to generating stigma and affecting societies, tourism, industries, and economics (34).

Ethnic minorities often get affected disproportionately in pandemics such as COVID-19 (35, 36). They might be at greater risk of infection due to several socioeconomic factors and inequalities in access to health care; where and in what circumstances they live, their access to good nutrition and legitimate information, their job situation that may necessitate social contact or increase potential exposure, as well as lack of paid sick leave and having hourly jobs. However, increased discrimination against them in almost every pandemic has been documented (1, 5, 25). In the US, Blacks, Asians, and minorities (BAME individuals) have been seriously affected by COVID-19 and experience a disproportionate number of deaths. Along with previously mentioned reasons, stigma, discrimination, and health disparities have been suggested to play a crucial role (36, 37).

## Double Stigma

People who have experienced stigma (whether due to a chronic health condition or other factors such as their sexual orientation or aging) are at the risk of experiencing double stigma (38, 39). In many countries, COVID-19 was first introduced as a disease that mainly affects the elderly or people with chronic health conditions. This was intended to prevent the panic that an epidemic might cause in the society but it backfired as emphasizing it on many occasions caused severe distress in the mentioned groups (11, 13). Here we see the subtle line between providing accurate and scientific information and overemphasizing that leads to misguidance and feelings of insecurity in society. Persistently opposing the “general public” to “at-risk group” carries out the message of “in-group” vs. “out-group” that contributes to stigma formation (11). Stigma makes vulnerable people more susceptible, as altering unhealthy behavior becomes even more challenging; it can also shift an extra burden toward them while directly affecting their mental health (26).

Aging has been associated with stigma and stereotypes in several cultures (40, 41). In many western countries, attitudes toward older adults are predominantly negative (42). The stigmatizing perspective is mostly related to being weak or non-productive in a society that overvalues being young, healthy, and productive (40, 42). The elderly are at risk of emotional distress by the messages they get from society. Self-Image, perceptions, and beliefs are strong moderators for age-related stigmatization and emotional consequences such as depression (43). It can even affect their social and cognitive capacity to respond to a new stressor. Evidence suggests that exacerbation of social isolation can be a consequence of overlapping previous stigma with a new one (38). In this case, previous stigma and social exclusion related to aging intersect the stigma related to COVID-19 infection. The elderly’s reactions are highly influenced by the created social atmosphere (40), which in the case of COVID-19, has caused further isolation. Also, deficiencies in health care policies for older adults, especially in terms of mental health, have been a source of stigma (40, 44). The same cycle of misleading information, lack of support, and isolation happens here in the face of the COVID-19 outbreak. On the other side, young people seem to avoid social distancing or staying at home, as a way of denying their vulnerability and being at risk (45) and as a mechanism of putting the elderly in the “them” group who are at risk, while categorizing themselves in the “us” group that is strong and not at risk.

## Quarantine and Physical Distancing

Health experts believe that currently, the most effective way to control COVID-19 is to quarantine or maintain physical distance. How to effectively exercise these measures, however, is controversial. Even applying the term “Physical distancing” or “Social distancing” seems to be controversial, as the former refers to keeping a two-meter distance “physically” apart from others while maintaining the necessary social interactions via different methods such as using social media. The latter, however, might induce a sense of social isolation in the long term (46). Although some degree of physical distancing seems to be necessary, related

isolation can lead to stigmatization and can be quite misleading. Quarantine and social isolation are often associated with poorer mental health outcomes and increased stigma (47, 48).

When, how long, to what extent, and who should be quarantined are critical questions that should be answered carefully and precisely. We mention here an extreme case of applying quarantine probably not based on scientific measures but as a measure of racial subjugation. During the plague pandemic in South Africa in 1901, evacuation of a whole ethnic group with forced arms took place without any evidence of exposure or scientific background (49). This is an example in which acting proactively against an infectious source blurred with preexisting racial disparities which resulted in an ethnically violent intervention. This is a lesson on the importance of applying careful consideration to recognizing which act is purely scientific and which one is influenced by preexisting social structures that can originate from or contribute to stigma.

## CONSEQUENCES OF STIGMA

### Fear and Social Disruption

Lessons from previous pandemics such as HIV show us that fear of being stigmatized, along with misbeliefs about the disease, can be a barrier in seeking and receiving treatment (1, 25). There is a report about patients suspected to be infected by COVID-19 escaping from a hospital in Afghanistan. “Why the individuals left the medical facility was not immediately clear, but videos on social media suggested they were at odds with the hospital over their treatment.” (36–38, 46, 50). The blaming model of stigma proposes that people use several defense mechanisms to reduce the tension and anxiety related to the stigma of the disease, which includes either mature forms such as altruism and humor or immature ones such as denial and splitting (51, 52). Although assessing all sociocultural aspects of this multifaceted phenomenon is beyond the scope of this discussion, miscommunication, fear of social stigma, and defense mechanisms such as denial are playing an overt part.

This is not the first time that fear has overridden the risk of the disease. Back in 1901, in the US, during an epidemic of smallpox, several Italian immigrants destroyed a hospital that was built in their neighborhood for isolating people with smallpox. The social reactions were diverse but many newspapers called them “mob, unfit for autonomous governance” (53). Jumping to a conclusion and inferring the cause of the reaction to the nationality, ethnic background, literacy, and other immediate factors might be easy to reduce immediate tension but, is not an efficient and organized response. Such labeling obfuscates the real reasons; that is why and how people consider some medical services, such as quarantine and physical distancing, threatening situations, and act against them. Condemning citizens and showing in the media that people are acting irresponsibly and are not capable of a rational reaction to the threat seems to be useless and can exacerbate the tension (53). One reason for people’s enactments might be that the emergency and extensiveness of the situation often hamper the effective communications of policymakers and health care professionals with general population. In these times, clarity, along with reassurance and communicating scientific

information in simple words, is crucial. Both confusion and misunderstandings, and the presentation of “false science” by sources deemed to be thrust worthy, are breeding grounds of stigma as they evoke stereotypes, discriminatory behaviors, and prejudice. On the other hand, the impact of cultural beliefs and socially accepted norms cannot be overestimated (17, 54). Some cultural or traditional perspectives are skeptical of science and modern medicine. Even an untrusting government can play a role. Interpreting complex social responses like these is not easy and goes beyond the scope of this article, but it is worth mentioning that scapegoating, labeling, and stigmatizing can further complicate the situation.

## Health Outcomes

Experiencing different levels of emotional distress is indisputable in general populations, and this is further increased in affected patients, their caretakers, their family members, as well as the medical staff (55). The health consequences of stigma, however, go far beyond these senses. Stigma worsens physical and mental health outcomes. Stigma related to HIV, for instance, is associated with depression, anxiety, emotional and mental distress, and reduced quality of life. It also decreases the rate of adherence to treatment and access to medical facilities (12, 56). The fear of getting stigmatized causes people to avoid getting diagnostic tests (10, 56) and to reduce compliance with self-isolation rules and guidelines. Lack of accurate information, fear of judgment, and being discriminated against can lead to subconscious denial, therefore preventing being tested and refusing preventive strategies and treatment. Although increasing knowledge is a crucial measure, it is not enough for behavior alteration (11).

The stigmatized population is distrustful of the health care staff or authorities and resists cooperation in the event of a social health emergency. Stigma leads to a social misunderstanding of risk and extreme fear amongst members of society; that is accompanied by the disproportionate allocation of health care resources by politicians and health professionals (23). During the COVID-19 pandemic, long periods of quarantine, fear of illness, despair, fatigue, lack of life and personal protective equipment, insufficient and inconsistent information, financial issues, loss of loved ones, and stigma have been identified as factors which have influenced each other and are related to health outcomes (5).

Health care providers, on the other hand, are at a great risk of being stigmatized (55, 57). There are reports from around the world that doctors and other health care providers have been isolated from loved ones because of anticipated risk of contamination and assaulted physically or emotionally due to fear and stigmatization (55). This makes this already tough situation even more challenging as the increased burden on medical staff's mental health may negatively affect their functioning and resilience (3).

Anticipating the stigma related to COVID-19 health outcomes is essential to planning protective measures and affects both patients and health care providers. Stigma should be addressed rigorously as it can complicate and worsen the outcome, which necessitates careful planning and considerations and postulates more in-depth studies in this area.

## WHAT NEEDS TO BE DONE?

Factors that cause stigma can be divided into three categories: predisposing (facilitators), precipitating (triggers), and perpetuating factors. Factors such as social structures and policies can increase stigma both as a predisposing and perpetuating factor, and require long-term planning. Factors such as insufficient information or contradictory messaging are precipitating factors and can be managed with immediate strategies that will be discussed here.

Predicting stigma related consequences of COVID-19 is essential in planning protective measures. Experiencing different levels of emotional distress is indisputable in general populations and is further increased in affected people. Patients' isolation and quarantine are effective measures, but they can increase stigma and severely impact on mental health and the economy. Isolation, loss of jobs, and financial burden, among other factors, can increase the risk of depression, especially in at-risk populations (47, 48, 58). Active screening and intervention, either through telephone, online communication such as video calling, or in-person, is essential in these situations.

To approach Covid-19 related stigma, one of the most important steps is to call it out. Lessons learned from HIV related stigma show that launching and supporting anti stigmatizing campaigns, adapting unifying symbols, and encouraging community activities are effective measures (1). The most famous symbol noticeable all around the world is the red ribbon, which is a symbol of HIV/AIDS awareness, care, empathy, and support. These measure also should include all people and how protective measures can adopt to the needs of people with especial needs. For instance, sunflower lanyard (hidden disabilities lanyard), prevents people who aren't able to wear face coverings from being isolated and stigmatized as not being compliant with the rules or designing lucent masks for people with hearing difficulties.

## Communication of Science

*“Despite the great discoveries and advances of science and medicine, primitive reactions to being confronted with disease continue to divide people and communities into ‘them’ and ‘us’”.*

Writes Gilmore in an article on HIV and stigma in 1994 (1). After almost 25 years, however, this is still the case. Although every literature on stigma suggests avoiding language and metaphors that polarize society, often the first reactions of authorities, hastily, is full of stigmatizing language.

The choice of language and metaphors is critical in de-stigmatizing efforts (1, 46, 59). It directs individuals and communities' reactions to obscure situations such as pandemics. Lessons learned from managing stigma in different infectious disease outbreaks suggest that military metaphors, such as fighting or combating COVID-19, can increase tension by inducing that there is an enemy in the society which everyone should fight (1, 60, 61). These metaphors even have been associated with self-willed death, such as suicidal ideations or requesting euthanasia in more chronic infections such as HIV (1).

Messaging seems to be the key. Conflicting messages from authorities, as well as misleading information from media, lead to fear and stigma (60). Pandemics provoke panic and anxiety due to their association with death and lack of certainty about the future. Encouraging empathy, altruism, and sublimation, along with focusing on human rights and respect, is essential (1). Promoting the concept that we are in this together “whether infected or affected by it” is critical to avoid polarization (1). Separating moral judgments and blame from physical avoidance and replacing it with empathy and care, as well as providing hope and an outlook to a brighter future, seems essential (21).

Although social media can be one of the most important sources of communication to eliminate feeling of loneliness and isolation during quarantine and periods of physical distancing, the downsides should be addressed carefully and step by step. Sending information through the influx of short and often non-transparent or even contradictory messages plays a role in increasing the anxiety, fear, and stigma felt in society. The sharing of inaccurate, nonscientific, and misleading information leads to further confusion and chaos. Therefore, proper training about using these networks and how to identify the source of messages, as well as increasing people’s ability to distinguish between legitimate vs. nonsense messages, is recommended. These efforts can be done through school programs, health communities, as well as online public education, which requires both immediate and long-term interventions. Modifying misinformation and revising some mottos- especially the ones with military language that induce the sense of fighting response toward a foreign enemy- is necessary (46, 60, 61). Clarity of information and guidelines is the key to avoid confusion, fear, and the proceeding stigma. Measures like hotline services for counseling and public education can reduce the harmful mental health consequences of pandemics as is the case with COVID-19 (62) and are also helpful in reducing stigma.

Designing and implementing strategies is important, but constant evaluation of strategies and feedback is also crucial. Health care providers must actively reach out to people in society. While telemedicine is currently used extensively in the face of COVID-19, tele-follow up strategies should be considered too, while many people might be unable to be reached in person (58, 63). This necessitates both immediate and long-term planning, depending on the current infrastructures of each country.

Supporting structures and empowering people to take necessary measures by their own choice, focusing on altruism and responsibility, and building social trust is useful (47). In pandemics such as SARS and HIV, personal resources have been associated with decreased stigmatization as they positively affect rational risk estimation and rational response (30). Empathy and validating the experiences of the patients and their families through psychoeducation is important. For instance, generalizing and normalizing the grief experience as a common and accepted reaction to distress, and training management strategies such as talking and active listening are recommended. People should not be ashamed of talking about their personal experiences. Being supportive, understanding, and informative instead of blaming

is helpful. Blaming and scapegoating people can cause prejudice and unnecessary guilt feelings, which increase stigma and non-compliance with public health directives (26).

A multidisciplinary workforce is essential. It is recommended that mental health assessment and treatment strategies get integrated into essential care needed for COVID-19 infected patients, their caregivers, and close relatives both in the hospital setting and community (19, 62). This should be addressed both by local treatment centers and policymakers to facilitate this integration by planning beneficial strategies of screening, diagnosing, referring, and treating psychiatric comorbidities (27). Currently, mental health providers have encountered an overwhelming challenge due to insufficient resources, lack of appropriate guidelines, and insufficient training in dealing with mental health consequences in the new situations due to COVID-19 (62). Guidelines and protocols of stigma reduction in health facilities and community centers are necessary. One of these guidelines has been provided by the WHO for public information and can be accessed through its website (57–64). Insights on the potential existence of double stigma and addressing it concurrently are vital.

In the global scope, pandemics have to be approached through international cooperation, which should replace localized and isolated strategies and mutual blaming. Empowering international organizations and improving collaborations are necessary measures (65). In the national scope, improving public confidence in health authorities can reduce stigma (23). This necessitates long-term planning and hard work to improve health care infrastructures accessible to every level of society. With the close collaboration of governments, health care providers, media, and communities to increase empathy and care and address misbeliefs and misinformation with accurately chosen terms and metaphors, the stigma related to COVID-19 will become manageable.

## CONCLUSION

Stigma is a barrier to medical evaluation, communication, delivering and receiving necessary care due to fear and is associated with both physical and mental health complications. COVID-19 related stigma needs to be addressed rigorously by professionals and health care providers as well as authorities. Gathering more specific information on its different facets seems urgent. Lessons learned from previous pandemics show that multidimensional approaches for health care, considering all bio-psycho-socio aspects and employing strategies to enhance communities’ empathy and resilience, pave the way toward the goal of reducing stigma. Clarity of information and guidelines, as well as continuous screening of speech pitfalls and inappropriate metaphors, is suggested. This in turn will lead to a stronger sense of unity, more effective scientific communication, increased compliance with rules and guidelines set out to battle the pandemic, more efficient use of medical pathways and eventually a better management of the pandemic as a whole.

## AUTHOR CONTRIBUTIONS

FS, RM, SZM, FB, RA, and SBM had considerable contributions to acquisition and interpretation of documents and drafting the manuscript. SBM and RR had substantial contribution

to the conception and revising the manuscript critically. All the authors have approved the submitted version and agreed to be accountable for all aspects of the work. All authors contributed to the article and approved the submitted version.

The coronavirus 2019 disease (COVID-19) is deepening the inequity and injustice among the vulnerable communities. The current study aims to present an overview of the impact of COVID-19 on equity and social justice with a focus on vulnerable communities. Vulnerable communities include, but not limited to, healthcare workers, those from lower socioeconomic backgrounds, ethnic or minority groups, immigrants or refugees, justice-involved populations, and people suffering from chronic diseases or mental illness. The implications of COVID-19 on these communities and systemic disparities beyond the current pandemic are also discussed. People from vulnerable communities' experience disproportionately adverse impacts of COVID-19. COVID-19 has exacerbated systemic disparities and its long-term negative impact on these populations foretell an impending crisis that could prevail beyond the COVID-19 era. It is onerous that systemic issues be addressed and efforts to build inclusive and sustainable societies be pursued to ensure the provision of universal healthcare and justice for all. Without these reinforcements, we would not only compromise the vulnerable communities but also severely limit our preparedness and response to a future pandemic.

**Keywords:** social determinants of health, COVID-19, vulnerable communities, mental health, health policy, health equity, social medicine, social justice

## INTRODUCTION

Outbreaks such as the coronavirus 2019 (COVID-19) challenge our existing health and justice systems (1–5). The health systems around the world have been repurposed to contain and mitigate the COVID-19 infection rate and provide acute care to COVID-19 patients requiring hospitalization (6). Furthermore, due to quarantine measures physical access to health and justice systems have been limited for those with ongoing and emergent needs. These systems have been forced to adapt and reconfigure (7, 8), with disproportionate implications on vulnerable populations (3, 9). For example, COVID-19 accelerated rapid adoption and expansion of telemedicine (10), and repurposing of existing clinical wards to provide COVID-19 clinical service (8, 11). In these unprecedented times, issues related to equity and justice must be considered (12, 13). Lack of these considerations will put those from vulnerable communities at harm (14). The

health, psychological, social and economic dimensions of an individual determine the opportunity, or the lack of it, to health and justice and the underpinning principles of equity, fairness and inclusiveness. Ensuring that the various risks to the vulnerable populations are identified early and appropriate measures are taken to prevent their impact. This article sought to present an overview of the impact of COVID-19 on vulnerable populations with regards to the issues of health equity and justice. We also provide targeted recommendations and call for a concerted action to address acute and system disparities in health equity and justice.

## METHODS

A scoping review on PubMed/Medline, media sources and official government websites were performed using the keywords “Equity,” “Justice,” and “COVID-19” until April 18, 2020, at the time of writing this manuscript. A Population, Intervention, Comparison, and Outcomes (PICO) search strategy was used (15), with the general population and healthcare workers as the study population, COVID-19 as the intervention, status of health equity and justice before COVID-19 as the comparison arm and impact of COVID-19 on equity and justice in the study population as the outcomes. Some recent publications were considered during the revision of the manuscript during October 2020 following a rather long review. The impact of COVID-19 on vulnerable populations including healthcare workers, people from lower socioeconomic backgrounds, ethnic or minority groups, immigrants or refugees, justice-involved populations, and people suffering from chronic diseases or mental illness were studied. Appropriate references relevant to COVID-19 vis a vis equity and justice issues were included in the final synthesis. Besides, we also provide targeted recommendations to address acute and systemic inequity and injustice issues during and beyond COVID-19.

## RESULTS

### Impact of COVID-19 on Healthcare Workers

Healthcare workers are disproportionately at higher risk in COVID-19 in comparison with the general community (16, 17). Extended exposure to large numbers of infected patients places them at direct risk of contracting the infection. This is exacerbated by the lack of personal protective equipment (PPE), which has been a subject of major concern across the world (18, 19). Reports of an increasing number of healthcare worker deaths due to COVID-19 have created a sense of fear and outrage (20–22). Workers have also reported anxiety about transmitting the infection to their families, elderly parents and young children (23, 24). There is a critical need for increased efforts to provide adequate PPE (18).

Healthcare workers are also suffering an immense psychological strain (22, 25–27), having to make difficult triage decisions and witnessing the loss of several patients and colleagues (28). Moreover, workers with young children are

likely to be dramatically impacted by school closures (23). To protect this population from extreme physical and mental exhaustion, governments must recognize their need for rest, and should also consider practical measures to provide support, such as the provision of food and care for young children. Targeted resources should be made available to enhance the mental health of healthcare workers. Healthcare workers, like the general population, also carry the burden of certain chronic conditions, which may put them at increased risk of COVID-19 infection (29). Considerations on age, underlying comorbidities and mental health of healthcare workers must be taken while rostering for frontline COVID-19 related care or repurposing (30, 31). Many healthcare workers may have to quarantine themselves to limit the risks to their families. It is also disheartening to note the stories of stigmatization of healthcare professionals in some parts of the world by refusing accommodation and targeting health care workers due to lack of concern and understanding.

There have been reports on disproportionately high rates of COVID-19 related death in medics from black and minority ethnic (BAME) backgrounds in the United Kingdom (UK) (32–34) and this has resurfaced the ongoing debate in the UK that those from BAME backgrounds are often not given adequate support from their peers and often struggle to be treated equally by peers (33, 35, 36). In addition to bullying and systemic racism (37), concerns about disproportionate representation in the senior management and decision-making teams or boards have also been reported by the BAME healthcare workers (38). The medical and public health administration must ensure that all clinicians, especially those from minority ethnic backgrounds, are provided adequate sponsorship and support including peer mentorship (39). Furthermore, COVID-19 has also impacted traditional medical education and training (40). Use of technologies in delivering medical education remotely could minimize the impact on medical students and medical education, alike.

### Impact of COVID-19 on Lower Socioeconomic Communities

Data shows that low socioeconomic communities are bearing a disproportionately higher brunt of the pandemic (41–45). These groups face a greater risk of detrimental financial and health outcomes during the crisis. Low-income workers in industries such as retail, transport and labor are unable to work from home and thus risk losing their source of income should they discontinue their on-site work to protect themselves and their families from COVID-19 exposure (46). Such interruptions in income can disrupt food security for families, and also limit their ability to afford treatment of existing health conditions. People working in essential sectors (e.g., transport, postal services), however, face an increased risk of contracting COVID-19 infection as they must continue working. Along with the increased risk of infection, they may also have greater difficulty in following evidence-based guidance like social distancing, accessing COVID-19 testing and care facilities. We implore governments and essential sector

organizations to provide financial support, a safe working environment to support the safe functioning of essential services during the pandemic. The government should consider looking at employment opportunities to enable lower socioeconomic groups to continue their livelihood. Moreover, there should be an increase in the access to and provision of free testing to people from low socioeconomic backgrounds, and deployment of mobile screening and infectious disease monitoring facilities in these communities.

Low socioeconomic groups are also at greater health risks due to unfavorable living conditions. Homeless people, or those living in overcrowded housing, are unable to adhere to social distancing guidelines and often lack access to personal hygiene facilities (47). Given the increase in the incidents of domestic violence, it is unsafe for them to adhere to lockdown laws and stay at home (48). We recommend the provision of temporary accommodation for people facing financial distress, homelessness, overcrowding or domestic abuse. Governments should also ensure essential supplies of electricity, water and sanitation be maintained. Furthermore, adequate access to the internet and technology should be provided to enable the continuity of education to children from lower socioeconomic households. Girls and women are more likely to be disproportionately impacted due to the closure of schools (49, 50). Increase in sexual exploitation, pregnancy and forced marriage due to closure of schools and a prolonged period of home quarantine would lead to higher drop-out rates among teenage girls (50). Furthermore, a disproportionate increase in unpaid household work burden on girls may limit their study time and hence negatively affect their academic performance and progression—causing an increase in school drop-outs (50). The government must work closely with grass-root non-government organizations to inform and educate people about the importance of continuity of education. Universal basic income could be considered to minimize the emergent effects of COVID-19 (51).

People from these communities also tend to have poor levels of education and literacy, and as a result, do not adequately receive public health messages (47). Adherence to public health recommendations is essential to reducing exposure to infection. Thus, there must be an increase in targeted efforts to improve awareness about public health measures such as social distancing, regular handwashing and use of masks among people from low socioeconomic backgrounds. Therefore, public health initiatives should aim to actively identify such communities and adapt suitable medium of communication utilizing community-level health workers.

## Impact of COVID-19 on Ethnic or Minority Groups

Pandemics invoke irrational fear and uncertainty (52). These are propitious grounds for the vagaries of hate, stigma, discrimination, racism and xenophobia to develop. Unfortunately, people from ethnicity/minority groups such as blacks, people from minority groups e.g., those from Asian and Indigenous backgrounds are more likely to be the target of hate, abuse, and sometimes violence (53). The act of xenophobia takes

various channels including social media. There are increasing reports of people from Asian backgrounds being targeted (54). It is a valid argument to postulate that these acts can rapidly scale through misinformation and social media and messaging applications, warranting a need for governments to continually monitor such events or sentiments. Targeted awareness programs are required by appropriate authorities to debunk the myth linking specific communities to COVID-19. Efforts to reinforce that pandemics such as COVID-19 affect one and all, irrespective of culture, community, creed, sex, race, and ethnicity. Infectious disease is agnostic of ethnicity, race, and cultural background of the people it affects. Political leadership must observe caution and desist from making inflammatory statements that could invoke stigmatization and xenophobia.

In the United Kingdom (UK), increasing concerns have been raised over the disproportionately higher proportion of deaths of people from the black and minority ethnic (BAME) background and those working for the National Health Service (NHS) during the COVID-19 (1). The UK government has launched an official review into why members of the BAME community are worst hit.

Previous data have shown that people of ethnicity and color have relatively poor access to healthcare services and the provision of treatment (55–58). During crises like COVID-19, these syndemic factors become important as to how historical health and social disparities along with emerging or current factors, such as epidemics, exacerbate the negative consequences on ethnic or minority groups (58). Therefore, authorities should ensure that pharmacies or local primary healthcare facilities are accessible to these communities in hours of need. Special consideration with regards to public health measures needs to be taken to protect and safeguard the health and well-being of people from indigenous backgrounds. One such measure taken by the Australian government was the limiting of travel to areas inhabited by indigenous populations in the Northern Territory, to isolate and protect these communities from exposure to COVID-19 (59).

Indigenous communities face a significant lack of access to health and justice systems (60, 61). Justice is critical to ensure that the individual rights of these communities are protected in these uncertain times. In a crisis like COVID-19, these communities are more likely to face a greater burden of unemployment, which may have a potentially cascading impact on their families. These considerations need to be addressed by the concerned family and welfare government institutions. Any public health preventative interventions or measures should be developed in consultation and with the informed consent of Indigenous people.

## Impact of COVID-19 on Immigrants and/or Refugees

Recent years have witnessed a meteoric rise in the mass-scale forced displacement of people due to climate change, political crisis, humanitarian disaster, war and violence. Tertiary care health systems remain the safety net to these vulnerable populations who have fled homes without a certain abode. Migrants and refugees are at a higher risk of infection and negative consequences of pandemics due to desperately poor

sanitation facilities, cramped conditions, limited access to healthcare and lack of financial resources to sustain families (62, 63). In places such as Kutupalong Camp in Bangladesh, currently housing over 600,000 displaced people in a mere area of 13 square kilometers, practicing social distancing is near impossible (64). Without access to clean water, promotion of hand-washing guidelines is also of little use in such camps. Should an outbreak occur in these areas, it is likely to spiral out of proportion. Authorities must make serious efforts toward providing clean water and sanitation facilities in these areas. Close monitoring of the spread of infection in these areas, including infectious disease control measures such as contact tracing, needs to be undertaken. In situations of extreme overcrowding and poor sanitation, evacuation of these camps must be considered. Currently, Doctors Without Borders is urging for the evacuation of refugee camps in Greece (65).

Language barriers also greatly limit the access of immigrants and refugees to public health messages (63). These populations must be empowered to take control of their health and engage with prevention strategies, by being provided accurate information in the appropriate languages. Given that refugees are often disadvantaged or vulnerable, they are less likely to trust governments or political systems. Thus, the involvement of stakeholders and leaders of these communities is critical to ensuring that preventative measures such as social distancing and handwashing are strictly adhered to whenever possible. Legal constraints decline refugees and immigrants' access to government welfare such as Centrelink (66). In such times of financial hardship, the livelihood of these populations is at risk of being severely compromised. To allow families to maintain food security, accommodation and health, governments should provide financial assistance, in recognition of these exceptional circumstances. Several countries have imposed strict border controls in response to the pandemic (67). This puts those who are seeking asylum at significant vulnerability and is against the spirit of international refugee law. Appropriate legal aid to asylum seekers should be provided by international humanitarian organizations. The long-term impact of COVID-19 on refugees and asylum seekers need further research.

### Impact on Justice-Involved Populations

The justice-involved population living in jails, prisons or custodial settings are particularly vulnerable in the COVID-19 era owing to the increased viral infection transmission risks due to crowded living conditions (68, 69), and relatively higher prevalence of specific medical conditions including poor cardiovascular disease profile, tuberculosis, sexually transmitted infection, substance abuse, and mental health disorder (70, 71). Jail inmates and prisoners have average to high cardiovascular disease (CVD) risk compared with community dwellers (72). Notably, individuals from lower socioeconomic backgrounds or belonging to ethnic or minority groups are inordinately incarcerated (73, 74). Moreover, history of incarceration is associated with CVD risk factors and poor prognosis (even death) from CVD (71). Therefore, targeted public health measures to minimize the transmission within this vulnerable population living in correctional facilities should be considered (75).

### Impact of COVID-19 on Remote Areas

People living in remote areas are more likely to be impacted by travel restrictions imposed by governments, as they need to travel long distances to access healthcare (76). This is particularly concerning for medical emergencies (31, 77). With the reorganization of health systems and repurposing of healthcare workers, it may be challenging to avail treatment at health facilities (29). Travel restrictions will also jeopardize ongoing care of chronic disease patients, who may not be able to access treatment locally.

Telemedicine facilities should be made available to enable the continued availability of healthcare to people living in remote areas (10, 78, 79). This has proven to be challenging as increased demand and inadequate staffing of internet providers have negatively impacted broadband services. Efforts must be taken to improve access to the internet, particularly for remote populations who are often unable to access healthcare by any other means. Deployment of mobile COVID-19 testing facilities should also be considered, to enable early detection and control of infection in rural and remote populations.

### Impact of COVID-19 on Chronic Diseases

The burden of COVID-19 has been severe for patients with chronic diseases such as obesity, cardiovascular diseases (heart disease and stroke), cancer, diabetes, chronic respiratory diseases, bone and joint disorders, genetic disorders, chronic neurological diseases (on immunosuppressive therapies (multiple sclerosis) and bulbar weakness (motor neurone disease) and mental disorders (29, 30). Patients with chronic disease are at increased risk of COVID-19 infection (80, 81). Mortality due to COVID-19 among chronic diseases could be substantial (81). Chronic disease patients with underlying risk factors such as age, obesity, lack of physical activity, tobacco use, poor nutrition and excessive alcohol consumption could be exposed to further risks due to COVID-19. Those with infection are at relatively higher risk of fatality (82, 83). Increased concerns about continuity of care, healthcare worker shortage, reorganization of health services, and limited access to testing and medical supplies have severely impacted patients with chronic diseases (83).

### Impact of COVID-19 on Patients With Cardiovascular Disease

Patients with underlying cardiovascular diseases, such as but not limited to—heart diseases, chronic stroke, obesity, and diabetes, are recognized to be at high risk of COVID-19 infection (29, 84–92). Substantially higher mortality risk has also been observed among critically ill COVID-19 patients. Acute cardiological manifestations of COVID-19 including heart failure, arrhythmia, left ventricular dysfunction and acute coronary syndromes have been observed (92). Indications on decreasing hospital presentations of acute cardiac events, presumably due to COVID-19 fear among patients, are concerning (93). Marked health inequities exist among individuals with cardiovascular diseases, diabetes and obesity across both low-income, middle income and high-income countries (94). The Prospective Urban Rural Epidemiologic (PURE) study found that the low-income and middle-income

countries (LMICs) carry the highest burden of cardiovascular disease (95). Lower levels of education in LMICs are associated with increased CVD incidence rates and CVD-linked absolute case fatality rates (CFRs) despite better overall CVD risk factor profiles. However, these individuals have markedly poorer medical care apropos to management of diabetes and hypertension, and secondary prevention (95). Moreover, ethnicity and race linked disparities exist in CVD disease risk and associated deaths, e.g., the higher prevalence of CVD risk factors among Black patients than the Whites (96, 97). The impact of psychosocial (e.g., stress among patients with CVD) and environmental (pandemic) stressors, due to social distancing and quarantine measures, on cardiovascular health in general, and those with CVD in particular warrant further research.

### Impact of COVID-19 on Cancer Populations

Cancer patients bear a great financial burden, due to the significant expenses associated with treatment. This has a disproportionate impact on people of low socioeconomic status (SES) who are often unable to afford therapy. Nationwide data from Australia showed that cancer outcomes in patients were influenced by patients' post-codes, with those living in low socioeconomic areas having the lowest 5-year survival and highest mortality rates (98). Another analysis of people with metastatic breast cancer in the United States (US) found that uninsured people were more likely to refuse or delay treatment due to cost, compared to those who were insured (99). As resources in public hospitals become increasingly scarce, patients of low SES that do not have access to private healthcare may experience greater delays in treatment. In Australia, remote areas receive an undersupply of medical practitioners and diagnostic facilities, resulting in diagnostic delays, limited early detection, and significantly poorer cancer outcomes in rural populations. Moreover, these patients are often required to travel to metropolitan areas to receive treatment (100). The COVID-19 pandemic is likely to exacerbate these conditions, as travel bans and disruption of existing cancer services further limit access to treatment for these populations (7). The burden is worsened in developing countries such as India, where nearly 70% of the national population resides in rural areas and must travel to urban tertiary care centers for treatment (101, 102). Studies have also revealed racial disparities in access to cancer treatment worldwide (103, 104). Furthermore, inequalities between SES groups are also significant within developing countries. Although data from low-income countries is sparse, the available evidence indicates higher mortality rates among people with lower SES (105).

### Impact of COVID-19 on Chronic Neurological Patients

The reorganization of the healthcare system, as well as travel restrictions, has made it challenging to maintain ongoing care of patients with chronic neurological conditions especially those on immunosuppressive treatment regimen (e.g., multiple sclerosis) or with bulbar weakness (e.g., motor neurone disease) (30). While telemedicine is being implemented as a substitute for in-person consultations, many patients, due to limited literacy and access

to appropriate technology may be unable to access services (10). Doctors have reported a sudden decrease in the number of patients presenting to hospitals with acute neurological events such as stroke, likely due to fear of contracting COVID-19 infection (31, 93, 106). This is problematic as the delay in reperfusion therapy may have fatal consequences (107–109), especially to patients with underlying chronic neurological disease (30). Likewise, there are also concerns related to the postponement of elective surgeries, therefore, the impact of delayed surgery on long-term morbidity needs further study. Health strategies to minimize the impact of the pandemic on patients with neurological conditions should include considerations of individual comorbidities or health profile as well as the socioeconomic variables associated with health. Patients who might be at high risk of an acute flare-up (such as transient ischemic attack or acute stroke) should be monitored using telemedicine and if necessary, be brought for the emergent procedure (30, 31). In the wake of COVID-19, certain diagnostic and treatment workups need to be reconsidered to limit infection exposure to patients and healthcare workers.

### Impact on Mental Health

Before the COVID-19, mental health has been a subject of major concern due to rising numbers around the world (110). In the pre-COVID era, worldwide, 800 000 people died due to suicide every year; it was a second leading cause of death among youth (15–29-year olds) globally (111). The major burden of suicides occurs in LMICs accounting for 79% of all suicides recorded globally in 2016. For example, in Australia alone, on average 8 Australians commit suicide every day, with suicide rates in 2015 amongst Aboriginal and Torres Strait Islander people (5.2%) were more than double the national rate (1.8%) (112). In addition to the personal and family suffering as well as damage to the community mental illness causes, the costs to the economy are gigantic (113).

In the COVID-19 era, social distancing, increasing joblessness and limited access to mental health services, mental health burden is bound to aggravate during and beyond the pandemic (110). Several surveys on general public have reported increase in COVID-19 related depression, anxiety, and stress owing to the psychosocial stressors (114–117). Among healthcare workers, clinical symptoms of depression, anxiety, insomnia, and distress have been reported with a prevalence rate higher than the general public (27). Lack of social support and communication, a lack of disaster training and maladaptive coping strategies increase the risk of negative psychological or mental outcomes (27, 118). To reduce adverse psychological outcomes among frontlines healthcare workers, targeted preventive and mitigation measures including stress coping strategies are recommended (118, 119).

Increasing loneliness, economic downturn, and stress invoked by living through a crisis place the entire population at high risk of psychological disorders such as depression, anxiety and substance abuse (120, 121). Zhang et al.'s study on health and well-being of normal adults after 1 month of confinement in China showed worse mental and physical health distress and life satisfaction among adults who did not work in the outbreak (122). This study gives insights on developing targeted

interventions to limit the negative impact on health and well-being of specific groups who might benefit from appropriate intervention including targeted treatment and social assistance.

Social restriction and quarantine imposed by various governments during COVID-19 will have a psychological and psychiatric impact (123, 124). Moreover, mental health consequences are likely to be more severe in socially vulnerable populations that are experiencing the greatest challenges during the pandemic (125, 126). Provision of remote psychiatric or psychological assistance through telemedicine should be considered (10). The vulnerable communities would need targeted interventions to help them cope with loneliness, fear, stigma and acute distress (127). Mental health screening programs to identify those at higher risk of suicide could be explored. Programs that have shown efficacy in improving psychological and mental health during previous epidemics such as the Zika virus outbreak could be used as a foundation to develop COVID-19 specific interventions (128). Population-level programs to monitor behavioral, interpersonal and psychological reactions to the COVID-19 could be considered to identify populations or communities at greatest risk.

## Impact of COVID 19 on Critically Ill Patients and Their Families

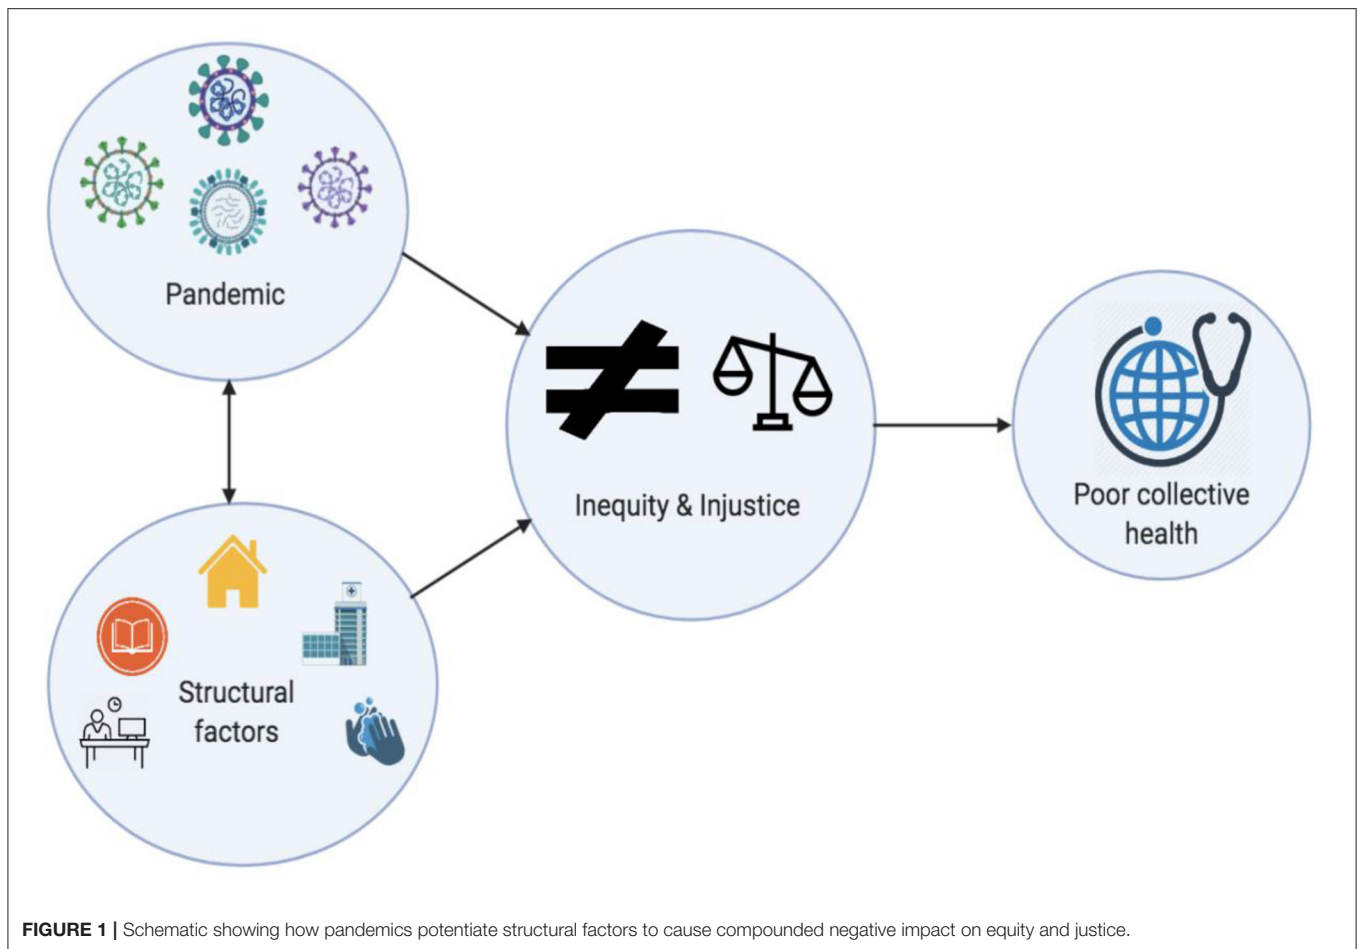

The COVID-19 patients who are critically ill, spend their last few days in ICU separated from their loved ones. The lack of PPE and strict ICU isolation protocols led to the death of most patients in ICU alone and away from their close family (129). The health care personnel who communicate to the close family members, experience extreme anguish, and this has a lasting psychological impact and moral injury on the health care workers. In several countries, visits to critically ill and funerals have been banned due to the high risk of contagion (129). This in several cultures would lead to intense pain and suffering to the family as it could be against their respective culture and tradition. Nobody wishes to die alone, but the fact that many patients are dying alone without being able to meet or communicate with their family one last time. Some countries are allowing family viewing of the deceased under strict infection control measures (130). Just like how telehealth and virtual meetings are becoming the new normal, we may have to use telecommunication for the patients to be able to communicate with their families remotely. This may not be evidence-based medicine, that we so wish to practice, but maybe considered part of compassionate care provided to the dying, as well as to their friends and family.

## DISCUSSION

Prolonged public health or humanitarian crises can act as a catalyst to realign civilizational priorities with a focus on health, equity and justice. COVID-19 has led to an unprecedented surge in fear, dismay and disbelief (22, 52, 121, 128). Pandemics have a disproportionate impact on the health and socioeconomic status of people from vulnerable backgrounds (Figure 1). These communities face exacerbated inequity and injustice (131). Healthcare workers, homeless, elderly, people

of lower socioeconomic backgrounds, those from ethnic or minority groups, immigrants and/or refugees, justice-involved populations (incarcerated), people with disabilities, those living in remote areas, with disabilities and with chronic conditions are experiencing a disproportionate burden of the COVID-19. Increasing media reports are highlighting the palpable inequity and injustice that are currently being experienced by the community, more so by those who come from vulnerable backgrounds. These vulnerabilities are further exacerbated in under-resourced settings. The impact of the disease has ramifications well-beyond those who have been infected and those who die from the infection. The pandemic of this scale and geographical breadth have raised serious concerns about the capacity of our health systems to cope (132). On a community level, we are witnessing a breakdown of existing infrastructures causing challenges in access and compliance. History tells us when aspects of equity and justice are neglected, the systems either have to be restructured or it will be forced to reboot by default (133).

Recent statements by the Director of National Institute of Allergy and Infectious Diseases in the United States of America, Dr Anthony Fauci, about the possibility “that Americans could eventually carry around certificates of immunity to the coronavirus once proper testing is widespread enough” raise concerns (134). How this will impact vulnerable communities remain to be seen. This along with the idea of creating an “immunity registry” are also concerning. There are concerns that such a registry could be misused to profile those from vulnerable communities leading to further marginalization. The announcement by the current administration in the United States, to put a halt on the funding to the World Health Organization (WHO), will severely impact the international coordination efforts to mitigate COVID-19 outbreak as the United States is a major funder (135). COVID-19 has invoked a raging debate on the urgent need to revisit commitments by individual governments toward health equity and justice (136). In this vein, models of universal healthcare that have been successfully implemented in some countries may act as templates for relevant governments to prioritize health and justice for their populations (137). Contemporary models to combat inequities in access to care and protect vulnerable communities give hope to build sustainable universal healthcare infrastructure. The *Ayushman Bharat Pradhan Mantri Jan Arogya Yojana* scheme introduced by the Indian government provides free health coverage to 500 million of the most disadvantaged members of the Indian population and its implementation has been promising (138). Brazil’s national health system—*Sistema Único de Saúde* (SUS)—provides financial support to approximately 70% of its population (139). Spain also has a public health system which assures universal coverage for all Spanish nationals regardless of economic background (140). These systems provide “safety nets” to the most vulnerable communities in hours of crisis. A more equitable allocation of funds for the improvement of primary healthcare in all countries across the globe is the need of the hour (141). The doctor-patient ratio has to be improved to provide a uniform distribution of healthcare to remote locations and lower socioeconomic status (142).

Ongoing management of patients with chronic disease is essential to minimizing the progression of the disease and should be ensured (29). Doctors are recommended to utilize telemedicine to reach out to patients virtually when possible and reduce in-person visits to the clinic (10). To facilitate this, we urge governments to reimburse all healthcare providers for teleconsultations. Patients should continue receiving treatment, unless the risks of doing so outweigh the benefits, as per the judgement of the responsible clinicians. If treatment cannot be administered remotely, patients should be encouraged to present to hospitals for treatment, and all necessary precautions must be taken to minimize the risk of COVID-19 infection transmission. For patients who do not have access to a private vehicle, provision of transportation to and from the hospital could be organized for patients with limited physical mobility. Early detection of chronic diseases is crucial to prevent fatal progression. Thus, we recommend the continuation of existing screening activities (e.g., breast cancer screening program), with strict adherence to PPE and handwashing guidelines. Patients with acute cardiac and/or neurological symptoms should be encouraged to access treatment as the absence or lack of treatment could have a devastating impact on individuals (31).

Contracting COVID-19 infection could be fatal for patients with chronic disease particularly those with severely

compromised immune systems and CVD risk factors including but not limited to obesity and advanced age (29). We recommend regular telemonitoring of all patients for COVID-19 symptoms, such that immediate action can be taken for suspected infection. Chronic disease wards should be divided into COVID-19 positive and COVID-19 negative wards. Patients with a suspected infection should undergo diagnostic testing, and those who test positive should be monitored for progression of symptoms. If their condition deteriorates, we recommend direct routing of these patients to COVID-19 positive chronic disease ward, to circumvent exposure to the emergency department. Critically ill patients and their loved ones should be given special consideration on compassionate grounds so that the families and the ICU staff could have closure and potential adverse psychological impact on healthcare staff (due to moral injury) and families could be thwarted.

In conclusion, unprecedented times deserve unprecedented measures. The social and economic determinants of health mediate the impact of crises such as a pandemic (41–45, 143). Factors related to individual socioeconomic status, underlying morbidity and external factors such as diminishing access to healthcare and justice systems could deepen the inequity and injustice divide during and beyond the COVID-19 era (13, 131, 141). Factors such as universal health care access, provision of

education for all, protection from disasters including caused by pandemics and climate change, justice to all, and equality in opportunity affect how communities and nations respond and cope with the crisis (51, 131). For us to have a comprehensive approach to be able to recoil back into a functioning society, efforts to address these determinants are important. Digital technologies such as big-data analytics and artificial intelligence could be leveraged in surveillance and care of people from vulnerable communities during and beyond-COVID-19 (79). Furthermore, individual governments should allocate dedicated funding to support ongoing research and development and public health surveillance of current and long-term impact of COVID-19 on vulnerable populations. Without a holistic approach to building sustainable and inclusive systems that address health inequity and injustice, we will continue to be vulnerable to pandemics such as one that we face now, and those that may occur in future (144). It is also important that COVID-19 mitigation strategies should not stigmatize or marginalize vulnerable communities (9). Identifying vulnerable members of the community and those at high-risk should be an integral part of pandemic public health response strategies. We urge governments to take a proactive approach toward realignment of national efforts on creating sustainable planetary health, justice and environmental systems—one that could protect our generations in face of a pandemic or prolonged crisis (12, 136, 145).

## AUTHOR'S NOTE

The COVID-19 pandemic is causing an unprecedented public health crisis impacting healthcare systems, healthcare workers,

and communities. The COVID-19 Pandemic Health System Resilience PROGRAM (REPROGRAM) consortium is formed to champion the safety of healthcare workers, policy development, and advocacy for global pandemic preparedness and action. This paper could only consider developments until April 30, 2020, at the time of manuscript writing and submission; however, some updates were considered and added during the revision of the manuscript in October–November 2020.

## AUTHOR CONTRIBUTIONS

SBh devised the project, the main conceptual ideas and proof outline, and coordinated the writing and editing of the manuscript. SBh and AR wrote the first draft of the manuscript. SBh encouraged AR to investigate and supervised the findings of this work. All authors discussed the results and recommendations and contributed to the final manuscript.

## ACKNOWLEDGMENTS

We would like to acknowledge the REPROGRAM consortium members who have worked tirelessly over the last days in contributing to various guidelines, recommendations, policy briefs, and ongoing discussions during these unprecedented and challenging times despite the incredibly short timeframe. We would like to dedicate this work to our healthcare workers who have died due to COVID-19 while serving the patients at the frontline and to those who continue to serve during these challenging times despite lack of personal protective equipment.

Coronavirus disease 2019 (COVID-19), as an infectious disease, is now prevalent in many countries around the world, which has recently led many governments to home quarantine and impose penalties for violating quarantine. Concerns and stress caused by lockdown and social isolation led to personal and interactive reactions in some families, which are also culturally important to address. This study was administrated to study the psychological well-being and the effect of home quarantine on marital satisfaction (MS) and parental burnout (PB) from parenting responsibilities during the prevalence of COVID-19 in Iranian parents. A total of 213 parents (140 mothers and 73 fathers) voluntarily participated in the online survey in the period of February to mid-April 2020 and completed the 5-item index of the well-being of the World Health Organization (WHO-5), the Kansas Marital Satisfaction Scale (KMSS), and the Parental Burnout Assessment (PBA). The results showed that the effect of home quarantine on MS and PB was not significant in parents ( $p > 0.01$ ). The interactive effect of home quarantine and gender was not significant on MS and PB ( $p > 0.01$ ). In addition, the mothers significantly reported higher PB than the fathers, but the fathers had higher scores in MS and psychological well-being ( $p < 0.01$ ). The effect of some demographic factors on the studied variables was also significant. Supportive resources in family-based culture may play an essential role to reduce the negative effects of stressful situations on family interactions.

**Keywords:** well-being, parental burnout, marital satisfaction, home quarantine, COVID-19

## INTRODUCTION

Coronavirus disease 2019 (COVID-19), as an infectious disease, is now recognized as a highly prevalent disease that affects a large number of people, especially the elderly and people with a background of health problems (World Health Organization [WHO], 2020). Since no definitive treatment has been discovered so far to treat this prevalent disease, the only way to cope with the disease and cut off the virus transmission chain is to do personal hygiene and keep physical distance from others in daily interactions. This has led governments to quarantine people at home and impose penalties for violating these laws. This type of home quarantine is called lockdown,

and with the onset of the COVID-19 outbreak, millions of people around the world are living in conditions of social isolation and constraint on social interactions (Taub, 2020).

In Iran, after closing all public places and forcing people to stay at home and not moving in public places, people's interactions were limited. This time almost coincided with the beginning of the Iranian New Year. Since Iranian culture is a culture based on family and kinship interactions, it imposed severe restrictions on an individuals' access to relatives and friends' networks; worry, death anxiety, and feelings of hopelessness were among the concerns raised in people's contacts with the counseling section of the Welfare Organization (Welfare Organization of Iran [WOI], 2020). Such a condition, as an external, major, non-normal, out of control and unpredictable stressor to cope, has been unprecedented in the history of the world and has led to different forms of self-isolation and can cause different behavioral and emotional reactions (Gallagher, 2020) in different individuals with different cultural backgrounds. Such psychological reactions due to the decline of social relations are more evident in traditional cultures; researchers have shown that decreased emotional contact and feelings of connection with family and friends are associated with symptoms of distress and depression in African-Americans (Taylor et al., 2016, 2020). Recent studies have shown that social distancing by creating a sense of loneliness, anxiety, suicide ideations (Armbruster and Klotzbücher, 2020), low perception of social support, and an inability to connect with others is associated with low well-being and low sense of social connectedness (Emerson et al., 2020; Garcia et al., 2020). In addition to the personal effects of the lockdown, home quarantine and social distancing challenged the value and the cost of relationships with others. In such situations, people accept staying at home and distancing from friends and family as the cost of maintaining their physical health, while with self-exclusion of the social network, they were imposed lots of psychological harm. However, the side costs of staying at home for a long time, such as multiplying the caring responsibilities of spouse and children (Long, 2020), are also a matter of consideration.

Due to the novelty of studies on the personal and interactional effects of home quarantine caused by the coronavirus outbreak, the current study was conducted to investigate the effect of home quarantine on psychological well-being and marital and parental outcomes in families living in Iran.

## Stressful Life Events and Psychological Well-Being

Mental health has been defined as the absence of mental disorder (which enables a person to fulfill the personal growth and experiences of happiness and satisfaction) (World Health Organization [WHO], 2001). Thus, psychological well-being is an integrated process apart from mental disorder that involves a concept of more than happiness and includes a concept of optimistic development (Fen et al., 2013). Psychological well-being is the first element that is threatened in the face of stressful life events. Stressful life events with dimensions including challenging the adaptive mechanisms of the individual

(Holmes and Rahe, 1967), being threatened (Cohen et al., 2016), imposing demands on the individual over accessible resources (Lazarus and Folkman, 1984), and disrupting the achievement of life goals (Kemeny, 2003) have many physical and psychological consequences for a person (Cohen et al., 2019). Cleland et al. (2016) showed that stressful life events, such as losing a good relationship, health problems, and economic problems, have negative impacts on mental health. Following some epidemic economic crises, negative social consequences, including declining economic well-being, physical and psychological problems, and the adoption of relevant coping strategies, are predictable (Aytaç et al., 2015). The prevalence of an unknown and epidemic disease, such as COVID-19, as a stressful event that affects a large number of people (Delle Fave, 2014) reduces the psychological well-being (Philip and Cherian, 2020; Sibley et al., 2020), threatens social relationships, social confidences, and maintaining connections (Delle Fave, 2014), weakens the socio-economic position of the individual, loses a sense of control over life events, and reduces the feeling of life satisfaction (Rubio et al., 2018), especially when it was considered as an unpredictable and chronic disease, and when it occurs for at-risk groups, such as the elderly or people with emotional disorders (Schneiderman et al., 2005; World Health Organization [WHO], 2009).

The prevalence of the unknown coronavirus disease as a stressful event, in addition to direct effects on health, due to forcing people to quarantine at home can have several psychological consequences on individuals. Limited studies in this area show that lockdown and being isolated have significantly increased feelings of loneliness, anxiety, stress, and suicide in people living in European and American countries (Brodeur et al., 2020). Other evidence suggests that children in quarantine situations experience feelings of anger, fear, loneliness, and boredom despite feeling happy and relaxed with family (Idoaga Mondragon et al., 2020). Conversely, the study of Recchi et al. (2020) on the French population before and after the outbreak of coronavirus indicated an improvement in well-being and health in the unaffected majority; however, people with low income and who lost their job or those who worked long hours at home reported higher levels of stress (Prickett et al., 2020).

## Stressful Life Events, Lockdown, and Parental Burnout

The home quarantine and lockdown situation caused by the COVID-19 crisis have affected the well-being of families and challenged the ability of parents to carry out parenting responsibilities by imposing more education and care responsibilities (Mangiavacchi et al., 2020). The closure of schools and some businesses imposed many housework and childcare responsibilities on parents, especially on mothers (Farré et al., 2020). Alon et al. (2020) and Hupkau and Petrongolo (2020) showed in a survey of United States and United Kingdom families that housework, childcare duties, and the role of teaching for children have put more pressure on parents, especially on mothers. Stressful situations by influencing people's coping strategies are associated with the high negative mood symptoms

of depression, anxiety, and stress in parents (Mather et al., 2014; Flouri et al., 2018), symptoms of burnout (Mather et al., 2014), and parent-child dysfunctional interactions (Platt et al., 2016). Some studies have shown that lack of control, household workload, role confusion, and irrational environmental demands especially caused by stressful events, such as the COVID-19 pandemic (Griffith, 2020), have led to negative emotions, such as exhaustion, feelings of helplessness, frustration, and finally parental burnout (PB) in caregivers (Vinayak and Dhanoa, 2017; Mikolajczak et al., 2018a).

Parental burnout is a state of emotional exhaustion that is associated with a change in positive attitudes toward children (Luescher et al., 1999) and is defined in four dimensions as the feeling of exhaustion of parental role leading to low parental efficiency, feeling of fed up, contrast with the past parental role, and emotional distancing from children (Roskam et al., 2018). Studies have shown that PB is associated with parent-child demographic factors, such as the age of mother and child, the number of children at home, the number and gender of caregiver, socio-economic status of the family, the physical and mental conditions of parent-child (Blanchard et al., 2006; Norberg, 2007; Lindström et al., 2011; Vinayak and Dhanoa, 2017; Le Vigouroux and Scola, 2018; Mikolajczak et al., 2018b; Mousavi et al., 2020), personal factors, such as emotional intelligence and high parental self-efficacy beliefs, and interactional factors, such as positive parenting practices, co-parenting, and marital satisfaction (MS) (Mikolajczak et al., 2018b).

## Stressful Life Events, Lockdown, and MS

Marital satisfaction as the indicator of the marriage quality (Fincham and Beach, 1999) is defined as the mental experience of happiness in a marital relationship (Hendrick et al., 1998), which reflects the perceived benefits and values of marriage (Baumeister and Vohs, 2007), a subjective evaluation that varies under the influence of happy and unpleasant life events (Li and Wickrama, 2014). The challenging events in the context of the family are changes, and people no longer simply feel satisfied after the changes (Maltas, 1992); changes caused by stressful events led to stress and act as a threat to satisfaction and intimate relationships (Randall and Bodenmann, 2009). Stressors, especially external factors, first by reducing opportunities to strengthen relationships and distracting couples from spending time to improve intimacy in relationships and then by weakening their abilities to cope with stressors, create problems for couples (Neff and Karney, 2017). Some studies have shown that external stressors including natural disasters are associated with decreased MS (Chi et al., 2011). Studies have also shown that stressful events (e.g., declining level of welfare and low income) have a significant association with decreasing marital stability (Bahr, 1979), poorer marital interactions and low MS, especially in the first years of marital life (Bodenmann, 2000; Bodenmann and Cina, 2006), sexual problems in intimate relationships (Bodenmann et al., 2007), criticism of spouse, and reduction of dyadic support (Neff and Karney, 2009), low MS, and high psychological distress with mediating role of problem-solving (Cohan and Bradbury, 1997)

or management skills (Li and Wickrama, 2014) and coping strategies (Fink and Shapiro, 2013).

The prevalence of the COVID-19 pandemic as an external stress has challenged the quality of couples' relationships; home quarantine with negative psychological effects, such as anxiety, stress, depression, and frustration (Brodeur et al., 2020; Idoiaga Mondragon et al., 2020), and making changes in the unemployment rate and reducing access to financial opportunities (Coibion et al., 2020), forcing distress couples to spend many hours of the day together and increase the capacity for marital conflicts (Perez-Vincent et al., 2020), can have negative effects on couples' relationships; these effects become more destructive due to different backgrounds, such as low economic quality and low levels of vulnerability (Pietromonaco and Overall, 2020). Kevin and Rislá (2020) showed that couples with low income reported low MS during the lockdown or distressed couples experience worse individual and dyadic outcomes in the face of external stress (Beach et al., 1994). Conversely, some other evidence suggests that external stresses in a good marital relationship, despite weakening the relationship at the beginning of the encounter to stress, cause spouses to adapt to new conditions and strengthen the dyadic relationship in later stages (Bonanno, 2004). Therefore, to clearly understand the effect of stress on couples' relationships, it is helpful to pay attention to the source of stress, the intensity of stress, and the duration of exposure to stress (Randall and Bodenmann, 2009) with regard to personal, relational, and cultural backgrounds of couples.

## Gender Differences in Well-Being, PB, and MS

Gender plays an essential role in the distribution of role and power in the family and social status (World Health Organization [WHO], 2019). High non-stop parental and household tasks, the monotony of endless daily affairs, and the low level of control in mothers can be an explanation for the poor mental health compared with fathers (Baruch et al., 1987). This is why the prevalence of emotional disorders is higher in women than in men (World Health Organization [WHO], 2019). In other studies, mothers reported more stress and anxiety, less well-being (Skreden et al., 2012; Meier et al., 2018; Nelson-Coffey et al., 2019), less happiness, more fatigue, and consequently, less leisure time and sleep (Musick et al., 2016), which is explained by the more limited role of fathers in parenting and social isolation (Skreden et al., 2012).

Many studies have shown that it is the mothers who, as the primary and permanent caregivers of the children, are more exposed to PB than the fathers (Le Vigouroux and Scola, 2018; Lebert-Charron et al., 2018; Mikolajczak et al., 2018b; Roskam et al., 2018; Roskam and Mikolajczak, 2020). Mothers, especially those who have young children or more children or who do not have the capacity of fathers to cooperate in parenting responsibilities, suffer from more PB (Hubert and Aujoulat, 2018; Mikolajczak et al., 2018b). Mothers also felt more burned out than fathers because of high parenting expectations and social pressures for being a

perfect mother (Meeussen and Van Laar, 2018; Sorkkila and Aunola, 2020) and were characterized by feelings of guilt, anxiety, and severe depression (Sánchez-Rodríguez et al., 2019), although fathers reported more negative consequences for PB, such as suicidal ideation, running away, and child neglect (Roskam and Mikolajczak, 2020).

Although parenting in mothers is associated with more reports of burnout (Roskam et al., 2018; Roskam and Mikolajczak, 2020), having children is one of the hallmarks of MS in mothers (Twenge et al., 2003). Beam et al. (2018) attributed the gender difference in MS to the difference in the structure of their marital quality. Olson et al. (2008) found that women were more likely to complain than men from distancing to successful marital life standards and were more sensitive to marital problems. Job satisfaction, communication, mutual understanding, and sexual satisfaction were reported as important components of MS in men and the same factors except for sexual satisfaction in MS in women (Ayub and Iqbal, 2012). In the study by Ogolsky and Bowers (2013), maintenance behaviors were reported to lead to MS in women more than in men, and women's MS was greater when their husbands accompanied them in spending time with their children and supported them in caregiving (Rhyne, 1981; Leung, 2020). Therefore, increasing MS in mothers is associated with increased participation of fathers in the home and high family cohesion (Korja et al., 2016; Liu and Wu, 2018) and parent-child interactions (Yoo, 2020).

## Current Study

The unexpected occurrence of infectious disease of COVID-19, the coercion of people into home quarantine, in addition to hearing the news of daily deaths, preventing people from holding mourning ceremony for lost loved ones, closing schools and businesses, and the resulting economic pressure on low-income groups, and so on, caused anxiety and seeing an uncertain future ahead, that the only way to cope with this phenomenon was to distancing from the community for cutting off the chain of disease outbreaks. The pressure of new circumstances on individual and relationship outcomes in Iranian families led the researcher to evaluate the effects of the coronavirus outbreak on well-being, marital outcomes, and parent-child interactions by investigating the families' perceptions of the pre-post outbreak of coronavirus condition. Hence, to assess MS and PB before and after the COVID-19 outbreak (home quarantine condition), the researcher presented both scales into two sections with past and present tense verbs (perception of MS and PB in the pre-outbreak condition and how they are feeling now about their marital and parental outcomes) to test the research hypotheses as follows:

*Hypothesis 1:* The home quarantine due to the COVID-19 outbreak has increased burnout and reduced MS among Iranian parents.

*Hypothesis 2:* The PB and MS scores of mothers and fathers are significantly different in the pre-post outbreak of COVID-19.

*Hypothesis 3:* The mothers and fathers are significantly different in well-being, PB, and MS scores.

## MATERIALS AND METHODS

### Participants

Due to the study of marital and parental outcomes, the statistical population of the current study includes all married fathers and mothers living in cities of Iran who have at least one child who needs care at home (without age limit), are literate, and have consented to participate in the study. From 215 parents who participated in this study with the exclusion of two mothers who had experienced death caused by COVID-19 in the family, a total of 213 parents remained, of whom 140 only mothers and 73 only fathers participated throughout Iran, and 91 parents were from Tehran (capital of Iran), and the rest of them were from different cities. The demographic characteristics of *mothers* were: age ( $37.43 \pm 7.22$ ), the length of the marriage ( $14.46 \pm 8.14$ ), the number of children (1-4 child), the level of education (up to graduation of high school = 38, bachelor = 49, MA/MS = 33, Ph.D. = 20), have paid activities ( $N = 67$ ) or not having ( $N = 73$ ), and welfare level of the neighborhood (non-prosperous = 6, average = 107, prosperous = 27).

The demographic characteristics of *fathers* were: age ( $41.95 \pm 8.6$ ), the length of the marriage ( $15.64 \pm 10.7$ ), the number of children (1-6 child), the level of education (up to graduation of high school = 6, bachelor = 24, MA/MS = 31, Ph.D. = 12), have paid activities ( $N = 72$ ) or not having ( $N = 1$ ), and welfare level of the neighborhood (non-prosperous = 4, average = 56, prosperous = 13).

### Procedure

The present study is cross-sectional and has a mixed factorial design. Therefore, this study has a within-subjects variable (home quarantine) with two facets (before and after the COVID-19 outbreak) and a between-subjects variable (gender) with two facets (fathers and mothers). The study was conducted for nearly 1 month and a half after the outbreak of COVID-19 that forced people to home quarantine in cities of Iran. Therefore, to evaluate the effect of home quarantine, the items of the scales were presented to the participants in both past and present tenses and in two sections including before and after the outbreak; thus, the research had two limitations: (1) the impossibility of conducting longitudinal research to evaluate the effect of home quarantine on the studied variables and (2) the impossibility of conducting a survey in paper-pencil to reach a high sample size; the online survey was used. The survey was administrated online (an Iranian online survey website<sup>1</sup>) from last February to mid-April 2020 for nearly a month and a half past the prevalence of COVID-19 in Iran and coincided almost with the beginning of the New Year (Nowruz Holiday) in Iran. The link of the survey was shared accompanied by a video clip introducing the research goal on social media including WhatsApp and Telegram, and so on. The project took almost a month to complete, and data analysis began after no one was added to the project for a week. All participants voluntarily participated in the online survey and were free to withdraw from participation. They were assured of

<sup>1</sup><https://porsline.ir>

the confidentiality of the information and the use of the results for academic research.

## Measures

*Demographic information* includes participants' information about the gender, the age of parents, the length of the marriage, the number of children, the level of education, have or not having paid activities, the welfare level of the neighborhood, and the experience of death due to COVID-19 in the family.

*Open-ended questions* are used to evaluate how the families react to hearing about outbreaks and deaths of COVID-19 and how to cope with this stress as well as how they spent time at home with their children. These questions were used for explaining the quantitative results, such as what is used in explanatory sequential designs (Wisdom and Creswell, 2013), and the well-being and parental outcomes of parents were described in details in the face of the COVID-19 outbreak and home quarantine.

*Marital satisfaction* is measured by the Kansas Marital Satisfaction Scale (KMSS). This 3-item self-reported scale assesses couples' satisfaction with the relationship, partner as a spouse, and marriage in a 7-point Likert scale from *extremely satisfied* (1) to *extremely dissatisfied* (7) (Nichols et al., 1983). Based on a meta-analysis study about MS tools, this scale had the highest reliability (Graham et al., 2011). Its convergent validity with the Relationship Assessment Scale (RAS) has been reported as 0.74 in Iranian couples (Dehshiri and Mousavi, 2015a). This scale is also used in two sections before and after the COVID-19 prevalence using the past (for example, "How satisfied were you with your relationship with your husband (or wife)?") and present tense verbs (for example, "How satisfied are you with your relationship with your husband (or wife)?"). In this study, Cronbach's alpha coefficient (before and after the outbreak) was obtained as 0.94 and 0.97, respectively.

*Parental burnout* is assessed by Parental Burnout Assessment (PBA). This self-report scale includes 23 items in a 7-point Likert scale from *never* (0) to *every day* (6) that was prepared by Roskam et al. (2018) to assess parental exhaustion from parenting responsibilities in four subscales: exhaustion of the parental role, contrast with the parental self in the past, feeling of being fed up, and emotional distancing from children. The scale was validated in Iranian by Mousavi et al. (2020), and Cronbach's alpha was obtained at the range of 0.60–0.93 for subscales. Participants were asked to express their perceptions of experiencing burnout before and after the COVID-19 outbreak that forced home quarantine in two sections with past (for example, "I couldn't stand my role as father/mother anymore.") and present tense verbs (for example, "I can't stand my role as father/mother anymore."). The Cronbach's alpha for the perceived PB before the COVID-19 outbreak was obtained at the range of 0.76–0.97, and after the outbreak it was at the range of 0.87–0.98. Since one of the points in the 7-point scale was "a few times a year" (6) and was not applicable for the post-outbreak condition, this point was removed from the scale, and it became a 6-point Likert scale (0–5). Like any disorder, PB naturally does not have normal distribution and positively skewed, so, to observe the

assumption of normality of the dependent variable for doing any parametric test, the natural logarithm conversion was used to normalize the scores.

*Psychological well-being* is assessed by the 5-item index of the well-being of the World Health Organization (WHO-5). This self-report scale is based on the WHO-10 scale that was prepared by Blom et al. (2012) and assessed the well-being of a person over the past 2 weeks on a 6-point Likert scale from *at no time* (0) to *all of the time* (5). Therefore, this scale was used in one section to assess the well-being of mothers and fathers in this situation (for example, "Over the last 2 weeks: I have felt calm and relaxed."). Higher scores indicate higher well-being, and lower scores show poorer well-being of a person. In a study to validate this scale in Iranian people, Dehshiri and Mousavi (2015b) found a Cronbach's alpha coefficient of 0.89. In this study, its Cronbach's alpha coefficient was obtained at 0.89.

## Data Analysis

After reporting the mean and standard deviation of well-being, PB, and MS, a mixed factorial design was used to assess PB and MS before and after outbreak conditions in both genders. To assessing its assumption, the normality test was applied. The skewness and kurtosis of well-being scores (−0.45 and −0.18) and the skewness (−0.155 and −1.8) and kurtosis (2.69 and 3.39) of MS scores showed that the distribution of scores is normal. Since the skewness (2.97 and 2.79) and kurtosis (7.54 and 7.41) of PB were not normal, so for the normalization of scores, the natural logarithm conversion was used, and the skewness (0.67 and 0.77) and kurtosis (−0.77 and −0.6) of PB were obtained. The Levene's Test results in MS scores also showed that the assumption of homogeneity of variance [ $F(1,211) = 1.07, p > 0.3$ ;  $F(1,211) = 2.91, p > 0.9$ ] was satisfied. However, the Levene's Test in examining the homogeneity of variance of PB scores showed that the variance of the two groups is not equal; based on variance ratio, the ratio of the biggest variance to smallest variance is less than 3, so, the variance of the two groups can be considered equal (Field et al., 2012).

To analyze the relationship between well-being, PB, and MS (in the present condition, i.e., after the outbreak) with other demographic variables, Pearson correlation analysis and one-way ANOVA were used in which the assessing of the assumptions of both tests showed, respectively, that the relationship between two variables was indicated as linear by the scatter plot and the normality of dependent variables distribution and the homogeneity of variances of dependent variables were satisfied.

In addition, the analysis type of open-ended questions was by content analysis that was done manually by analyzing, categorizing, and coding the themes in the responses of 213 participants. In coding the responses using inductive or open coding method, first, after getting a sense of all the answers to each question, a sample of data was read, and based on the themes, they were categorized, and their codes were assigned in Excel sheet; this process was continued until all the participants' responses were coded, similar responses were placed in pre-assigned codes, and new codes were assigned to new responses. Finally, all the categories and codes were reviewed to ensure that similar codes can be merged, and some irrelevant responses were

also removed. In total, out of three open-ended questions, 256 responses and 5 codes were assigned to the first question (how to react to the news of the coronavirus outbreak); 601 responses were analyzed, and in two coding steps, 11 and 3 codes were assigned, respectively, to the second question (how to reduce stress); and 528 responses were analyzed, and in two coding steps, 22 and 4 codes were assigned, respectively, to the third question (how to spend time with children).

## RESULTS

*Analysis of the responses to short questions:* In analyzing the psychological reaction to hearing the news about the outbreak of COVID-19, 45.6% reported that they are trying to be calm and relax, 22.13% showed anxiety, 16.60% showed stress, 12.56% showed fear and apprehension, and 3.56% reported no reaction. For reduction of stress, participants also reported doing the following activities: prayer, talk to GOD, and strengthen religious beliefs with 34.45%, housework (cooking and baking bread and cookies) and doing art and handicrafts with 20.80%, and the expansion of virtual communication with family, friends, and relatives with 11.98%. For spending free time with the children, parents also reported the following activities: planning intellectual and group games and competitions at home with 73%, monitoring school assignments and playing the role of teacher for children with 8.52%, experience a variety of cooking and confectionery for them with 7.01%, and playing virtual and computer games with 5.87%.

The descriptive statistics including mean and SD in **Table 1** show the scores of parents in well-being, MS, and PB according to gender and time periods, the level of education, and have or not having paid professional activities.

### The Effect of Home Quarantine and Gender on MS, PB, and Well-Being

In testing Hypothesis 1, the analysis of variances in **Table 2** showed that the effect of home quarantine was not significant on MS,  $F(1,211) = 1.32, p > 0.25, \eta^2 = 0.006$ , and PB too,  $F(1,211) = 0.26, p > 0.61, \eta^2 = 0.001$ .

**Table 2** also shows that the interactive effect of home quarantine and gender was not significant on MS,  $F(1,211) = 0.13, p > 0.72, \eta^2 = 0.000$ , and PB,  $F(1,211) = 0.71, p > 0.49, \eta^2 = 0.003$ . **Figure 1** shows the effect of home quarantine across the genders.

In examining Hypothesis 3, after controlling the effect of pre-prevalence, the result in **Table 2** also revealed that the gender effect for both of the two variables MS,  $F(1,211) = 5.6, p < 0.02, \eta^2 = 0.26$ , and PB,  $F(1,211) = 7.8, p < 0.006, \eta^2 = 0.36$ , was significant. The mean comparison in **Table 1** showed that the fathers ( $18.37 \pm 3.56$ ) have reported more MS than the mothers ( $17 \pm 4.38$ ) and lower burnout ( $1.03 \pm 1.23$ ) than the mothers ( $1.52 \pm 1.53$ ). The ANOVAs showed that gender has a significant effect on well-being too,  $F(1,211) = 7.82, p < 0.01, \eta^2 = 0.19$ . A comparison of the means of the two groups of mothers and fathers in **Table 1** shows that the mothers ( $15.76 \pm 5.41$ ) reported poorer well-being than the fathers ( $17.93 \pm 5.34$ ).

**TABLE 1** | Mean and SD of wellbeing, marital satisfaction and parental burnout according to gender, education, and job before and after home quarantine.

	Gender						Education						Job					
	Mothers (N = 140)		Fathers (N = 73)		Total (N = 213)		Up to graduation of high school (N = 44)		Bachelor (N = 73)		MA/MS (N = 64)		Ph.D. (N = 32)		With paid (N = 139)		Not paid (N = 74)	
	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)	Pre M (SD)	Post M (SD)
Wellbeing	15.76 (5.41)	17.93 (5.34)	17.05 (5.9)	17.07 (5.9)	16.50 (5.47)	17.05 (5.9)	17.05 (5.9)	15.68 (5.81)	16.66 (5.3)	16.98 (5.3)	16.66 (4.31)	17.29 (5.43)	15.01 (5.29)					
Marital satisfaction	16.86 (4.008)	18.11 (3.7)	17.29 (3.93)	17.07 (4.49)	17.47 (4.16)	17.07 (4.49)	17.07 (4.49)	17.38 (4.42)	18.47 (2.7)	17.19 (3.82)	18.47 (2.7)	17.69 (3.58)	16.54 (4.48)					
Parental burnout	1.54 (1.51)	1.03 (1.23)	1.33 (1.47)	1.3 (1.62)	1.35 (1.46)	1.27 (1.55)	1.27 (1.55)	1.58 (1.51)	1.11 (1.25)	1.07 (1.29)	1.24 (1.44)	1.16 (1.42)	1.67 (1.51)					

**TABLE 2** | Analysis of variance of MS and PB before and after COVID-19 outbreak.

	Source of variation	SS	df	MS	F	p	$\eta^2$
Marital satisfaction	<b>Between subjects</b>						
	Gender	164.07	1	164.07	5.6	0.02	0.26

**FIGURE 1** | MS and PB of parents before and after the COVID-19 outbreak.

## Additional Analysis With Demographic Factors

The results showed that there was no significant relationship between the *length of marriage* and well-being ( $r = -0.05$ ,  $p > 0.4$ ) and PB ( $r = -0.09$ ,  $p > 0.19$ ), but a significant negative relationship with MS ( $r = -0.15$ ,  $p < 0.02$ ). The results showed that there was no significant relationship between the number of children and well-being ( $r = 0.10$ ,  $p > 0.1$ ) and PB ( $r = -0.09$ ,  $p > 0.1$ ) and MS ( $r = -0.005$ ,  $p > 0.9$ ). In addition, no significant relationship was observed between parents' *age* and well-being ( $r = 0.04$ ,  $p > 0.6$ ) and PB ( $r = -0.1$ ,  $p > 0.7$ ) and MS ( $r = -0.09$ ,  $p > 0.1$ ).

The results of ANOVAs showed that parents were not significantly different in terms of *education* in well-being  $F(3,209) = 0.86$ ,  $p > 0.5$ ,  $\eta^2 = 0.012$ , MS  $F(3,209) = 1.53$ ,  $p > 0.2$ ,  $\eta^2 = 0.021$ , and PB  $F(3,209) = 1.51$ ,  $p > 0.2$ ,  $\eta^2 = 0.021$ ; but in terms of *job*, parents having a paid profession had higher scores on well-being  $F(1,211) = 8.7$ ,  $p < 0.004$ ,  $\eta^2 = 0.4$  and MS  $F(1,211) = 6.89$ ,  $p < 0.009$ ,  $\eta^2 = 0.3$ , but did not differ

significantly in PB  $F(1,211) = 3.57$ ,  $p > 0.06$ ,  $\eta^2 = 0.017$  rather than those not having a paid profession. In terms of *neighborhood* welfare, parents were significantly different in the scores of well-being and PB, the results showed that parents living in average neighborhood reported higher well-being than parents living in disadvantaged neighborhood ( $\Delta M = 4.47$ ,  $p < 0.04$ ), parents living in prosperous neighborhoods reported the highest scores in well-being compared with the other two groups ( $\Delta M = 6.8$ ,  $p < 0.002$ ), and parents living in prosperous neighborhoods reported lower scores on PB than parents living in average neighborhoods ( $\Delta M = -0.69$ ,  $p < 0.03$ ).

## DISCUSSION

Crises caused by epidemics lead to many psychological reactions in individuals. The coronavirus epidemic caused by acute respiratory syndrome, which has spread to many Asian, European, and American countries, has become a global public health concern. The disease has affected many people so far and

has led to the death of a number of people in each country, depending on the health facilities and financial and supportive resources; due to the possibility of recurrence and lack of vaccines or definitive drugs for treatment (so far), the only mechanism is restricting the social interactions of people, which led to many closed centers, in addition to severe disruption in the economy and negative psychological outcomes in people around the globe.

The current study was administrated to examine the effect of the outbreak and home quarantine on psychological well-being, PB, and MS of Iranian mothers and fathers. The results showed that home quarantine did not have a significant effect on PB. Although studies in the field of PB are still in their infancy, some of these studies have shown that negative life events, increased environmental demand, problems due to poverty, unemployment, and low economic status, and stress, such as lack of physical and mental health of children and parents, can predict parental exhaustion (Blanchard et al., 2006; Norberg, 2007; Mikolajczak et al., 2018b). Accordingly, the finding of this study is not consistent with these studies. Iranian society is a family-based society in which many sources of support come from the family. Hence, many individual and interactive outcomes can be explained and interpreted in the context of the family. According to the parents' answers to the open questions, it can be seen that the parents for leisure time during the quarantine period provided different activities, such as planning intellectual and group games and competitions at home and playing the role of coach for children as compensation for absence at school; such activities have involved children in various activities, so, staying at home instead of threatening seems to provide a good capacity to pay more attention to housework and children.

Despite the insignificance of the interaction between home quarantine and gender, we can still see an increase in the average scores of fathers in burnout compared with mothers after the outbreak of the disease and staying at home. The presence of fathers at home and their involvement in the performance of household chores and children, although an opportunity to reduce the pressure of permanent and pre-defined parenting and housekeeping duties for mothers and also compensates for the lost educational opportunities of the children, but due to the lack of experience of fathers being at home so much and the division of such responsibilities for them in home quarantine conditions, led to the exhaustion of the fathers; this can be a matter of concern, especially in traditional cultures, such as Iran, where traditional gender roles are defined and accepted for men. The findings by Mangiavacchi et al. (2020) also showed that the closure and lockdown, by restricting the taking of the children to nursing centers, has led to positive changes in the involvement of fathers in caring and educational tasks of children at home and increasing children's well-being. Such involvement of fathers has also been seen, given the distribution of gender roles in European countries, such as Italy (Barigozzi et al., 2020).

The results also showed that the home quarantine does not have a significant effect on MS. This finding is inconsistent with the results of some studies based on the effect of external stress on MS reduction (Maltas, 1992; Neff and Karney, 2009, 2017; Randall and Bodenmann, 2009; Chi et al., 2011). New studies

on the effects of coronavirus and lockdown outbreaks on family interactions have shown that the lockdown has weakened the marital interactions by increasing the rate of unemployment and reducing access to financial resources (Coibion et al., 2020), especially in troubled couples (Perez-Vincent et al., 2020). The findings by Kevin and Rislá (2020) indicated the association between low income and reduced MS, especially in distressed couples. Other findings of this study showed that parents having a paid profession and are living in prosperous neighborhoods reported higher MS and well-being and lower PB. On the other hand, MS as a couple's perception of the multidimensions of marital life and the perceived benefits of a long-term relationship was formed over months and years of communication and affected by different factors, such as life skills, understanding and intimacy, and the feeling of security in the relationship, and so on (Fincham and Beach, 1999; Baumeister and Vohs, 2007). Couples with well-functional interactions support each other and use dyadic coping strategies in coping with external sources of stress (Randall and Bodenmann, 2009), as well as problem-solving techniques and marital life management skills as dyadic coping behaviors have shown a moderating role in the effects of the stressful events on marital quality (Cohan and Bradbury, 1997; Li and Wickrama, 2014). Despite the limitation of the current study in collecting data from distressed couples, an increase in the MS scores of mothers and fathers in the period of post-outbreak rather than pre-outbreak is important, although this difference is not significant, considering the family-oriented culture of Iran, it is important to pay attention to the impact of couples' participation in household chores and parenting responsibilities on MS (Rhyne, 1981; Korja et al., 2016; Liu and Wu, 2018; Leung, 2020; Yoo, 2020). In contextual explanation, as described in the descriptive analysis, engaging of parents in different activities, such as art and household activities, the extending of virtual relationships with family and relatives, the strengthening of religious beliefs, and asking help from supernatural powers, etc. can play an important role in reducing the impact of stressful events on family outcomes.

The results also showed that fathers had higher psychological well-being than mothers. Baruch et al. (1987) and World Health Organization [WHO] (2019) reported that women have poorer well-being due to more responsibilities of family based on unequal distribution of roles, as well as feeling less control over life. These studies have shown that mothers experience high stress and anxiety and low well-being due to the pressures of housekeeping and parenting responsibilities and high societal expectations of motherhood (Skreden et al., 2012; Musick et al., 2016; Meier et al., 2018; Nelson-Coffey et al., 2019). Consistent with this finding, another finding of this study showed that the mothers were more burned out than the fathers. Few evidences showed that burnout is higher in mothers or female caregivers than in fathers (Le Vigouroux and Scola, 2018; Lebert-Charron et al., 2018; Mikolajczak et al., 2018b). In many cultures, women play a permanent role in childcare. Excessive and uninterrupted childcare responsibilities, along with other responsibilities in life and trying to being a perfect mother, make them exhausted from parenting tasks, reduce their mental health, and cause emotional

problems (Meeussen and Van Laar, 2018; Sánchez-Rodríguez et al., 2019; Sorkkila and Aunola, 2020).

The finding also revealed that fathers reported greater MS than mothers. This finding is consistent with many studies on gender differences in MS (Rhyne, 1981; Olson et al., 2008; Ogolsky and Bowers, 2013; Beam et al., 2018). Women are more concerned about intimacy than men, have certain standards for being satisfied with their spouses, and are sensitive to relationship problems more than men (Olson et al., 2008; Ayub and Iqbal, 2012).

The present study is one of the few surveys done in a limited time, so it is not possible to study the longitudinal effect of home quarantine (before, now, and after quarantine). Therefore, to overcome this limitation, parents' perceptions of MS and PB in the pre- and post-prevalence period by asking questions in the form of past and present tenses were assessed; conducting the research nearly after 1 month and a half of prevalence and quarantine and its coincidence with the beginning of the New Year in Iran, type of home quarantine and not punished for leaving home, not focusing on living space and the children's age due to focus on the number of children makes the researchers to be cautious in interpreting the findings. Therefore, to study parent-child backgrounds, increase sample size, pay attention to high-risk groups, and those who lost a member of the family to COVID-19 are recommended for further research.

## DATA AVAILABILITY STATEMENT

Francisco R, Pedro M, Delvecchio E, Espada JP, Morales A, Mazzeschi C and Orgilés M (2020) Psychological Symptoms and Behavioral Changes in Children and Adolescents During the Early Phase of COVID-19 Quarantine in Three European Countries. *Front. Psychiatry* 11:570164. doi: 10.3389/fpsy.2020.570164

The coronavirus disease (COVID-19) pandemic forced the home confinement of the majority of population around the world, including a significant number of children and adolescents, for several weeks in 2020. Negative psychological effects have been identified in adults, but research about the impact of this type of social distancing measure on children and adolescents is scarce. The present study aimed to describe and compare the immediate psychological and behavioral symptoms associated with COVID-19 quarantine in children and adolescents from three southern European countries with different levels of restrictions (Italy, Spain, and Portugal). Parents of 1,480 children and adolescents (52.8% boys) between 3 and 18 years old ( $M = 9.15$ ,  $SD = 4.27$ ) participated in the study. An online survey using snowball sampling techniques was conducted during 15 days between March and April 2020, representing the early phase of the quarantine associated with COVID-19 outbreak. Parents answered questionnaires about sociodemographic data, housing conditions, immediate psychological responses during quarantine (e.g., anxiety, mood, sleep, and behavioral alterations), patterns of use of screens, daily physical activity, and sleep hours before and during the quarantine. The results revealed an increase in children's psychological and behavioral symptoms, increased screen-time, reduced physical activity, and more sleep hours/night. Italian children presented less psychological and behavioral symptoms compared with Portuguese and Spanish children. In general, hierarchical multiple regressions revealed that having an outdoor exit in the house (e.g., garden, terrace) contributed to lower levels of psychological and behavioral symptomatology. Future studies are needed to identify family and individual variables that can better predict children and adolescents' well-being during and after quarantine. Recommendations for families and implications for practice are discussed.

**Keywords:** COVID-19, quarantine, psychological symptoms, behavioral symptoms, child habits, housing conditions, children, adolescents

## INTRODUCTION

Evidence regarding experiences from past outbreaks reveals that quarantine can create a substantial strain on the population and create mental health problems [e.g., (1, 2)]. However, most studies have been focused on adult populations and the psychological impact of quarantine on children remains unclear. The worldwide coronavirus disease (COVID-19) pandemic has caused several governments in Europe to determine quarantine and home confinement. However, restrictions have been quite diverse across different European countries, and the impact of these differences on young people's mental health remains unknown. This present public health crisis and the risk of second-wave outbreaks make it urgent to investigate the psychological effects of this type of social distancing measure on children and adolescents, taking into account the different levels of restrictions established in three European countries: Italy, Spain, and Portugal.

Quarantine is a public health measure that includes the restriction of activities or the separation of healthy individuals who may have been exposed to an infectious agent or disease with the aim of monitoring symptoms and ensuring the early identification of cases (3). Throughout Europe, the severity and timing of restriction measures has differed from country to country. The point at which social distancing was enforced occurred at different dates in each country based on the infection curve. Italy, the first European Union nation to put its entire population under quarantine, closed schools on 5 March (24 February in Lombardy), 16 days after the first 50 cases of COVID-19 were reported. On the other hand, Spain and Portugal closed schools on 13 March, 4 and 12 days after the first 50 cases, respectively.

Another important difference pertains the quarantine status. In general, compliance with quarantine may be voluntary or ensured by governmental orders. Italy and Spain ordered mandatory quarantine, whereas Portugal ordered voluntary quarantine (more specifically, a "general duty of home confinement"). More importantly, no studies to date have examined whether mandatory vs. voluntary quarantine has differential effects on psychological outcomes. However, it has been suggested, for example, that the perception that others may benefit from one's situation can help to endure stressful situations and this might be the case for home-based quarantine (2).

Although the employment of lockdown practices is highly necessary to control the spread of COVID-19, public health organizations worldwide have noted the importance of supporting mental and psychosocial well-being during social isolation and restriction of movements imposed to people during quarantine (4). Consistent with these recommendations, studies from previous epidemics and recent research on COVID-19 unequivocally demonstrate the negative psychological impact of quarantine and home confinement in the general population [e.g., (2, 5–8)]. A recent review of evidence indicates several negative psychological effects associated with quarantine, including posttraumatic stress, depression, anxiety, confusion, and anger (2). This review also suggests that quarantine and home confinement may also have long-lasting psychological

effects. Other studies report emotional reactions to social distancing such as fear, isolation, loneliness, and insomnia, highlighting boredom as the greatest emotional disincentive to compliance with quarantine (1).

Experience with previous quarantine outbreaks highlights the results of prolonged quarantine periods in aspects that may indirectly influence mental health, including loss of income during quarantine, loss of job after quarantine, and disturbances in family relationships (1, 9). Some have argued that this type of disease-containment measures could cause tensions within households, inhibiting family rituals, norms, and values, that may contribute to regulate family functioning in times of crisis (1, 10).

Public health organizations and mental health experts have also acknowledged the potential adverse psychological effects of quarantine on children and adolescents [e.g., (11–13)]. Children have unique and specific needs that are disturbed by COVID-19 quarantine that includes not only home confinement but the inability to go to school and interact with peers and teachers (14). However, significantly less evidence exists regarding the psychological impact of quarantine in children and adolescents. One of the few studies concerning this population (10) found that children who had been quarantined exhibited increased rates of posttraumatic stress symptoms compared with children who were not quarantined, indicating that home confinement can be traumatizing to a significant number of children. A recent study conducted in China in February 2020 with children aged 3–18 years concluded that the most frequent psychological and behavioral problems included clinginess, distraction, irritability, and fear of asking questions about the outbreak (12).

Some authors have suggested that stressors such as lengthy confinement, fear of infection, boredom, inadequate information, lack of contact with peers and significant others, and family economic stress, can have even more significant and enduring effects on young people. The lack of personal space at home and other housing conditions can also have a significant impact on the mental health of children and parents based on previous evidence (15). For example, housing conditions, such as small apartments with limited views and indoor qualities, were related to depressive symptoms in a recent original study that investigated the effects of housing environment characteristics on mental health during the COVID-19 lockdown using a large sample of Italian university students (16). In addition, psychosocial stress and lifestyle alterations caused by home confinement could exacerbate the negative consequences on a child's physical and mental health, which may create a vicious circle (12, 17). Children's particular vulnerabilities to trauma (18), adverse events (12), and environmental risks (17) make them an important group to study the negative psychological effects of COVID-19 quarantine. Despite its importance, this topic has been somehow neglected in the literature and young people's reactions during epidemics remains understudied. This is unfortunate given that understanding young people's behaviors and emotions is essential to (1) accurately address their needs and (2) develop contextually relevant material and preventive actions for children and adolescents that may help to protect their mental health during quarantine measures. The abovementioned research indicates that the psychological effect

of quarantine can be long lasting (2), emphasizing the need to ensure that effective mitigation measures are developed as part of the quarantine planning process. Therefore, there is a global and urgent responsibility of parents and governments to guarantee that children and adolescents are protected from the psychological and physical impact of COVID-19 quarantine (17).

## The Current Study

This study aims to compare immediate psychological effects of COVID-19 quarantine in children and adolescents from three southern European countries with different levels of restrictions: Italy, Spain, and Portugal. The specific objectives are (a) to identify differences in sociodemographic variables and housing conditions across countries; (b) to describe child immediate psychological and behavioral alterations (anxiety, mood, sleep, behavioral, feeding, and cognitive alterations) during COVID-19 quarantine and compare across countries; (c) to describe child habits (use of screens, daily physical activity, and hours of sleep) before and after quarantine and explore differences across countries; and (d) to identify explanatory factors for the

psychological and behavioral alterations during quarantine by considering housing conditions.

## MATERIALS AND METHODS

### Participants

Parents ( $M = 42.26$  years,  $SD = 5.92$ ) of a total of 1,480 children and adolescents between 3 and 18 years old ( $M = 9.15$ ,  $SD = 4.27$ ) from Italy ( $n = 712$  from 94 cities), Spain ( $n = 431$  from 84 cities), and Portugal ( $n = 335$  from 94 cities) participated in the study. The majority of respondents were women (87.8%) and reported a monthly family income between 2,000 and 2,999 euros (31.8%). **Table 1** presents the characteristics of the sample and its equivalence by country. No differences were observed across countries with regard to parents' gender and age, monthly family income, and children's gender. Spanish children are younger than Italian children (but with a small effect).

Significant differences (large effect) on housing conditions were reported between participants from the three countries. Portuguese homes are larger (more square meters) than Italian or Spanish homes. Regarding exits to the outside, Italian houses

*M*, mean; *SD*, standard deviation.

<sup>a</sup>Cross-table ( $\chi^2$ ) for categorical variables and Kruskal-Wallis ( $\chi^2$ ) for continuous variables.

<sup>b</sup>Cramer's *V* for multi-categorical variables and Epsilon-squared for continuous variables.

more frequently have gardens than Spanish houses, and houses with a terrace are more frequently found in Spain compared with Portugal. Houses with only windows or a balcony are more frequently noted in Spain and Portugal compared with Italy. Greater than half of the participants (58.2%,  $n = 862$ ) had an outdoor exit. In general, most of the Italian children live in houses with a garden (51.7%), and most Spanish and Portuguese children have a balcony (33.5 and 38.6%, respectively).

The number of people living at home during quarantine is significantly lower in Spain compared with Italy and to Portugal. The frequency of people who do not leave the house (unless they have to buy groceries or other allowed activities) or who still work outside the home is not different among the three countries.

## Procedure

A cross-sectional design was used to assess the psychological symptoms and behavioral changes in children and adolescents during the early phase of the quarantine associated with COVID-19 from parents' perspective. Participants were recruited via social networks, including social media platforms (Facebook, LinkedIn, Instagram) and researchers' acquaintances (e-mail), using a snowball sampling strategy. An online survey was created *ad-hoc* and distributed in each country (via Qualtrics or GoogleForms) and data were collected for 15 days between March and April 2020. Before completing the survey, information about the objectives of the study was provided, and informed consent was requested. Each participant took ~10 min to complete the survey, and no compensation was provided. The study was approved by the Ethics Committees of the authors' institutions.

## Measures

The survey was constructed initially in English and *ad-hoc* for this study and included multiple choice and rating scale questions. The final version was pilot-tested by 10 families with children aged 3–18 years per country. Comprehension was adequate, and no changes were required in the survey.

A general questionnaire included sociodemographic questions (e.g., participant age and gender, marital status, family income, and number of children) and questions about housing conditions (e.g., square meters and outdoor exits) and specifics about the period of quarantine (e.g., number of people living in at home during quarantine).

The questionnaire about children's immediate psychological responses during quarantine ("During the past few days, compared to before quarantine, to what extent have you noticed that your child...") included 10 items related to "anxiety" (e.g., "is worried" and "is afraid of COVID-19 infection"), 6 items related to "mood" (e.g., "is sad"), 5 items related to "sleep" (e.g., "is afraid to sleep alone"), 6 items related to "behavioral alterations" (e.g., "argues with the rest of the family"), 2 items related to "feeding" (e.g., "eats a lot"), and 2 items related to "cognitive alterations" (e.g., "has difficulty concentrating"). Each item had two possible responses (yes or no). Ordinal alpha in the current sample is excellent ( $\alpha = 0.96$ ). Evidences of validity were found between the subscales and measures of anxiety (SCAS-P) and depression (SMFQ-P). Moderate correlations were observed

between depression (SMFQ-P) and mood ( $\rho = 0.39$ ) as well as between anxiety (SCAS-P) and anxiety ( $\rho = 0.46$ ).

The questionnaire about children's habits included items about the patterns of use of screens (e.g., "Before quarantine, how long did your child use screens such as iPads, TVs, mobiles, or computers daily?") and daily physical activity (e.g., "During quarantine, how much time did your child spend daily on physical activity?") before and during the quarantine with six answer options (from "<30 min" to "more than 180 min"). Parents were also asked about the number of hours their children sleep during the weekdays (before and during the quarantine).

## Data Analyses

All calculations were performed using SPSS 26 for Mac. The Kolmogorov-Smirnov test was used to assess the normality of the data. Given the lack of normality in the continuous variables, non-parametric tests were used. Ordinal alpha, which is considered the most appropriate for ordinal items is calculated. Kruskal-Wallis tests were performed to compare continuous variables across countries (Italy, Spain, and Portugal) and Chi-squared tests were used to compare proportions across these groups. Differences were considered statistically significant when the  $p < 0.05$ . Bonferroni corrections applied to  $p$ -values were used to reduce the risk of type I errors *post-hoc* analysis of Chi-squared tests. In cross-tables, Chi-square *post-hoc* tests using adjusted residuals were calculated (19). Epsilon-squared ( $\epsilon^2$ ) was used as an effect size, where small effect sizes ranged from 0.01 to <0.08, medium effect sizes ranged from 0.08 to <0.26, and large effect sizes ranged from  $\geq 0.26$ . Cramer's  $V$  was calculated as a measure of association between multicategorical variables, and interpreted as follows: >0.25 very strong, >0.15 strong, >0.10 moderate, >0.05 weak, and > 0 none or very weak (20).

The Wilcoxon matched-pair signed rank test was used to evaluate change in patterns of use of screens, daily physical activity, and hours of sleep before and during the quarantine within a group. The effect size of the statistically significant differences was estimated using Rosenthal's  $r$ , which is interpreted as follows: 0.10 = small, 0.30 = medium, and 0.50 = large (21). Mann-Whitney  $U$ -test was performed to analyze the relationship between outdoor exit (yes/no) and main outcomes.

Spearman correlations were calculated to analyze the relationship between continuous variables included in the hierarchical regression analyses. To test the association between having more symptoms in these six areas ("anxiety," "mood," "sleep," "behavioral alterations," "feeding," and "cognitive alterations") during quarantine and housing conditions, six separate hierarchical regression analyses were run using anxiety, mood, sleep, behavioral alterations, feeding, and cognitive alterations as dependent variables. Children's sex and age were included in a first step as covariates. Outdoor exit (yes/no), number of people living at home during quarantine, and square meters home were included in the second step as independent variables. Having a garden or terrace was recoded as 1 (= outdoor exit). Options "only windows," "balcony," and "other exits" were coded as 0 (no outdoor exit). Interactions between variables were analyzed in step 3. Continuous variables were mean centered to avoid multicollinearity.

## RESULTS

The present study aimed to compare immediate psychological and habit changes during COVID-19 quarantine in children and adolescents from Italy, Spain, and Portugal. We also intended to identify explanatory factors for the psychological and behavioral symptoms based on housing conditions.

### Immediate Psychological and Behavioral Symptoms in Children During Quarantine Across Countries

**Table 2** presents parents' perception of their children's anxiety, mood, sleep, behavioral, feeding, and cognitive alterations during quarantine and differences across countries. *Post-hoc* analysis revealed significant differences across countries in all dimensions in total scores (small effects) and in almost all specific items that contribute to each dimension (with small and medium effects), which are detailed in **Table 2**.

In general, children from Italy had significantly lower levels of anxiety, sleep, feeding, and cognitive alterations compared with children from Spain and Portugal. Portuguese children presented significantly more mood alterations than Spanish children. Spanish children presented significantly more behavioral alterations than both Italian and Portuguese children.

Of note, approximately one-third of children are restless, nervous, worried, uneasy, and anxious. Additionally, 27.2% are afraid of COVID-19 infection, and Portuguese children are significantly more afraid of infection compared with the other children. Greater than half of the samples are bored (52.2%) and 1/3 feel lonely, especially Portuguese and Italian children. Considering behavioral alterations, >40% of children are irritable (especially the Portuguese and Spanish), and ~1/3 argues with the rest of the family more than before home confinement.

### Children's Patterns of Use of Screens, Daily Physical Activity, and Hours of Sleep Before and During Quarantine

Significant differences were found before and during quarantine in all habits analyzed both in the total sample and in the samples of each country. **Table 3** presents children's patterns of use of screens, daily physical activity, and hours of sleep during weekdays before and during quarantine and differences across countries.

Daily use of screens noticeably increased during quarantine ( $z = -30.34$ ,  $p < 0.001$ ,  $r = 0.78$ ). Before quarantine, most children used screens from 30 to 60 min/day (35.7%), whereas the majority of children had more than 3 h of screen time during quarantine (30.1%). This pattern is roughly the same in all countries (Italy:  $z = -20.33$ ,  $p < 0.001$ ,  $r = 0.76$ ; Spain:  $z = -16.91$ ,  $p < 0.001$ ,  $r = 0.81$ ; Portugal:  $z = -14.90$ ,  $p < 0.001$ ,  $r = 0.79$ ). Differences across countries (medium effect) before quarantine were found only for the use of screens for <30 min; specifically, Spanish children more frequently used screens <30 min/day. However, during quarantine, more differences were noted across countries (see **Table 3** for detailed *post-hoc* analyses); for example, Italian children use screens less

(<30 min or between 30 and 60 min), whereas Spanish children significantly use screens more frequently (between 120 and 180 min).

Regarding patterns of physical activity, large effects were found when comparing changes before and during quarantine, for all the sample ( $z = -25.56$ ,  $p < 0.001$ ,  $r = 0.66$ ) and for each country in particular (Italy:  $z = -16.08$ ,  $p < 0.001$ ,  $r = 0.60$ ; Spain:  $z = -15.45$ ,  $p < 0.001$ ,  $r = 0.74$ ; Portugal:  $z = -12.48$ ,  $p < 0.001$ ,  $r = 0.66$ ). Before quarantine, most children practiced 30 to 60 min of physical activity daily (33.1%). However, in quarantine, most children experienced <30 min of physical activity (53%). Significant differences across countries (medium effects) were also found (see **Table 3**). For example, before quarantine, Spanish children more frequently practiced physical activity between 120 and 180 min. During quarantine, Portuguese children less frequently participated in <30 min of physical activity.

The mean number of hours of sleep during weekdays significantly increased during home confinement for the total sample ( $z = -11.75$ ,  $p < 0.001$ ,  $r = 0.30$ ) and for each country (Italy:  $z = -8.78$ ,  $p < 0.001$ ,  $r = 0.32$ ; Spain:  $z = -3.02$ ,  $p < 0.001$ ,  $r = 0.14$ ; Portugal:  $z = -8.74$ ,  $p < 0.001$ ,  $r = 0.46$ ). Additionally, significant differences (small effects) were found across the countries. Italian children slept significantly less than Spanish and Portuguese children both before and during quarantine. Before quarantine (but not during this period), Spanish children slept more than Portuguese children.

### Housing Conditions and Children's Psychological and Behavioral Symptoms During Quarantine

**Table 4** presents the descriptive statistics and correlations among children's age, housing conditions, and psychological and behavioral symptoms in study. The size of the home (square meters) was unrelated to the outcome variables. Fewer people at home during quarantine were significantly related to having more mood symptoms, and child's age was significantly related to less symptoms of sleep and behavioral alterations. Children who did not have an outdoor exit at home (garden or terrace) were significantly more likely to present anxiety ( $U = 249,292$ ,  $z = -2.13$ ,  $p < 0.05$ ,  $r = 0.05$ ), sleep ( $U = 234,875.50$ ,  $z = -4.59$ ,  $p < 0.001$ ,  $r = 0.11$ ), behavioral ( $U = 244,057$ ,  $z = -2.85$ ,  $p < 0.01$ ,  $r = 0.07$ ), feeding ( $U = 245,348$ ,  $z = -3.28$ ,  $p \leq 0.001$ ,  $r = 0.08$ ), and cognitive alterations ( $U = 251,278.50$ ,  $z = -2.35$ ,  $p < 0.05$ ,  $r = 0.06$ ) during home confinement compared with those who had an outdoor exit. Compared with girls, boys presented significantly increased levels of anxiety ( $U = 97,292.50$ ,  $z = -3.82$ ,  $p < 0.001$ ,  $r = 0.09$ ), mood ( $U = 95,936.50$ ,  $z = -4.11$ ,  $p < 0.001$ ,  $r = 0.10$ ), sleep ( $U = 99,242$ ,  $z = -4.02$ ,  $p < 0.001$ ,  $r = 0.10$ ), behavioral ( $U = 98,791.50$ ,  $z = -3.61$ ,  $p < 0.001$ ,  $r = 0.09$ ), feeding ( $U = 108,639.50$ ,  $z = -2.09$ ,  $p < 0.05$ ,  $r = 0.05$ ), and cognitive alterations ( $U = 103,479$ ,  $z = -3.30$ ,  $p \leq 0.001$ ,  $r = 0.08$ ).

Hierarchical multiple regression was performed to examine whether housing conditions (outdoor exit and number of people at home) predicted children's psychological and behavioral symptoms during quarantine after controlling for the influence

of children's age and sex. Because the square meters of the home did not have a significant correlation with psychological or behavior symptoms, it was not included in the models. As shown in **Table 5**, both the presence of an outdoor exit and the number of people at home were significant predictors of symptomatology. Specifically, having an outdoor exit at home (garden or terrace) was a significant predictor of lower levels of all symptoms, except mood alterations. This was the only significant predictor of lower levels of anxiety, sleep, and cognitive alterations. The number of people living at home was another housing condition with a significant contribution to children's symptoms, particularly mood alterations. These results indicate that the lesser the number of people at home the higher the levels of mood alterations. After controlling for the effects of child age and sex, housing conditions explained between 1.2 and 3.9% of variance. Finally, age and sex were also significant predictors of children's symptoms. To be male was a significant predictor of anxiety symptoms, feeding, and behavior alterations and to be younger was a significant predictor of behavior and sleep alterations.

## DISCUSSION

Despite previous research demonstrating the psychological impact of the imposition of quarantine in past pandemics, few studies have investigated the negative effects on children's and adolescents' mental health. The present study aimed to identify and compare immediate psychological and behavioral effects of COVID-19 quarantine in children and adolescents from Italy, Spain, and Portugal.

## Child Habits and Psychological and Behavioral Alterations During COVID-19 Quarantine

According to parents' perceptions, greater than half of the children feel bored, 40% were irritable, and approximately one-third feels more lonely, restless, nervous, worried, anxious, and uneasy, compared with the period before quarantine. This increase in symptomatology was expected based on past evidence regarding children and adults who experienced previous quarantine outbreaks (2) and recent studies on adults from China during the actual COVID-19 pandemics [e.g., (23)]. Parents also reported that their children argue more with the rest of the family during home confinement. Evidence shows that quarantine has adverse psychological effects on adults' mental health, causing depression, stress, anger, and boredom (e.g., 1,2) and that confinement of people at home can produce tensions within households (1, 10). Considering that parents in COVID-19 quarantine may be particularly distressed, these results might reflect less parental emotional availability to support children, increasing inadequate parenting practices, such as hostility or inconsistent discipline (24, 25). Consequently, children's and adolescents' symptomatology may increase, as well as the probability of arguing with family members. These findings seem to highlight the concerns from international health organizations regarding the impact of COVID-19 quarantine on children and adolescents' mental health and family relationships (4, 26, 27).

Children from the three countries have consistently changed their habits during home confinement, which can also explain the increase in children's psychological and behavioral symptoms. Most children before quarantine used screens (e.g., tablets, TVs, mobiles, computers) <1 h. During home confinement, children

are using screens for more than 3 h, which is definitely higher than levels recommended by international health organizations. For example, the WHO (28) suggests limiting screen time to 1 h for children under 6 years, and diverse studies have revealed associations between screen time and lower psychological well-being among children and adolescents (e.g., 28). In addition, physical activity was reduced in children given that greater than half now practice <30 min. However, before quarantine, children practiced between 30 and 60 min. This level is clearly below the WHO recommendations (28, 29) for at least 180 min of moderate to vigorous physical activity for children under 5 years and at least 60 min for children aged 5–17 years.

On the other hand, the results showed a positive change in children habits during quarantine, indicating an increase in the amount of sleep on weekdays. On average, children are sleeping 9.51 h per night (0.40 h more than before quarantine), which is more in accordance to WHO (28) and American Academy of

Sleep Medicine (30) guidelines (10–13 h of good quality sleep for children under 5 years; 9–12 h for children 5–12 years; 8–10 h for adolescents). However, if this increase in sleep hours is associated with delays in bedtime (frequently related to the use of screen-based activities) (31), it could be problematic. This notion should be explored in future studies.

### Differences Across Italy, Spain, and Portugal

Considering differences of social distancing measures used in the three countries (i.e., mandatory quarantine in Italy and Spain vs. voluntary quarantine/duty of home confinement in Portugal), it was hypothesized that Italian and Spanish children would present higher psychological and behavioral symptoms associated with home confinement compared with Portuguese children. However, Italian children presented less symptoms of anxiety, as well as less sleep, feeding, and cognitive alterations

\* $p < 0.05$ ; \*\* $p < 0.01$ .

compared with the other two groups of children. One possible explanation for this surprising result might be related to the fact that schools in Italy closed 8 days before schools in Spain and Portugal. Given that the data collection period occurred simultaneously in the three countries, the results may indicate that Italian children had more time to adjust to and accept the situation of home confinement and find strategies to cope with it (similar to a grief process) (32). Nevertheless, longitudinal studies are needed to explore this hypothesis. Another possible explanation might be associated with differences across countries in housing conditions and screen time. Greater than half of the Italian children live in homes with a garden, and these children spend less time on screens. On the other hand, although Portuguese children are living in larger houses, most Portuguese and Spanish children do not have outdoor exits, such as gardens or terraces, thus limiting available space for outdoor activities. Taken together, these results may suggest that Italian children are probably having more “quality play time” and engaging in activities that are healthier, screen free and in contact (although restricted) with nature compared with their counterparts, which can contribute to their reduced levels of psychological and behavioral symptoms during quarantine. These findings support studies showing children’s positive outcomes associated with less screen time (33) and indicating that engagement in outdoor activities can play a protective role in terms of young people’s mental health (34, 35).

Another important result pertains to Spanish children who presented more behavioral alterations. In particular, compared with Italians, Spanish children argue more with the rest of the family, have more behavioral problems, are angrier and are more dependent on their parents. These symptoms may be related to modifications in children’s habits during quarantine

given that this group exhibited a higher decrease of physical activity and higher levels of screen time. Previous studies have highlighted the consequences of oversedentary lifestyle and the use of screens by children and adolescents on their psychological well-being, including lower self-control, less emotional stability, more depressive and anxiety symptoms, and being more difficult to care for [e.g., (33, 36, 37)].

In turn, Portuguese children presented more mood alterations than Spanish children (e.g., feeling more lonely, sad, and frustrated) and are more children in this group feeling anxious and afraid of COVID-19 infection. This result is surprising considering that Portugal has adopted a less restrictive quarantine measure compared with the other countries in study. Some possible explanations may account for this finding. First, parental psychopathology (e.g., anxiety, depression) and offspring emotional disorders have been associated in the literature [e.g., (37, 38, 38–40)]. Consistent with this evidence, Portuguese adults present higher levels of psychiatric disorders compared with Spanish and Italian adults (22.9 vs. 9.2 and 8.2%, respectively; (41), and results showed high parental low mood and preoccupation with COVID-19, which seem to suggest the transmission of anxiety and distress from parents to children and/or within family relationships, contaminating children’s mood. Second, these differences might also be related to the Portuguese quarantine status. It is possible that the non-mandatory nature of Portuguese home confinement may be confusing to children and adolescents in the sense that it might expose them to inconsistent situations of social contact (e.g., they might see children playing on the street while are told by their parents that they cannot do it). Future studies should explore these and other possible explanations for these results.

Categorical variables: child sex (0 = male/1 = female) and outdoor exit (0 = no/1 = yes).

DV, dependent variable; B, unstandardized regression coefficient; CI, confidence interval;  $\beta$ , standardized regression coefficient; t, obtained t value for each predictor variable; p, probability;  $\Delta R^2$ , proportion of variance explained; Adj.R<sup>2</sup>, adjusted proportion of variance explained.

## Housing Conditions Predict Children's Psychological and Behavioral Symptoms During COVID-19 Quarantine

Our findings suggest that housing conditions, including having an outdoor exit such as a garden or terrace, and the number of people living at home, predicted children's psychological and behavioral symptomatology during COVID-19 quarantine. The results showed that having an outdoor exit in the house contributed to lower levels of all symptoms analyzed, except mood alterations. These findings are consistent with previous studies demonstrating that housing characteristics have a direct impact on people's well-being and mental health in general (42, 43), children's development and psychological health in particular [e.g., (44)], as well as young adults' mental health during COVID-19 lockdown (16). Evans et al. (15) argue that housing is not only a physical shelter but also a significant mental health and well-being resource. Having an outdoor exit might mean that children have more space to play freely in the house or direct contact with nature (in the case of houses with garden) and increases visual exposure and access to neighbors, thus elevating social contact (15). This feature is particularly important in a situation of home confinement and restriction of movements, promoting psychological well-being. In turn, not having these types of housing conditions may exacerbate the feeling of social isolation associated with being quarantined. This notion is consistent with evidence suggesting that families living in multiple-dwelling units experience more

social isolation and lack of access to play spaces, thus keeping children inside apartment (15, 42). In accordance with previous evidence (15), the existence of possible underlying mechanisms that may account for the link between housing conditions and children's psychological symptoms but were not investigated in this study should be considered. Having more access to play space provided by outdoor exits may also promote more opportunities for parent-child positive interactions, facilitating more adequate parenting practices (less restrictive and less rigid control over children's activities) which is particularly important to foster children's psychological well-being in times of family stress such as COVID-19 quarantine.

Findings also showed that the number of people living at home contributed significantly to children's mood alterations. A possible explanation for this finding of the "the more the merrier" may be that in times of quarantine, where children have so few opportunities for social interaction and are deprived from contact with peers, interaction with siblings acquires an even greater importance in terms of psychological well-being. This relationship may act as a buffer against the stress caused by quarantine by providing playful interactions and a peer to whom to ask for help if needed, subsequently mitigating mood swings. This result adds to evidence demonstrating the importance of siblings relationships for children's and adolescents' well-being and mental health (45, 46).

Child sex and age also contributed significantly to children's psychological symptomatology. Being a boy predicted behavioral

and feeding alterations, which is consistent with studies demonstrating that boys present higher levels of externalizing behaviors compared with girls (47). However, being a boy also predicted higher levels of anxiety symptoms, which is contrary to most of the studies that show higher prevalence of internalizing disorders among girls compared with boys (e.g., 46). Considering evidence demonstrating gender differences in physical activity levels, whereby boys are generally more physically active than girls (48, 49), these findings indicate that boys under quarantine are especially prone to develop diverse symptoms and behavioral alterations probably due to the restriction of movements and lack of opportunities to participate in physical activity that prevent boys from satisfying their developmental needs for physical activity. Actually, when compared with girls, boys presented higher levels of all studied symptoms. On the other hand, being younger also predicted behavior alterations as well as sleep changes, suggesting that younger children may be more vulnerable to the effects of home confinement. This finding is consistent with studies showing that young children are particularly vulnerable to stressful events (12) probably due to their needs of physical mobility and limited cognitive capability to understand the quarantine situation, as well as guidelines from international health organizations regarding young children responses to stress (50).

## Limitations and Implications for Future Studies

Some limitations of the present study should be mentioned. First, the cross-sectional nature of the study does not allow conclusions on cause-effect relationships, and the recruitment conducted through social networks with snowball sampling may have caused bias. Longitudinal studies and with representative samples will be crucial to deeply understand the real consequences of home confinement during COVID-19 pandemics. Second, this study relies on parent's perceptions about their children's psychological and behavioral alterations during quarantine. Parents' own level of distress may interfere with their perceptive capacities regarding children's functioning. In this sense, future studies should be based as much as possible on the report of the children and adolescents themselves regarding their home confinement experience. Because this experience and its consequences on mental health and well-being should differ according to the level of maturity of the individuals, future studies also need to compare different age groups in children and adolescents. Furthermore, it is necessary to identify and study other variables that may explain the higher levels of psychological and behavioral symptoms of children and adolescents (e.g., coping strategies, amount and quality of information about COVID-19) (17) given that the variance explained by hierarchical multiple regression models was very small. Future studies should also explore possible mediating variables related to parents or family environment (e.g., parental stress, number of hours working from home) that may diminish parental availability and attention as well as parental capacity to manage offspring difficulties and needs.

## Implications for Practice

It is essential that professionals and families are aware that being in home confinement is a hard, strange, and stressful situation for children and adolescents. It is expected that emotional and behavioral changes will occur as a way of expressing the difficulty in understanding, accepting, and adjusting to the situation. In addition, it is expected that most children return to their typical functioning provided that adequate routines and healthy habits are maintained during quarantine and children can receive consistent support from responsive caregivers (51, 52). However, some children may need psychological support after quarantine, especially those with previous psychological or development problems or those with parents struggling with mental problems or economic instability (51). To detect risk situations derived from the pandemic and home confinement (using validated multi-informant and multiproblem approaches), integrative intervention protocols are considered essential during and after home confinement (52).

Similarly, indicated preventive actions are absolutely crucial for the period after home confinement (e.g., at schools), which will allow the early detection of at-risk children, timely mitigation of the effects of a stressful situation for children and adolescents, and the reduction of mild symptoms before their aggravation (52).

Finally, because parents' and children's symptomatology are significantly related, specifically after pandemic disasters (10), and may have deleterious effects on parenting and family relationships, the identification of anxiety, depression, or posttraumatic stress disorder in children should lead clinicians to suggest screening parents' mental health.

## Recommendations for Families With Children and Adolescents

Emotional and behavioral changes are expected reactions in response to completely new situations for children and adolescents, such as being bored, lonely, irritable, uneasy, and worried, or having nightmares. It is therefore essential to pay particular attention to parenting practices at this stage, including adopting an even more authoritative discipline, talking to children about the situation using reliable and appropriate information for the child's age, and showing empathy with regard to their emotions, concerns, and frustrations for the losses that the pandemic is causing in their lives (e.g., being with friends, school routine, sport activities). It is important to set aside time to play with children, especially the smallest ones, increasing physical activity at home, for example, carried out with the family.

Children need structure, so it is essential to maintain rules and routines but also to create new "quarantine routines." It could be helpful create a flexible but consistent daily routine, including time for schoolwork and chores in which children could participate, a specific bedtime and wake-up time, and playtime with and without the family. It is important that children and adolescents can use their phone to connect with friends,

compensating for the absence of face-to-face interactions. However, they should also have technology-free time.

To compensate for the lack of space for outdoor activities (especially for those who do not have houses with gardens or terraces), it is important to engage in family activities and games that increase positive parent-child interactions and physical activity and consequently avoid excessive screen-time increases. As stated by Wang et al. (17), “with the right parenting approaches, family bonds can be strengthened, and child psychological needs met.”

Finally, it is also important that parents also monitor their own behavior and adopt self-care behaviors given that children’s and adolescents’ adaptation and coping with this situation is largely mediated by the role of parents and other relevant social agents (52).

## CONCLUSION

Our study contributes to an emergent body of literature regarding the adverse psychological outcomes associated with COVID-19 quarantine on children and adolescents, consequences that remain uncertain in a population still understudied in the field of pandemic research. The psychological stress as well as individual and family patterns’ alterations imposed by home confinement interact with housing conditions, contributing to detrimental effects on children’s and adolescents’ physical and mental health. Primary and secondary prevention measures are urgently needed to mitigate these effects; otherwise, they can be long lasting and negatively influence youth development.

The COVID-19 pandemic is showing a strong impact on people in terms of uncertainty and instability it has caused in different areas of daily life. Uncertainty and instability are also emotions that characterize emerging adulthood (EA). They generate worries about the present and the future and are a source of anxiety that impacts negatively on personal and interpersonal functioning. Anxiety seems a central effect of the pandemic and recent studies have suggested that it is linked to COVID-19 risk perception. In the present study, a sample of 1045 Italian emerging adults was collected: (1) to assess anxiety severity and perceived risk related to COVID-19 and their association and (2) to compare general health and protective factors such as attitudes about security, relationships, self-esteem, and self-efficacy across anxiety severity and perceived risk categories. The findings of this study highlighted that anxiety severity categories were distributed homogeneously across the sample and that half of the participants referred to moderate-severe anxiety. A series of analysis of variances and *post hoc* comparisons showed that general health and all protective factors decreased according to anxiety severity. They were higher in participants with high perceived risk, with the exception of self-efficacy. Given the challenging features of the pandemic and EA, it is crucial to monitor anxiety severity in order to prevent last longing effects on mental and physical health, as well as keeping emerging adults informed about the risks related to the pandemic. Intervention and supportive programs based on improving self-esteem and self-efficacy, as well as confidence in relationships, should be offered to emerging adults over the long term, beyond the current outbreak.

**Keywords:** anxiety, emerging adulthood, instability, isolation, quarantine, risk perception, SARS-CoV-2

## INTRODUCTION

The Coronavirus disease (COVID-19) (WHO) is a respiratory infection caused by a novel coronavirus named 2019-nCoV or SARS-CoV-2 or HCoV-19 (Jiang et al., 2020). In the beginning, it was identified in China where it caused an epidemic that started in December 2019 (Wu et al., 2020; Zhou et al., 2020), since which time its incidence has increased exponentially. Within months, it was declared a global pandemic by the World Health Organization. Italy was one of the first

countries hit and one of the most affected by the pandemic in terms of morbidity and mortality (Dong et al., 2020; Johns Hopkins University and Medicine, 2020).<sup>1</sup> The health system in Italy was, at one point, overwhelmed, with full intensive care departments. In response to the growing pandemic of COVID-19, on March 11, and March 21, 2020, the Italian Government imposed a national lockdown and all individuals were quarantined and forced to maintain strict social distancing from other people.

Uncertainty, insecurity, and instability in different areas of daily life including health, work and relationships were common feelings during the pandemic (Germani et al., 2020a). Moreover, they were exacerbated by scant and inconclusive information about 2019-nCoV and its deep social and economic impact (Ornell et al., 2020). Borrowing the title of a recent paper (Briem, 2020), we can say that during “COVID-19. The only certainty is the uncertainty.” Previous research emphasized the negative impact of uncertainty, insecurity, and instability on mental health and psychological well-being (Ornell et al., 2020; Torales et al., 2020). They underlined that uncertainty and the low predictability of COVID-19 personal, social, and financial consequences, are affecting people’s mental health, due to their difficulty to react successfully and satisfactorily to the situation, especially with regard to anxiety management (Jeong et al., 2016; Cao et al., 2020; Li et al., 2020a,b; Li S. et al., 2020; Wang et al., 2020). In a pandemic, fear and insecurity increase anxiety levels in healthy individuals and intensify the symptoms of those pre-existing psychiatric disorders (Shigemura et al., 2020). The number of people whose mental health is affected tends to be greater than the number of people affected by the infection (Reardon, 2015).

Studies among the Chinese general population have found that symptoms of anxiety have shown a higher increase due to COVID-19 (Li et al., 2020a,b; Wang et al., 2020). In one study, about a third of the interviewees reported moderate to severe anxiety, while they reported lower depressive and stress scores (Wang et al., 2020). In another study (Li S. et al., 2020), the most relevant change between before and after the declaration of the outbreak referred to anxiety levels, followed by depression and problems sleeping. Anxiety seems to be the central effect for populations throughout the world during the pandemic, which is raising anxiety levels in many countries (Fardin, 2020; Limcaoco et al., 2020).

However, anxiety is not always negative. It is important to highlight that it might have a positive effect on the preventative health behavior of individuals, which is strictly related to perceived risk (Brewer et al., 2007; Weinstein et al., 2007; Lin et al., 2020). Risk perception refers to people’s evaluation of the hazards that they are exposed to (Cori et al., 2020). An accurate perceived risk is crucial for managing public health risks during a pandemic because it is potentially a strong modifier of the evolution of the epidemic, since it could influence the number of new positive cases (Rogers, 1975; Ferguson, 2007; Cowling et al.,

2010; Ibuka et al., 2010; van der Weerd et al., 2011; Cori et al., 2020; Dryhurst et al., 2020).

Anxiety and perceived risk, require special attention in emerging adults during the COVID-19 pandemic. Emerging adulthood (EA) was defined as the transition period of life from adolescence to adulthood (Arnett, 2000). Because emerging adults have more autonomy than adolescents and can change their lives in terms of work, residence, and relationships, EA is considered an age of identity exploration, a stage in life where there are many possibilities. However, EA is also characterized by instability and it is a very critical period (Arnett, 2000, 2004). Emerging adults are often fraught with precarity and worry about the future (Côté, 2014; Schwartz, 2016). If, on the one hand, psychological well-being can improve during this period (Galambos et al., 2006), many emerging adults are, on the other, more vulnerable to a worsening of the symptoms of anxiety, which can impact negatively on personal and interpersonal functioning (Kessler et al., 2005; Arnett, 2007; Schwartz, 2016). Moreover, EAs engage in more risky behaviors than adults (Nelson and Barry, 2005).

At the beginning of the pandemic, experts and social media emphasized that emerging adults were not so likely to catch COVID-19, which was considered similar to the flu and thought to be a disease of the elderly (Liao et al., 2020). In line with this, in many countries, Italy included, younger people paid less attention than others to COVID-19 (Barari et al., 2020; Van Bavel et al., 2020). The news and the media reported less preventative health behavior in EA, and some people ignored advice that people practice social distancing and stay at home. When the Italian government imposed the national lockdown, specifically in the period March 18–20, Italian emerging adults (aged 18–30) practices significantly less social distancing compared to adults and the elderly and left home for non-essential reasons more often than others. Italian emerging adults reported anxiety levels lower than in other stages of life, suggesting that they had no accurate risk perception (Barari et al., 2020). However, since this time, the findings indicate that the younger population has been increasingly affected by the virus, as well as other aspects related to the pandemic, and measures implemented by the government, and there are reports that younger participants experienced higher levels of anxiety than older participants (Casagrande et al., 2020; Rossi et al., 2020). This result is in line with findings from studies on the Chinese population, which confirmed that after 10–25 days of lockdown, younger participants (<35 years old) reported significantly higher levels of anxiety than older ones (Huang and Zhao, 2020). Anxiety severity and duration predict long-term outcomes and are linked to crucial aspects of psychological functioning in EA. Moreover, Germani et al. (2020a) found that Italian emerging adults reported higher levels of anxiety than the normative sample (Pedrabissi and Santinello, 1989). At the same time, Germani et al. (2020a) showed that Italian emerging adults were aware of the severity of the COVID-19 pandemic and they were worried and concerned about it. This study (Germani et al., 2020a) therefore suggested that after an early phase of the epidemic from which emerging adults seemed to be exempt (Liao et al., 2020), there is a growing number of positive cases and first deaths in youths, the awareness-raising

<sup>1</sup> <https://www.arcgis.com/apps/opsdashboard/index.html#/bda7594740fd40299423467b48e9ecf6>

implemented by all institutions and media, and the measures taken to fight the pandemic, have affected Italian emerging adults.

This developmental phase of life can seriously impact general health status, the perception of one's value, a sense of personal competence, and security versus insecurity in relationships (Cozzarelli et al., 2003; Galambos et al., 2006; Arnett, 2016). Self-esteem (Rosenberg, 1965) is an important predictor of healthy development. Low self-esteem predicts poor mental and physical health, income, delinquency, and depression (Trzesniewski et al., 2006; Orth et al., 2009). A secure attitude in relationships is another crucial factor in EA, both in terms of changes in interpersonal relationships that occur in that period and of social cognition development (Lapsley and Woodbury, 2016; Tanner, 2016). In addition, it has a role in successful adaptation, mental health outcomes, and subjective well-being in EA (Bartholomew and Horowitz, 1991; Lopez and Brennan, 2000; Surcinelli et al., 2010; Mikulincer and Shaver, 2012; Marganska et al., 2013; Germani et al., 2020b).

Research has shown that anxiety is related to personal and interpersonal functioning such as general health (Baksheev et al., 2011), secure attitudes in relationships (Ditzen et al., 2008; Riggs and Han, 2009; Surcinelli et al., 2010; Marganska et al., 2013), self-esteem (Riggs and Han, 2009; Keane and Loades, 2017), and self-efficacy (Muris, 2002; Scholz et al., 2002). A secure attitude in a relationship, self-esteem, and self-efficacy, act as protective factors against anxiety related to the pandemic. They allow emerging adults to draw upon inner resources and to ask for help when they need it. Moreover, in general, emerging adults do not seem to have an accurate perception of risk, meaning they do not undertake preventative health behaviors in response to the COVID-19 pandemic (Barari et al., 2020; Van Bavel et al., 2020). This could be related to personal and interpersonal functioning, since perceived risk and protective versus risk behaviors in the spread of infection are associated with self-esteem and self-efficacy (e.g., Golub et al., 2007) as well as to attitudes in relationships (e.g., Feeney et al., 2000).

In light of the above, it is relevant to evaluate anxiety severity and the perceived risk related to COVID-19 among Italian emerging adults. Moreover, it is of interest to test the association between anxiety severity and perceived risk with personal and interpersonal functioning. The present study aimed: (1) to assess anxiety severity and perceived risk related to COVID-19 and their association and (2) to compare general health and protective factors such as secure attitude in a relationship, self-esteem, self-efficacy across anxiety severity categories and perceived risk. It hypothesized that: (1) anxiety severity was higher than normative level and perceived risk related to COVID-19, indicating both a stressful reaction to the quarantine as well as a high risk perception; (2) that perceived risk partially increased according to anxiety severity, highlighting an association between them. However, considering the difference between these constructs, a small-moderate association was expected; and (3) on the one hand, emerging adults' personal and interpersonal functioning becomes worse with anxiety severity, but on the other, it was better with an awareness of perceived risk about the pandemic, suggesting a positive link between high risk perception and personal and interpersonal functioning.

## MATERIALS AND METHODS

### Participants and Procedure

The sample included 1045 Italian emerging adults (aged 18–29; Mn age = 24.18; SD = 3.60) from all over Italy. About 30% of the sample were male, around the same percentage were workers. About a third of participants reported a history of psychiatric/psychological disorders, and a small percentage (6.5%) disclosed a history of chronic physical diseases. **Table 1** reports data on confirmed cases and health behaviors according to the main containment measures.

Participants filled in an online survey form from March 17 to 26, 2020. Data was collected through convenience sampling. The inclusion criteria were: (1) agreed to participate after reading the study description; (2) that they were aged between 18 and 29 years; and (3), that they completed the entire online survey form.

We obtained approval from the Ethics Committee approval from the Department of Philosophy, Social Sciences, and Education, University of Perugia (Italy). Participation was voluntary, anonymous, and no incentive reward was given. All participants were given the option to withdraw at any moment.

### Measures

#### COVID-19 Perceived Risk (PR)

Participants indicated on a five-point scale (from 1 = “not at all” to 5 = “very much”) the risk perceptions to whom they were or could be exposed to, replying to the following questions: In general, how serious do you think COVID-19 is? How much are you worried about being infected with COVID-19? How worried are you about infecting your relatives?). PR was the average score of the three items.

**TABLE 1** | Descriptive Analysis: Percentage of COVID-19 confirmed cases and health behavior and mean ( $\pm$ SD) scores and Cronbach's alpha of the measures analyzed.

	N	%
<b>COVID-19 Confirmed cases</b>		
Participants	0	0
Participants' relatives and/or friends	246	23.5
<b>COVID-19 Health behaviors</b>		
Stay at home	877	83.7
Social distancing	1036	99.2
Better personal hygiene	995	95.6
	<b>Mn <math>\pm</math> Sd</b>	<b><math>\alpha</math></b>
STAI-State	48.53 $\pm$ 12.64	0.94
COVID-19 PR	3.85 $\pm$ 0.69	0.65
RQ-SA	3.99 $\pm$ 1.85	
RSES	29.38 $\pm$ 6.34	0.89
GSE	28.38 $\pm$ 5.15	0.88
GHQ	16.24 $\pm$ 0.62	0.80

STAI, State and Trait Anxiety Inventory; PR, Perceived Risk; RQ-SA, Relationship Questionnaire – Secure Attitude; RSES, Rosenberg's Self-esteem; GSE, General Self-Efficacy; GHQ, General Health Questionnaire.

### State and Trait Anxiety Inventory-Y – State Scale (STAI-Y, Spielberger, 1989)

We used 20 items assessing how prone each participant was to anxiety in a specific moment. All the items were rated on a 4-point Likert scale from 1 (not at all) to 4 (very much so). Total scores ranged from 20 to 80, with higher scores, indicating a higher level of anxiety. Previous studies showed the *State Scale* is a reliable measure with good convergent and discriminant validity (Spielberger, 1989). The Italian version of the STAI-Y State Scale was used (Pedrabissi and Santinello, 1989).

### Relationship Questionnaire – Secure Attitude (RQ, Bartholomew and Horowitz, 1991)

We used a questionnaire asking participants to describe their secure attitude in a relationship, which had the following options: “It is easy for me to become emotionally close to others. I am comfortable depending on others and having others depend on me. I don’t worry about being alone or having others not accept me.” Participants were asked to rate their attitude from 1 (does not describe me at all) to 7 (describes me exactly). The RQ showed adequate psychometric properties (Ravitz et al., 2010). The Italian version of the RQ (Fossati et al., 2007) was administered.

### Rosenberg’s Self-Esteem Scale

Rosenberg’s Self-Esteem Scale (RSES, Rosenberg, 1965) is a 10-item self-report measure for evaluating the self-worth with a 4-point Likert scale from 1 (Strongly Disagree) to 4 (Strongly agree). A higher score indicates higher self-esteem. RSES showed adequate internal consistency and its validity has been demonstrated in different cultures and languages (Schmitt and Allik, 2005). The Italian version of the RSES (Prezza et al., 1997) was used.

### General Self-Efficacy Scale (GSE, Schwarzer and Jerusalem, 1995)

This scale evaluates an individual’s self-efficacy. It is composed of 10 items, scored on a 4-point scale from 1 (not at all true) to 4 (exactly true). The higher the score the higher the self-efficacy. GSE psychometric characteristics have been extensively studied across several countries by Scholz et al. (2002). The Italian version (Sibilia et al., 1995) was used.

### General Health Questionnaire -12 (GHQ-12, Goldberg and Blackwell, 1970)

This questionnaire assesses general and psychological distress through 12 items rated on a 4-point Likert scale from 0 (less than usual) to 3 (much more than usual). Lower scores indicate lower distress and better general health. A previous study showed GHQ-12 as a reliable and valid measure (Werneke et al., 2000). The Italian version of the GHQ-12 (Piccinelli et al., 1993) was used.

### Data Analysis

Descriptive statistics in terms of mean, standard deviation, and percentage were run for describing, anxiety, and PR related to COVID-19. Four categories of anxiety severity were created according to STAI-Y clinical cutoff (Knight et al., 1983): (1)

scores <40 indicate low anxiety symptoms, (2) scores from 40 to 50 indicate mild anxiety symptoms, (3) scores from 51 to 60 indicate moderate anxiety symptoms and finally (4) scores >60 indicate severe anxiety symptoms. Furthermore, two categories of PR were created by using the median (50th percentile).

Internal consistency was calculated based on Cronbach’s alpha. According to Vaske (2008), alpha values between 0.65 and 0.80 are considered “adequate” for scales adopted for research on human dimensions. Pearson correlation was performed to analyze the association between anxiety severity and PR. A series of Univariate Analysis of Variance (ANOVA) were run to compare secure attitudes in a relationship, self-esteem, self-efficacy, and general health across anxiety severity and PR categories, controlling for the potential interaction between them. The effect size was measured using partial eta-squared, in which small, medium, and large effects were 0.0099, 0.0588, and 0.1379, respectively (Cohen, 1988, p. 283). *Post hoc* comparisons with Bonferroni correction were conducted for anxiety severity categories. All analyses were performed using SPSS, release 25 (IBM Corp, 2017).

## RESULTS

Descriptive statistics and the internal consistency of each of the variables were reported in **Table 1**.

Results showed that 17.6% ( $n = 184$ ) of emerging adults referred to severe levels of state anxiety, 25.8% ( $n = 270$ ) moderate levels, 28.4% ( $n = 297$ ) mild levels, and then 28.1% ( $n = 294$ ) reported low levels of anxiety related to COVID-19. Referring to PR, 536 participants (51.3%) were rated as Low PR, while 509 (48.7%) participants were rated as High PR. The Pearson correlation highlighted a positive significant relationship between state anxiety and PR ( $r = 0.255$ ;  $p < 0.001$ ).

The first ANOVA showed a significant main effect of anxiety severity [ $F_{(3,1037)} = 16.72$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.046$ ] and PR [ $F = 6.47$ ;  $p = 0.011$ ;  $\eta_p^2 = 0.011$ ] categories on secure attitude in relationships, while the interaction between them was not significant [ $F_{(3,1037)} = 1.08$ ;  $p = 0.358$ ;  $\eta_p^2 = 0.003$ ]. *Post hoc* comparisons related to anxiety categories are shown in **Table 2** and they indicate that a secure attitude in a relationship was the highest in low anxiety, followed by mild-moderate, and severe anxiety. As shown in **Table 3**, a secure attitude in relationships was higher in the High PR group than the Low PR group.

The second ANOVA showed a significant main effect of anxiety severity [ $F_{(3,1037)} = 116.41$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.252$ ] and PR [ $F_{(1,1037)} = 14.01$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.013$ ] categories on self-esteem, while the interaction between them was not significant [ $F_{(3,1037)} = 0.73$ ;  $p = 0.534$ ;  $\eta_p^2 = 0.002$ ]. *Post hoc* comparisons related to anxiety categories are shown in **Table 2** and they indicated that self-esteem was highest in low anxiety, followed by mild, moderate, and severe anxiety. As shown in **Table 3**, self-esteem was higher in the High PR group than the Low PR group.

The third ANOVA showed a significant main effect of anxiety severity [ $F_{(3,1037)} = 70.91$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.170$ ] on self-efficacy, but not for PR [ $F_{(1,1037)} = 2.26$ ;  $p = 0.133$ ;  $\eta_p^2 = 0.002$ ]. The interaction between anxiety severity and PR was considered

negligible due to its effect size [ $F_{(3,1037)} = 2.88$ ;  $p = 0.035$ ;  $\eta_p^2 = 0.008$ ]. *Post hoc* comparisons related to anxiety categories are shown in **Table 2** and they indicated that self-efficacy was the highest in low anxiety, followed by mild, moderate, and severe anxiety.

The last ANOVA showed a significant main effect of anxiety severity categories on general health status [ $F_{(3,1037)} = 147.15$ ;  $p < 0.001$ ;  $\eta_p^2 = 0.299$ ]. The effect of PR was negligible [ $F_{(1,1037)} = 6.02$ ;  $p = 0.014$ ;  $\eta_p^2 = 0.006$ ] and the interaction between anxiety severity and PR was not significant [ $F_{(3,1037)} = 1.33$ ;  $p = 0.261$ ;  $\eta_p^2 = 0.004$ ]. *Post hoc* comparisons related to anxiety categories are shown in **Table 2**. They indicated that general health status was lower (less distress) in low anxiety, followed by mild, moderate, and severe anxiety.

## DISCUSSION

Uncertainty for the future and anxiety are core feelings for both this pandemic (Jeong et al., 2016; Cao et al., 2020; Fardin, 2020; Li et al., 2020a,b; Li S. et al., 2020; Limcaoco et al., 2020; Ornell et al., 2020; Shigemura et al., 2020; Torales et al., 2020; Wang et al., 2020) and the developmental phase of the life that EAs experience (Arnett, 2000, 2004, 2007; Kessler et al., 2005; Côté, 2014; Schwartz, 2016; Germani et al., 2020a). Another crucial feature of EA is the low perception of risk, which leads some

emerging adults to engage in more risky behaviors than adults (Nelson and Barry, 2005). Thus, they could represent one of the main categories of people who are vulnerable to the effects of the pandemic (Casagrande et al., 2020; Germani et al., 2020a; Huang and Zhao, 2020; Rossi et al., 2020). For this reason, the current paper explored emerging adults’ personal and interpersonal functioning taking into account anxiety severity and PR.

Italian emerging adults have reported high perceived risk about the pandemic. They rated it as severe, and they were aware of the elevated risk of being infected and infecting others, although none were directly or indirectly affected by COVID-19 (i.e., through relatives and/or friends). Moreover, their accurate perceived risk helped them in respecting the key containment measures imposed by the government, namely staying at home, maintaining social distancing, and washing hands (Brewer et al., 2007; Weinstein et al., 2007). On the other hand, it is reasonable to assume that those who underestimated the risk and severity of COVID-19, had scant knowledge and awareness of the pandemic or a denial of the risk, probably unconsciously (Cava et al., 2005; Larsman et al., 2012).

About half of emerging adults referred to moderate-severe levels of anxiety, suggesting very high distress. In response to the pandemic, they experienced a strong feeling of insecurity, of powerlessness in the face of perceived damage that can lead either to concern or to flight and avoidance. This finding is in line with previous studies that reported very high anxiety

levels among emerging adults during the pandemic (Casagrande et al., 2020; Cellini et al., 2020; Huang and Zhao, 2020; Lin et al., 2020; Rossi et al., 2020). Specifically, we found an average score very close to the one found by Lin et al. (2020) among Chinese, who assessed state anxiety with STAI-Y. However, Cellini et al. (2020), who administered the short version of the Depression Anxiety Stress Scale which distinguishes normal, mild, moderate, severe, and extremely severe anxiety symptoms during the last week, and found that 32.6% of the sample reported moderate to extremely severe scores. Moreover, Rossi et al. (2020), used the Generalized Anxiety Disorder scale in Italian adults (Mage = 38 years old) and found that 20.8% reported severe anxiety symptoms. Although the number of participants who reported moderate-severe anxiety in the present study is higher than the ones from the aforementioned studies, due to the different questionnaire administered to them and/or the different age range of the participants, it is not possible to compare these results. Finally, anxiety was partly related to risk perception, in line with the literature (Lin et al., 2020), suggesting that it may have a positive effect on preventative health behavior (Brewer et al., 2007; Weinstein et al., 2007).

Personal and interpersonal functioning such as a secure attitude in relationships, self-esteem, and self-efficacy, as well as general health status, were linked to anxiety severity. The higher the anxiety severity, the lower the general health status and protective factors. These strong feelings and responses to the instability and uncertainty caused by the pandemic, seem to be strongly related to a negative model of self and others. In other words, low self-esteem and confidence in relationships were reported by participants with severe-moderate anxiety. The latter and low self-esteem are the main characteristics of the ruminative identity style in EA as well as intrusive thoughts, which expose to depressive symptoms (Crocetti et al., 2011). Attachment is considered a crucial factor for the challenges of EA, changes in the world of interpersonal relationships that take on new significance during EA, social cognition development, and subjective well-being (Arnett, 2016). Self-esteem is an important predictor of healthy development. Instead, emerging adults with positive self-esteem and trust in relationships can face the daily challenges by using their internal sources, as well as by asking for help when they need it (Murray et al., 2000; Germani et al., 2020b). Self-esteem increases from childhood to adolescence and reaches its peak in EA (Bleidorn et al., 2015). Thus, it is of crucial relevance to take this into account as a protective factor during the health emergency. This sense of self-confidence and confidence in others could help them in controlling their anxiety and enable awareness about the severity of the pandemic. It is noteworthy that we found larger effect sizes in the comparison between anxiety categories in self-esteem and general health status than in the other psychological features assessed.

Shifting to perceived risk, positive self-esteem, and a secure attitude in relationships were reported by emerging adults who showed a high PR, namely a more accurate understanding of the situation. In other words, this finding indicates that positive self-esteem and trust in relationships might have allowed emerging adults to fully perceive and feel the severity of the COVID-19 pandemic and preoccupation for risk infection and that a

good and stable general perception of one's-own value, as well as confidence in self and others, are key factors of emotional resilience in this age group.

The limitations of this study are connected to the generalizability of the findings due to the convenience sampling method, the direction of causality between the selected variables because this study is cross-sectional, and the common variance between variables due to the measurement method (i.e., self-report questionnaires). Moreover, the fact that the entire online survey had to be completed before participants were enrolled in the study, could potentially represent a further threat to generalizability.

To conclude, the present study indicated that during the first weeks of the quarantine, Italian emerging adults evaluated the pandemic as severe with a very high risk of infection, showing a realistic perception of the situation. Anxiety was a common feeling during those weeks and its severity was positively associated with perceived risk. Both self-esteem and a secure attitude in relationships seemed to protect EAs emotionally in this context.

This study recommends monitoring emerging adults and their psychological functioning throughout all the stages of the health emergency. COVID-19 has crucially affected emerging adults' work, study, social lives, and caring responsibilities in a time of personal and interpersonal change. The various restrictions have exacerbated both economic and social inequalities. However, the current study underlined that a greater contributory factor to anxiety about this situation is connected to people's ability to understand the severity of the virus. It suggests that it is important to track anxiety severity in emerging adults during the next steps of the COVID-19 pandemic, considering that high and prolonged anxiety exposes them to mental and physical disorders. This study suggests that continuing to keep emerging adults informed about the risks related to the pandemic will promote preventative health behaviors. At the same time, public health and health policy should track anxiety severity and help emerging adults in understanding and accepting the common psychological reactions to COVID-19 without avoiding and/or denying them and the related risks. Finally, mental health interventions such as psychological therapy sessions (i.e., psychodynamically and/or behavioral cognitive-oriented) and supportive programs based on maintaining and improving self-esteem and self-efficacy, as well as confidence in relationships, which aim to help them cope with anxiety related to the pandemic, should be offered to emerging adults over the long term, far beyond the current outbreak.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Ethics Committee of the Department of Philosophy,

Social Sciences and Education of the University of Perugia (Italy). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

LB and GG organized the database and performed the statistical analysis. AG and ED wrote the first draft of the manuscript.

# Bibliotherapy: Reading OVID During COVID

*Emmanuel Stip\**, *Linda Östlundh* and *Karim Abdel Aziz*

*Department of Psychiatry, College of Medicine and Health Sciences, United Arab Emirates University, Al Ain, United Arab Emirates*

An epidemic of an infectious disease such as COVID-19 is often a source of emotional distress, even among those who have not been directly exposed to the disease. The period following the acute phase of the coronavirus epidemic and the mitigation measures will likely be hardest for medical professionals in terms of psychological impact. Bibliotherapy is a systematic intervention regarding the use of carefully selected reading materials in order to help persons to cope with stress and personal problems. This therapy can be used easily during the pandemic. The review of evidence shows that this kind of intervention can be helpful in educational and clinical contexts. During the crisis, it can be an alternative to video and film entertainment and a transition from serious medical journal clubs to a softer medical humanities experience. In this article, we summarized the historical background of bibliotherapy. We also proposed a reading list from different times, and cultures relating to pandemic, quarantine, symptoms, confinement, and social impacts (e.g., Camus, Moravia, London, Le Clezio etc.). Bibliotherapy can be a way for doctors and healthcare workers fighting on the frontline of the pandemic to find psychological support and for debriefing. Bibliotherapy can help individuals that need support for emotional distress during the pandemic to verbalize their feelings and emotions and identify new ways of addressing problems.

## INTRODUCTION

Some of us are in exile, far from our families, trapped and confined, sometimes in quarantine or starting a risky de-confinement (1–3). Remote work is possible. Television is accessible with series and continuous information. And sometimes when we choose television and are tired of counting deaths by country or county, we watch action films. And there, we no longer count the deaths and the machine-gun shots wielded by heroes rescued from so many shots and explosions. So we lean toward reading as a way of healing and not counting anymore. Sometimes, in our exile, we are not lucky to have taken a library in our suitcases with the chosen books and in a familiar language. Fortunately, there are electronic libraries and e-books. And there, we start reading and dreaming. And we are rediscovering Ovid, our alternative to Covid. Ovid, in Latin Publius Ovidius Naso, is a Latin poet who lived during the period which saw the birth of the Roman Empire. He too had to exile or confine himself to an island. The reasons for his exile remain mysterious: the subversive remarks made in “The Art of Loving” is the main reason cited by critics. One of us (ES) was able to find and read it and it was a therapy, a bibliotherapy.

This article emphasizes the importance of bibliotherapy during the COVID-19 crisis. In this article, we propose to reposition bibliotherapy as a means of treating psychological distress, boredom, isolation, and limitations during the pandemic. Bibliotherapy can be a way for doctors

and healthcare workers fighting on the frontline of the pandemic to find psychological support and for debriefing.

Confinement weighs on us and deconfinement stresses us (4, 5). Every book we love is a treasure. A window on a world, fantastic, dream-like, whacky, childish, foreign, from another era, which one then has either jealously stored in their library or carelessly buried in the back of a closet. But some volumes are even more than that. They are talismans, protective cocoons, in which we delve back into delightful times. We re-read them to soften our spleen, soothe our panic, or escape from an everyday life that has become too heavy.

## BIBLIOTHERAPY

Bibliotherapy is a form of clinical or self-developing therapy, often used in connection to psychotherapy, that includes reading as a part of a treatment (6, 7). More specifically, therapeutic reading is a source of appeasement for mental health disorders (namely, anxiety disorders, mood disorders, depressive episodes, phobias, sleep disorders, etc.) or for strengthening psychological well-being (8–12).

In the midst of the First World War, doctors and booksellers at the Alabama Military Hospital in the United States used books to relieve posttraumatic stress disorder for soldiers returning from combat (13). Then, the 1950s marked the proliferation of research on bibliotherapy in a wide variety of fields (nursing, social work, education, etc.), mainly in North America, to which booksellers largely contributed. In 1961, the definition appeared in Webster International: “bibliotherapy is the use of a set of selected readings as therapeutic tools in medicine and psychiatry; and a way to solve personal problems through directed reading.” In the 1970s, experiences multiplied and really rubbed shoulders with the mental health sector in North America and Europe (13). Care through reading applies to the elderly as well as to individuals suffering from eating disorders or childhood disorders. The experiences are numerous but nevertheless *ad hoc* and emanate from localized initiatives, often within hospital libraries. In this context, the trend cannot flourish on a larger scale because no reproducibility has been observed or implemented from one project to another (13).

Three categories of books used in bibliotherapy are identified (14): the classical repertoire (novel, poetry, biography, fiction) which, often by a process of identification, brings better well-being to the patient, and works whose theme is psychology—their approaches are varied; they can describe a current disorder as well as provide information on a specific disorder. These specifically aim to assist readers. There is a fine line between this category and the last, coined as “self-help books,” to be linked to so-called cognitive development publications of personal inspiration, offering a precise methodology to relieve a malaise.

## HISTORY

It was religious texts that came to be the most used literature for early bibliotherapy up until the mid-nineteenth century (15). The

first known organized form of bibliotherapy in clinical settings can be dated back to thirteenth century Egypt where the hospital staff and religious leaders at the Al Mansour Hospital in Cairo read the Quran to their patients in addition to medical treatment (16, 17).

The therapeutic benefit of reading was first identified by the ancient Romans and Greeks and can be found in theories by well-known scholars and thinkers throughout history (17, 18). In “Poetics,” the Greek philosopher Aristotle (384–322 BC) presented the concept of using literature and drama for healing and purification (catharsis) of negative emotions. Later, the philosopher Friedrich Nietzsche (1844–1900) and the neurologist Sigmund Freud (1856–1939) referred to Aristotle’s idea of catharsis when describing how literature can have a therapeutic effect on negative emotions (19). Similar connections between literature and therapy can also be found in the architecture of some of the earliest known libraries. The inscription “The House of Healing for the Soul” was, according to the Greek historian Diodorus Siculus (9–30 BC), written over the entrance to Ramses II library in Thebes, Egypt, around 300 BC (16, 20–23), and the inscription “apothecary of the soul” can be seen in the medieval library of the Abby of St. Gall in Switzerland (20). Inspired by Freud’s work, fairytales, symbols, and myths became a central theme within the Jungian psychoanalytic context in the mid and late twentieth century (22). Key publications such as Carl Gustav Jung’s “Man and his Symbols” (23), Marie Louise von Franz’s “Interpretation of Fairy Tales” (24), and the psychotherapeutic and gender political books “Iron John: A Book About Men” by Bly (25) and “Women Who Run with the Wolves: Contacting the Power of the Wild Woman” by Estés (26) are a few examples of how fairytales and myths can be used for self-development.

In addition, according to some authors, Bibliotherapy can be called developmental bibliotherapy (17, 27), or affective bibliotherapy (28) to differentiate it from cognitive behavioral bibliotherapy (CBT). CBT mainly uses self-help books (9).

## CURRENT RESEARCH AND PRACTICAL FRAMEWORK

In modern clinical or developmental bibliotherapeutic settings, mental health professionals may prescribe selected fiction or non-fiction materials such as novels, short stories, biographies, dramas, tales, fables, and poetry as a part of a patient’s treatment (17). A study by Bruneau and Pehrsson emphasizes the importance of choosing personalized reading materials and encourages bibliotherapists to involve their clients in the selection process as an opportunity to foster self-insight and motivation to read (28). The growing and increasingly popular self-help books are an additional form of bibliotherapy that can be used in conjunction with cognitive behavioral therapy (17). Depression, anxiety (29), posttraumatic stress disorder (30), panic attacks (31, 32), insomnia (33) and stress (34), and strokes and their psychological consequences (35) are some examples of psychiatric and psychological conditions where self-help books have been proven to be helpful.

A study published in PLOS One showed convincing results for the effectiveness of this form of care. The Scottish research team brought together more than 200 patients diagnosed with depression; half were put on antidepressants while the other followed a therapy program through reading the book “Overcoming Depression” and having related discussions with psychologists. At the end of 4 months, 42.6% of patient-readers saw their degree of depression reduce significantly compared to 24.5% of patients on medication. After 1 year, they were more able to manage depression than the other group (36). However, this study was conducted using a guided self-help CBT treatment, whereas our attempt to currently review literature on bibliotherapy is more about another category (mainly the “classical” repertoire such as novels, poetry, and biographies) and not works whose theme is psychology. One of us (ES) used a book, “Address Unknown,” a novella written by K. Kressmann Taylor, to assess the theory of mind and to propose a cognitive remediation for patients with schizophrenia. Simply reading a 20-page novella became a cognitive task, with a good ecological component (37).

Recent studies from Sweden (2020) and Poland (2017) indicate that bibliotherapy can be an efficient complement to therapy and traditional medical interventions (38, 39). However, more clinical studies are needed to support physicians and psychologists with an evidence-based framework for clinical bibliotherapy (10, 29, 34, 39).

Bibliotherapy was originally developed to treat depression. It has also been used among caregivers in recent years (40).

## CAREGIVERS AND HEALTH TEAMS

The effectiveness of bibliotherapy for caregivers has been achieved through a series of different studies. The results of these studies suggested that bibliotherapy was effective in improving the care experiences of caregivers of people with psychosis (40), as well as the resilience of caregivers who care for people with depression (41).

Several studies, including a meta-analysis, using bibliotherapy to improve the mental well-being of caregivers with neurocognitive disorders have also been considered and suggest a favorable effect on their well-being (8, 42).

With new technology and easy access to literature through online libraries and bookshops, bibliotherapy has become an efficient and inexpensive alternative to traditional face-to-face therapy (29). Self-paced reading with follow-up sessions over the phone, videoconferencing, or being in virtual reality settings enables individuals with economic, geographical, physical, or mental barriers to benefit from bibliotherapy (17). The new online or telemedicine options for bibliotherapy have the potential to work very well in pandemic and self-isolation settings.

With the pandemic, overexposure to the stressful news magnifies the feeling of threat, becomes a waste of time, and can even paralyze the individual, preventing them from protective behaviors and facing life demands. Mental health professionals may treat patients with increased emotional distress caused by the

effects of the pandemics on them, on their families, or on their community. Several recent studies highlight the psychological impact of COVID-19 and the need for guidelines and increased psychological interventions (43–45). Depression, anxiety, and insomnia are some examples of psychological distress found among the general population as a result of self-isolation, social distancing, and safety concerns (43–45). The period following the acute phase of the coronavirus epidemic is the hardest for medical professionals in terms of psychological impact (46, 47).

Despite a call for more evidence-based research about the wider effectiveness of bibliotherapy (11, 18, 30, 39, 48, 49), the reported benefits and zero harm makes bibliotherapy an effective form of therapy for individuals with mental and personal development issues (30, 49). Bibliotherapy can be useful for health professionals and physicians. Prescribing a “transitional book” means that the content is part “microbes” and part “magical realism.”

## PROPOSAL: FROM JOURNAL CLUB TO BIBLIOTHERAPY

The information explosion in the pandemic era poses a challenge on how to extract useful resources from a multitude of publications on a daily basis. Doctors and healthcare professionals are bombarded with data. The publication rate is exponential. There are already academic structures for sorting and synthesizing literature. A journal club is an effective approach to tackle these problems; therefore, it has already become an integral part of university education in almost all medical specialties. A journal club is a form of meeting regularly organized between health professionals to discuss related recently published literature. The first organized newspaper club was awarded to Sir William Osler in Montreal, Canada, in 1875, although Sir James Paget described a kind of club among some students at St Bartholomew Hospital in London to read newspapers together between 1835 and 1854 (50). Several decades later, Osler started the first journal club in the United States at Johns Hopkins Hospital in 1889. Over the next 100 years, journal clubs flourished in various medical disciplines in many countries (50).

One of the great challenges of medical education these days is the efficient selection and refinement of relevant literature from a plethora of available information. Journal club formats have evolved over time. However, with this pandemic, physicians, students, and health professional are overloaded and need to find a moment of relaxation where the knowledge can be exposed differently. In addition, exposure to so much data is very heavy. This can be a factor in increasing pressure or stress on mental health. We must arrange different times or ways of doing things to also allow an escape while reflecting on the area around us. The literature-based reading exercise can be an alternative to the austere conference of scientific articles.

The book can be a pretext for sharing experience and novels, comics, and other literary fiction invite you to escape. In these pandemic times, it may be necessary to change or also alleviate the minds of professionals and the public by offering transitional

books, i.e., that concern the subject but allow a distance and a new hedonism in the company of a book.

## POTENTIAL READING LIST

The following are some examples of bibliotherapy that one of us (ES) prescribed to their colleagues:

**The Plague** by Albert Camus has been acclaimed in Italy since the start of the pandemic. In France, sales of this novel have exploded since its appearance. In terms of containment, it ranks among the top 20 best sellers of digital books. “What you learn in the midst of the plagues is that there is more to admire in men than to despise” writes Camus. This novel, which takes place in the 1940s in Oran, Algeria, begins when a strange disease kills very large numbers of rats, then humans. Camus used an allegory to speak of evil, of everything that oppresses us that we have to fight against. This use of allegory means that a 2020 reader can find himself completely and project the coronavirus onto it. The novel lists the multiple reactions of a community to the epidemic: the authorities which are slow to react, the underestimation of the danger, the containment measures, the solidarity which is being put in place but also the profiteers who are getting richer thanks to the black market, etc. Dr. Rieux, the central figure in the novel, reflects the committed, courageous, and generous medical personnel on the front line in the fight against the epidemic. The hero of the story is a modest office worker called Grand. This character would like to write a novel and spends his time repeating the first sentence. At the start of the novel, a journalist called Rambert has only one idea in mind: to join his fiancée who is outside the city. Initially he seeks to flee as someone who today would rather follow his personal desire than obey the common good and accept this confinement which is difficult. Little by little, he will enter the solidarity movement. But as the days go by, he begins to fear that this misfortune will have no end and, at the same time, the cessation of the epidemic becomes the object of all hopes. The end of “The Plague” encourages us not to forget too quickly what we have experienced. Camus reminds us that we must not “forget what we experienced, the unhappiness that happened to us, and everything that has taken place in our capacity to be united in times of trial, to get out of our selfishness.”

**Love in the Time of Cholera.** At the end of the nineteenth century, in a small Caribbean town, Florentino, a poor young telegraph operator and a lovely schoolgirl, swore to marry and live in eternal love. For 3 years they live together, but Fermina marries Juvenal Urbino, a young and brilliant doctor. So Florentino, the betrayed lover, turns into an unrepentant seducer and strives to make a name and a fortune to deserve the one he will never cease to love, in secret, lasting for 50 years, until the day when love will triumph. The analogy proposed by the Colombian writer Gabriel García Márquez between the epidemic and the amorous passion which shakes beings is particularly deep and conducive to reflection. Cholera is not the central subject of García Márquez’s book, published in 1985, 3 years after being awarded the Nobel Prize for literature. Evil, as with Camus, is invisible. It strikes this one or that one, according to its pleasure

and according to the rules of love and chance. But with Camus, the epidemic was a metaphor for war. With García Márquez, it is closer to a loving “passion” that sneaks into the body, nourishes the same symptoms, grows and shakes the body.

**Geopolitique du Moustique** (Mosquito Geopolitics): Following in the footsteps of mosquitoes to write this book, Erik Orsenna has traveled to some of the countries where the diseases transmitted by mosquitoes are rife. In addition to his travels, there are regular visits to the Institut Pasteur in Paris. You only learn about yellow fever there. About 27,500 people died on the two shipyards, French and American, of the Panama Canal between 1882 and 1914, in particular from yellow fever without anyone really knowing what this epidemic was. It was only at the beginning of the twentieth century that we were really able to discern the causes and that the Americans, successors of the French, resolved this problem, both major and unforeseen, which did not exist in Suez. Yellow fever brought its share of corpses every day, and gave the survivors a feeling of precariousness.

**Death in Venice.** At the beginning of the twentieth century, a famous writer wrote an astonishingly topical text in these days of confinement. In his short story *Death in Venice*, Thomas Mann has indeed described the process which leads tourists to be caught in the cracks of which they can hardly root out. Beyond his masterful literary text and his intrigue which sees a writer, Gustav Aschenbach capturing a mad passion for a teenager, he works as a very discerning observer by showing the sneaky diffusion in Venice of what he called “Asian cholera.” Mann’s text helps to see how the epidemic has spread in Europe and particularly in Venice and how it is affecting the city and its people, especially tourists. We complete the list which is not exhaustive in the **Table 1**.

In Japan, Amabie, a legendary creature whose image is supposed to protect against epidemics, has emerged from oblivion since the Covid-19 crisis. In early March 2020, a tweet about this from the Kyoto University Library went viral and triggered an “Amabie-challenge” where many artists began to draw Amabie and publish their works on social networks. This helped foster creativity in a large network, an essential element of resilience.

## CONCLUSION

In this article, we presented the historical background of bibliotherapy and then suggested some books by authors, which can be used independent of culture. Even if reading does not replace a session with the psychologist or therapist, scientific studies have proven the many benefits of reading: it reduces stress, improves the quality of our sleep, and stimulates emotional intelligence. Even if it is rather a solitary activity, reading can really facilitate human relationships by making you more empathetic, provided you feel overwhelmed and transported by the story of the novel you are reading. Reading improves memory and involves memorizing to keep the plot in mind, as well as the names of the characters and their relationships. During this pandemic and in anticipation of several new waves, it is necessary to create strategies and propose concrete therapies favoring groups constrained by social distancing but

**TABLE 1** | A subjective collection of potential books covering topics relevant during times of the COVID-19 pandemic.

<b>Titles</b>	<b>Authors</b>	<b>Themes</b>	<b>Commentaries</b>
The Plague ( <i>La Peste</i> )	Albert Camus	Epidemic Plague	The characters of <i>La Peste</i> are lucky to be able to circulate in Oran, in Algeria during the ongoing plague. Camus reminds us that it's important to have moments when you recharge your batteries and regain your strength at the heart of the plague.
Love in the Time of Cholera	Gabriel García Márquez	Epidemic Cholera	Cholera epidemic forms the backdrop to a doomed love story, with an analogy being made between the epidemic and amorous passion. The cholera randomly strikes at its pleasure like the rules of love and chance, sneaking into the body, and nourishing the same symptoms.
Death in Venice	Thomas Man	Epidemic	The author describes a process which is divided into several stages: 1. Asian origin of the epidemic – > 2. Arrival of the epidemic in Europe – > 3. Identification of the “zero patient” – > 4. Transmission of the epidemic – > 5. Events – > 6. Measures taken by the authorities – > 7. Reactions from the public – > 8. Implications (departure or confinement).
The Perfume	Patrick Süskind	Olfaction	Loss of smell can be the first symptom of COVID. Süskind has put an anti-hero at the center of his action. Ironically, he throws Jean-Baptiste Grenouille, a Parisian orphan, into the world of smells. He can perceive odors from afar and dissect them. He's a stranger with a unique talent and a murderous idea. Grenouille wants to create the largest of all perfumes to finally be part of the world.
Geopolitics of the Mosquito ( <i>Géopolitique du Moustique</i> )	Erik Orsena	Infections Yellow Fever	The precariousness experienced by survivors of Yellow Fever epidemics in the early Twentieth Century is explored and how it incited self-destructive behaviors such as gambling, drugs and prostitution.
Little Women or Meg, Jo, Beth and Amy	Louisa May Alcott	Epidemic Scarlet fever	Scarlet fever is caused by group A streptococcus, transmitted through the air and most often from an affected child (a sore throat, inflammation of the tonsils, and small scarlet red spots). Treatment is based on antibiotics. One child character died from complications which was contracted after she visits the sick children of an impoverished neighbors.
The Lady of the Camellias	Alexandre Dumas	Epidemic Tuberculosis	Climbing the ranks of prostitution in record time, the heroine, passed in a few months from misery to fortune. Pulmonary tuberculosis had a venereal connotation in the nineteenth century. The novel was then adapted for the stage and performed at the Vaudeville theater before inspiring Giuseppe Verdi to play the character of Violetta in <i>La Traviata</i> .
The Masque of the Red Death	Edgar Poe	Epidemic	Poe highlights the principle of the equality of all humans in the face of death. Prince Prospero, the main character favored the knights and ladies of his court who resolved to barricade themselves against the sudden impulses of external despair. This protectionism operated to the detriment of the people kept outside the walls. Poe draws a distinction between masque and mask. Masque as expressing a dance, a masquerade, a farandole composed of masked characters.
The Scarlet Plague	Jack London	Epidemic	Jack London speaks of the carefree people spared by the disease as they watch it spread to other regions, never imagining that it will 1 day reach their own.
The Stand	Stephen King	Epidemic	Stephen King dedicates several chapters of his long novel to the transmission of the virus, by characters who do not know that they are already sick.
Station Eleven	Emily St. John Mandel	Epidemic	The author describes the collapse of our societies in the face of a lightning flu.
The Epidemic ( <i>L'epidemia</i> )	Alberto Moravia	Epidemic	The book is a satirical text on fascism.
The Horseman on the Roof	Jean Giono	Epidemic Cholera	The hero, an Italian hussar from Piedmont, is on the run after winning a deadly duel. His tribulations lead him to Manosque, in Provence, where a cholera epidemic is raging. Pursued by the authorities, who believe him guilty of poisoning the city's fountains, he wanders over the roofs of abandoned houses. Armed with inexplicable immunity and noble devotion, he put himself at the service of a few convicts in the hope of saving them.
The Quarantine ( <i>La Quarantaine</i> )	Le Clézio	Quarantine Smallpox	On a ship, passengers develop symptoms of smallpox. All are forced to land on Flat Island, a volcanic haven in the Indian Ocean, where they will have to remain in quarantine for an indefinite period. Le Clézio reports in <i>La Quarantaine</i> the experience of forced isolation, on an island where colonization separates Europeans from Indian immigrants hired to work in the colonies.
In a Perfect World	Laura Kasischke	Epidemic Influenza	The epidemic story is a tool to paint a vitriolic portrait of the American middle class.
Nemesis	Philip Roth	Epidemic Poliomyelitis	Philip Roth peels at the emotions aroused by the fury of an epidemic.
Peloponnesian War	Thucydide	Epidemic Plague	The plague of Athens devastates Greece and describes the anarchy which is spreading in the city with the disease.
The Last Man	Mary Shelley	Plague Pandemic	The author asks her readers to imagine a world in which only humans are becoming extinct. Attacked by a new, unstoppable plague, the human population collapses within a few years. Other species flourish. A rapidly decreasing band of survivors watches as the world begins to return to a state of conspicuous natural beauty, a global garden of Eden.

(Continued)

TABLE 1 | Continued

Titles	Authors	Themes	Commentaries
A world without female ( <i>Il mondo senza donne, Italian</i> )	Virgilio Martini	Unspecified virus	Conceived in the secrecy of a laboratory, at the beginning of the twenty first century, by a club of American homosexuals who have sworn the disappearance of women, the virus attacks only the weak sex, between puberty and menopause, and mows down its first victims in Haiti. Over time, the demographics are collapsing
All Fools' Day	Edmund Cooper	Radiations Mental illness	Only the eccentrics, the obsessed, creative artist, fanatics of various kinds and psychopaths seem to be immune and survive this mysterious radiation
The Ninth Day ( <i>Le neuvieme jour, French</i> )	Hervé Bazin	Influenza "super-flu"	This describes a society which flirts between the benefits of technical and technological progress and the dangers, which allows a reflection on science and the new role of men
The Eyes of Darkness	Dean Koontz	Unspecified virus	Dean Koontz novel describes a killer virus developed in a Chinese bioweapon lab called "Wuhan-400." First published in 1981 under a pseudonym, the virus, originally produced in Russian, became Chinese in a 1996, post-cold war revision of the book
Plague	Graham Masterton	Epidemic	Department of Public Health support the thesis of the ephemeral phenomenon, but the situation is deteriorating. It is a very contagious fatal disease, the virulence of which is increased 10-fold by an unknown mutation Little by little, the city sinks into chaos. The American authorities use radical methods to contain the epidemic
Pandemic 1918	Catharine Arnold	Pandemic Influenza	Rapid spread of the disease as infected populations were shifted in the wake of the war, the vicious nature of the "second wave" of the disease Spanish flu was that it often struck the healthiest rather than the elderly, young or weak

able to exchange content from a book with a therapist. This review describes bibliotherapy as a means of coping with the extraordinary situation of the COVID-19 pandemic and the associated challenges for mental health. We highlighted that bibliotherapy can be helpful to support people (mainly frontline workers) who are under emotional stress or suffering from mental illness. We provided a historical overview of bibliotherapy and also examples of potential books covering topics relevant to the times of the COVID-19 pandemic.

## LIMITATIONS

The limitation of this article is that it reflects subjective views rather than statistically sound evaluated findings. The literature for the evidence for the efficacy of bibliotherapy is still heterogeneous but is more homogenous in the field of education, school, etc. There are some studies in depression but very few well-controlled studies that often include the bibliotherapy as a part of CBT. A meta-analysis is still possible but difficult at this stage (51–54). For instance, the effects on reducing depression should be still viewed with caution due to high heterogeneity. The effects on other mental well-being outcomes are inconclusive due to limited number of studies, and this underscores the need for further research. The selection of these literary works is also

limited to a certain western culture. It would be necessary to extend it to other cultures, Asian, African, Amerindian etc.

The COVID-19 pandemic is still raging, and it is very likely that, for a relatively long time, we will have to live with it. It is the evolution of the global health situation that will dictate how we operate, its progress, and its possible setbacks. Caution is required in our collective decisions as in our individual behaviors, and the responsibility for each and every one is engaged here. We have listened to science from the start, and that is what we will continue to do in the weeks and months to come. We must also create moments of escape because our physical space to travel is no longer the same. Imaginary trips can be shared, through the literature. Bibliotherapy is a way to structure these trips in order to improve mental health resilience.

Even if containment or social limit measures are in place, technology with ZOOM, MS teams, Blackboard, etc., allows the realization of meetings based on the effects of reading on each of us.

## AUTHOR CONTRIBUTIONS

ES wrote the first version. LÖ and KA reviewed it and added complementary section. All authors contributed to the article and approved the submitted version.

(2020) Psychological Typhoon Eye  
Effect During the COVID-19 Outbreak.  
*Front. Public Health* 8:550051.  
doi: 10.3389/fpubh.2020.550051

**Background:** The COVID-19 outbreak in Wuhan, Hubei, has brought serious consequences to the lives and mental health of people and has induced psychological stress and affected behavior.

**Methods:** This study used self-designed questionnaires and SPSS to analyze the psychological and behavioral responses of people in different regions during the COVID-19 pandemic and to check for the presence of “psychological typhoon eye” (PTE) effects. The questionnaires adopted three measurement subscales, namely, the risk cognitive subscale, stress response subscale, and behavioral response subscale, and these were administered online (www.wjx.cn) to investigate the psychological and behavioral conduct of respondents from three areas that have been affected by COVID-19 to varying degrees. Exploratory factor analysis and principal component analysis were conducted to explore the factorial structure of these subscales, and confirmatory factor analysis was conducted to explore the structural validity of the questionnaires. The analysis results were used to build a revised 18-item questionnaire which validity was evaluated via ANOVA and LSD.

**Results:** Results confirm the presence of PTE in the research areas during the onset of the COVID-19 outbreak and highlight some significant differences in the cognition and emotions of the residents in these areas. PTE affected the cognition, emotions, and cognitive and emotional responses of the respondents but did not affect their behavioral responses.

**Conclusion:** The findings underscore the urgency of providing sustainable mental health care services across different areas during the COVID-19 outbreak. The residents of those areas worst hit by the pandemic, who may not have taken the situation seriously, require emotional guidance the most. Meanwhile, the residents of other areas, who showed the most negative psychological reactions to the pandemic, require a sense of security, a timely “disconnection” from negative information, an accurate cognition of stress, and an acceptance of self-responses.

**Keywords:** COVID-19 epidemic, psychological typhoon eye effect, mental health intervention, psychological stress, self-designed questionnaire

## INTRODUCTION

A new pneumonia infection was reported for the first time in Wuhan, Hubei province, China, at the end of December 2019 (1). On January 12, 2020, the World Health Organization (WHO) temporarily recommended labeling the pneumonia as a new coronavirus: “2019-nCoV acute respiratory disease” (2). On February 8, 2020, the official for China’s National Health Committee issued a notice on the temporary naming of the pneumonia as a new coronavirus infection, and the Chinese name for the coronavirus pneumonia was the “new coronavirus pneumonia” or “NCP” (3) when there was no official English name. On February 11, 2020, the novel coronavirus pneumonia was named “COVID-19” by WHO director-general Tan Taisai in Geneva, Switzerland, and the official English name became “COVID-19” (4, 5).

Based on the rapidly increasing number of confirmed and detected cases reported in Wuhan (6), COVID-19 is highly contagious, and it had posed a great threat to the health of the people of China and the world within a very short time (7, 8). The notification of the WHO on December 31, 2019, by the Chinese Health Authorities prompted health authorities in Hong Kong, Macau, and Taiwan to increase border surveillance, and this generated concern and fear that it could mark the emergence of a novel and serious threat to public health (9, 10). The virus was recognized by China and the WHO as a major public health event because of the uncertainty and complexity of its development (4), its ability to cause group behavior and the spread of public negative emotions, and its ability to have a serious impact on people’s mental health and affect their normal life, work routines, and social stability (11, 12). As a major catastrophic emergency, COVID-19 also had a broad and lasting influence, attracting the extensive attention of the media and being the subject of comprehensive media broadcasts as its influence has expanded further. Due to a variety of factors, such as environmental change (social development), humans are increasingly susceptible to both natural and technological disasters (13). In addition, with the rapid development of network communications, information cost is cheap and dissemination speed fast, and the masses were easily affected by the network of public opinion, which has led to deepening panic and uneasiness within this epidemic situation (14).

Previous studies have reported two special phenomena of regional perceived risk, namely, the typhoon effect and the ripple effect. The typhoon eye effect (15) indicates that the cognition of risk events at the epicenter is lower than the perceived risk at the surrounding areas, whereas the ripple effect (16, 17) indicates that the impact of risk events spreads out in a circle and gradually declines along with an increasing geographical distance. The psychological typhoon eye (PTE) effect focuses on the feelings and needs of people. After a disaster, those people living close to the center of the event or in high-risk areas are at risk of experiencing the worst consequences, hence triggering a “ripple effect” (18, 19). Zhang et al. (17) revealed an inverted U-shaped relationship between the distance of working adults from the pandemic epicenter and their burnout and found that

both typhoon and ripple effects may be observed in the same disaster event.

Maderthaner et al. (20) found that those residents living near nuclear reactors have a lower risk assessment of nuclear reactors than those living farther away. Melber et al. (21) also found that people living within the vicinity of nuclear facilities have a better evaluation of the safety of these facilities than the public. Lima (22) examined the distance between residents and waste incinerators in a 5-year longitudinal study and found that people who are living closer to incinerators have a higher risk perception and show less support for these structures compared with those living farther away. However, over time, these subjects developed a habitual response, that is, their risk perception was reduced.

Based on this phenomenon, Liang and Xue (23) introduced the concept of PTE, which posits that the psychological response of an individual located closer to the center of a disaster is calmer than that of an individual located farther away (24). For instance, the 2003 SARS outbreak in China triggered significant PTE effects where the risk awareness and psychological stress of people during the peak period were lower than those during the off-peak period (15). The same psychological effect was reported by Li et al. (25) after the 2008 Wenchuan earthquake. Meanwhile, Zheng et al. (26) proposed an “involvement” version of PTE and argued that the more they are involved in mining, the less villagers are concerned about pollution risks. Many scholars have also explored the causes of the PTE effect by using cognitive dissonance theory (27), simple exposure effect (21), and individual knowledge and experience theory (28).

Inspired by these theories, this study checks for any differences in the psychological and behavioral responses of people living across different regions during the early stage of the COVID-19 pandemic and determines whether a PTE effect has emerged during this period. This study defines the PTE effect as the spread of psychological and behavioral responses (15) and contends that the behavioral and psychological distress (29, 30) of people living in the worst-hit areas are less severe than those of people living outside these areas (i.e., those people living at the COVID-19 epicenter are the calmest). Given that the residents living outside the worst-hit areas show poorer cognition, emotions, and behaviors than those living at the epicenter, the impact of the COVID-19 pandemic has spread out and gradually increased along with geographical distance, thereby canceling out the ripple effect.

## METHODS

### Questionnaire Measurement Procedures

Following environmental psychology research (31) that examines the effects of the environment on individuals especially in the face of danger, this study investigates the PTE effect of the COVID-19 outbreak in Wuhan, Hubei, by using self-designed questionnaires. The pandemic has seriously affected the lives and mental health of people, thereby warranting an examination of their psychological stress and behaviors. We collected data on the risk cognition, stress response, behavioral response, and socio-demographic information [i.e., age, gender, marital status, education level, and physical conditions (i.e., COVID-19

infection)] of individuals living in three areas, namely, Wuhan, the cities around Wuhan in Hubei Province, and the cities outside Hubei, that have been affected by COVID-19 to different degrees. The questionnaire employed three subscales. First, the risk cognitive subscale (RCS) asked the questions “Do you think the NCP is serious now?,” “Do you think that you are in danger in the face of the pandemic?,” “What are your chances of catching the NCP?,” and “Do you think that the NCP can be cured?” The respondents can respond positively or negatively. Second, the stress response subscale (SRS) asked the questions “Have you been afraid of the pandemic for no reason?,” “Do you feel more nervous than usual?,” “Do you feel depressed?,” “Are you under great pressure?,” “Are you losing weight?,” and “Are you becoming sensitive and suspicious?” The respondents can answer in a variety of ways, including calm, tension, anger, fear, bored, worry, and happy, among others. Third, the behavioral response subscale (BRS) asked the questions “Do you pay attention to authoritative information?,” “Do you focus on information related to the pandemic?,” “Are you eager to investigate?,” “Do you talk to strangers?,” and “Do you look for information related to self-adjustment?” (32).

Each question was rated on a 4- or 5-point scale, with 1 denoting “least severe or not consistent” and 4 or 5 denoting “most severe or very consistent.” The scores received by each item were then averaged. For example, the item related to the severity of the epidemic in Wuhan can receive a compound score of 4.33 (32).

Sampling was conducted in three areas between January 29–31, 2020, when the epidemic had been spreading for 1 month. This period fell during the second week after the regional governments adopted policies closing cities on January 23, 2020 (33); people were seriously threatened by the epidemic, and their lives and mental health are severely affected. The questionnaire was compiled through the Questionnaire Star platform (Wenjuanxing, <http://www.wjx.cn>), and the distribution and completion of the questionnaire were accomplished using WeChat, QQ, and Sina microblog.

A total of 2,046 residents from the three selected areas completed the questionnaire on 29 January, and exploratory factor analysis (EFA) and principal component analysis (PCA) were conducted to explore the factorial structure of the three subscales. Meanwhile, 2012 residents completed the questionnaire on January 30, and confirmatory factor analysis (CFA) was conducted to explore the structural validity of the subscales.

### PCA of the Risk Cognitive Subscale (RCS)

The KMO test and Bartlett’s test of sphericity (Kaiser–Meyer–Olkin measure of sampling adequacy = 0.62, chi-square = 815.17,  $df = 15$ ,  $p < 0.001$ ) indicated that the correlation matrices on which the PCA was based were suitable for analysis. An examination of the scree plot indicated that the extracted components could be restricted to two, suggesting a two-factor model with 6-item: cognition of danger and cognition of protection consciousness. Exploratory factor analysis showed that the eigenvalues were greater than one (altogether explaining 49.51% of the variance), and the factor loadings ranged from 0.52

**TABLE 1** | Items loadings, eigenvalues and variance of the RCS with PCA.

Factor	Item	Number	Loading	Eigenvalue	% of variance
Recognition of danger	The severity of the epidemic	R1	0.62	1.74	25.25
	Necessary isolation of villages	F2	0.64		
Cognition of protection consciousness	Own risk	R2	0.6	1.23	24.26
	Probability of catching the NCP	R3	0.52		
	Protective measures’ identification	F1	0.69		
	NCP can be cured	R4	0.72		

to 0.72, suggesting that the risk cognitive subscale’s structural validity was acceptable (see **Table 1**).

### PCA of the Stress Response Subscale (SRS)

The KMO test and Bartlett’s test of sphericity (Kaiser–Meyer–Olkin measure of sampling adequacy = 0.92, chi-square = 10,587.91,  $df = 55$ ,  $p < 0.001$ ) indicated that the correlation matrices on which the PCA was based were suitable for analysis. An examination of the scree plot indicated that the extracted components could be restricted to two, suggesting a two-factor model with 11 items: emotional responses and somatic reactions. Exploratory factor analysis showed eigenvalues greater than one (explaining a total of 58.27% of the variance) and factor loadings ranging from 0.50 to 0.83, suggesting that the structural validity of the SRS was acceptable (see **Table 2**).

### PCA of the Behavioral Response Subscale (BRS)

The KMO test and Bartlett’s test of sphericity (Kaiser–Meyer–Olkin measure of sampling adequacy = 0.84, chi-square = 4,604.52,  $df = 28$ ,  $p < 0.001$ ) indicated that the correlation matrices on which the PCA was based were suitable for analysis. An examination of the scree plot indicated that the extracted components could be restricted to two, suggesting a two-factor model with eight items: attention to information and behavioral reactions. Exploratory factor analysis showed eigenvalues greater than one (altogether explaining 57.22% of the variance) and factor loadings ranging from 0.56 to 0.84, suggesting that the structural validity of the BRS was acceptable (see **Table 3**).

To further verify the consistency between the model and the real situation, we conducted a confirmatory factor analysis on the data obtained from the formal questionnaire. The fit indexes of the 3-subscale model of 25 items (see **Tables 1–3**) were not ideal. After deleting the items with low correlations with this factor in the RCS, SRS, and BRS, it can be seen from **Table 4** that the fit indexes of the 3-subscale model with 18 items (**Figure 1**) were higher than those of the 3-subscale model with 25 items and

**TABLE 2** | Items loadings, eigenvalues and variance of the SRS with PCA.

Factor	Item	Number	Loading	Eigenvalue	% of variance
Emotional responses	More nervous and anxious	Q1	0.73	5.26	35.33
	Afraid for no reason	Q2	0.74		
	Easily upset or frightened	Q3	0.82		
	Feel depressed	Q4	0.77		
	Unable to calm down	Q5	0.83		
Somatic reactions	Losing weight	T1	0.50	1.15	22.94
	Feel tired for no reason	T2	0.62

	Focusing on the epidemic information	X1	0.70		
	Dare not talk to strangers	J3	0.56		

conform to the theoretical concept of this study. The fit indexes of the two models are shown in **Table 4**.

Briefly, the questionnaire was divided into three subscales: the risk cognition subscale (RCS), the stress response subscale (SRS), and the behavioral response subscale (BRS). Each subscale had two factors representing different psychological and behavioral states. The RCS consisted of five items, the SRS consisted of seven

**TABLE 4** | Evaluation of questionnaire models.

Index	CMIN/df	RESEA	NFI	IFI	CFI	GFI
3-sub-scale model of 24 items	20.92	0.10	0.70	0.72	0.71	0.85
3-sub-scale model of 18 items	25.67	0.11	0.73	0.74	0.74	0.89

items, and the BRS consisted of six items. The structure of the RCS, SRS, and BRS are shown below (**Table 5**).

## Formal Investigations

### Participants

A revised 18-item questionnaire (**Table 5**) was closed on January 30–31 by 4,076 residents after the exploratory factor analysis. Participants included 1,363 (33.44%) residents of Wuhan, 1,320 (32.38%) residents of cities around Wuhan in Hubei province, and 1,393 (34.18%) residents of cities outside Hubei province. There were 1,929 males and 2,147 females with an average age of  $20.17 \pm 2.88$  years; this was a representative group, generalized due to the homogeneity of the group, and young people were recruited via social media. All respondents had not been infected with the COVID-19 and voluntarily participated in the survey (**Table 6**).

The variables were generally distributed, and the multiple testing was controlled.

### Statistical Analyses

The statistical analyses were performed using SPSS 20.0 for Windows (SPSS Inc., Chicago, Illinois). The statistical methods and data analysis results were described in detail as follows.

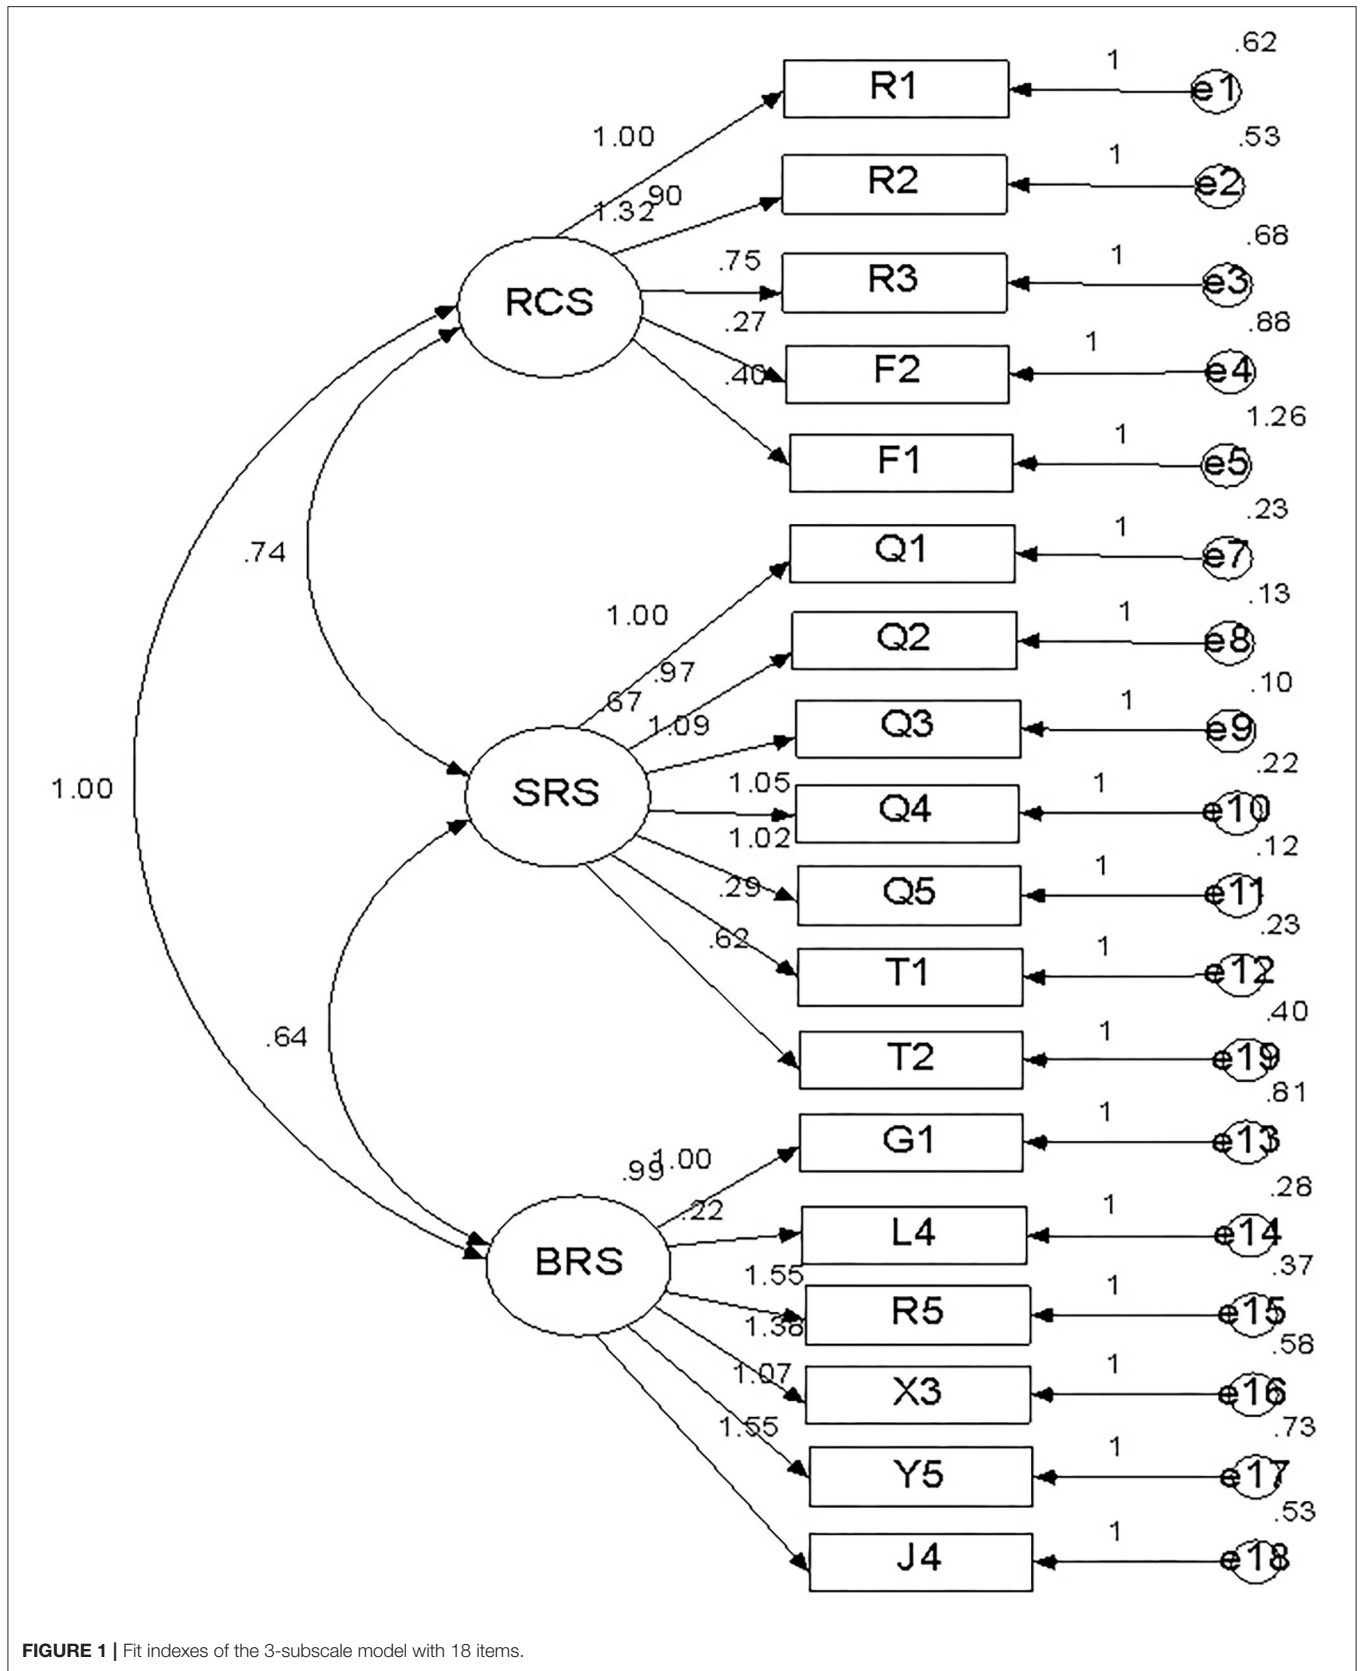

We conducted the ANOVA for the items in the three subscales for the three regions and the LSD for the multiple comparisons. The results of the ANOVA and LSD showed that there were statistically significant differences among the three groups with respect to their RCS, SRS, and BRS scores, and there were some commonalities among some items with regard to the three subscales (see **Figures 2–4**).

## RESULTS

### Differences in Risk Cognition Among the Residents of the Three Areas

#### Cognition of Danger

The ANOVA and LSD showed that there were no significant differences in cognition of the epidemic severity [ $F_{(2, 4,073)} = 0.083, P = 0.921$ ] among the residents of the three areas. Most of the participants agreed that the epidemic was very serious. However, there was a major difference in terms of the necessary isolation of villages [ $F_{(2, 4,073)} = 10.498, P < 0.001$ ] among the residents of the three areas. Residents of cities around Wuhan in Hubei province were the most supportive of social isolation, they had the greatest fear of the virus spreading, and they supported combating the virus through isolation. Conversely, the residents of Wuhan city were the least supportive.

**TABLE 5 |** The structure of the RCS, SRS, and BRS.

Factor	Recognition of danger	Cognition of protection consciousness
RCS	The severity of the epidemic Necessary isolation of villages	Protective measures' identification Own risk Probability of catching the NCP
Factor	Emotional responses	Somatic reactions
SRS	More nervous and anxious Afraid for no reason Easily upset or frightened Feel depressed Unable to calm down	Losing weight Feel tired for no reason
Factor	Attention to information	Behavioral responses
BRS	Attention to authoritative information Information of self-adjustment	Think all have novel coronavirus Washing or cleaning hands Eager to have an investigation Initiative to avoid strangers

**TABLE 6 |** Description of samples in three areas.

Areas	N	Gender (M/F)	Mean age (SD)
Wuhan City	1,363/1,363	600/763	19.85 (2.80)
Cities around Wuhan in Hubei province	1,320/1,320	630/690	19.52 (1.74)
Cities outside Hubei province	1,393/1,393	699/694	21.11 (3.50)

**Cognition of Protection Consciousness**

The ANOVA and LSD showed that there were significant differences in people's own risk cognition [ $F_{(2,4,073)} = 6.625, P = 0.001$ ], the probability of catching the NCP [ $F_{(2, 4,073)} = 15.865, P < 0.001$ ], and protective measures' cognition [ $F_{(2, 4,073)} = 18.073, P < 0.001$ ] among the residents of the three areas. Residents of cities outside Hubei province thought they were in the greatest danger, but the residents of Wuhan city and of the cities around Wuhan in Hubei province felt less danger. In addition, residents of cities outside Hubei province thought they were the most likely to be infected, but the residents of cities around Wuhan in Hubei province felt that they were less likely to become infected, and the residents of Wuhan city thought they were the least likely to become infected. Compared to the residents of Wuhan city, the residents of cities around Wuhan in Hubei province and outside Hubei province had the greatest belief in the effectiveness of wearing masks, washing hands and disinfecting, and they were more confident that they could prevent infection in this way. Participants from Wuhan city were the least cautious or most skeptical regarding virus protection measures. The statistical analysis results are shown in **Figure 2** below.

**Stress Response Differences Among Residents of the Three Areas Emotional Responses**

The ANOVA and LSD shown there are the significant differences in the emotional responses among the residents of the three areas, including being more nervous and anxious [ $F_{(2, 4,073)} = 8.985, P < 0.001$ ] afraid for no reason [ $F_{(2, 4,073)} = 12.273, P < 0.001$ ], easily upset or frightened [ $F_{(2, 4,073)} = 9.931, P < 0.001$ ], depressed [ $F_{(2, 4,073)} = 5.541, P = 0.004$ ], and unable to calm down [ $F_{(2, 4,073)} = 7.335, P = 0.001$ ]. Residents of cities outside Hubei province were the most nervous and anxious, the most afraid for no reason, the most easily upset or frightened, the most depressed, and the most unable to calm down, while the residents of Wuhan city and cities around Wuhan in Hubei province reported these negative feelings less frequently. The residents of Wuhan city were the least afraid for no reason, and the residents of cities around Wuhan in Hubei province were the least nervous and anxious, least upset or frightened, least depressed, and least unable to calm down.

**Somatic Reactions**

The ANOVA and LSD showed that there was no significant difference in losing weight [ $F_{(2, 4,073)} = 2.58, P = 0.076$ ] among the residents of the three areas. Most participants did not significantly lose weight as a result of the epidemic. However, there was a significant difference in the participants' moods and whether they felt tired for no reason [ $F_{(2, 4,073)} = 3.077, P = 0.046$ ]. The residents of cities outside Hubei province were the most prone to feel tired for no reason. The residents of Wuhan city and of cities around Wuhan in Hubei province felt comfortable, and the residents of cities around Wuhan in Hubei province were the most comfortable. The statistical analysis results are shown in **Figure 3** below.

**Behavioral Response Differences Among the Residents of the Three Areas Attention to Information**

The ANOVA and LSD showed that there were significant differences in terms of the participants' attention to authorities [ $F_{(2, 4,073)} = 16.076, P < 0.001$ ] and whether they looked for information resources for self-adjustment [ $F_{(2, 4,073)} = 6.005, P = 0.002$ ]. The residents of cities outside Hubei province paid attention to authoritative information, but the residents of Wuhan city and of cities around Wuhan in Hubei province were less concerned. The residents of cities outside Hubei province more frequently searched for psychological adjustment information, while the residents of Wuhan city and the residents of cities around Wuhan in Hubei province needed less psychological adjustment.

**Behavioral Responses**

The ANOVA and LSD showed that there were no significant differences among the residents of the three areas in terms of thinking (making some judgments) that all strangers have the novel coronavirus [ $F_{(2, 4,073)} = 0.118, P = 0.897$ ], frequently washing or cleaning hands [ $F_{(2, 4,073)} = 2.186, P = 0.112$ ], and taking the initiative to avoid strangers [ $F_{(2, 4,073)} = 2.753,$

**FIGURE 2** | Mean Z-scores of the Risk Cognitive subscale (RCS). \*\*\* $P < 0.001$ .

**FIGURE 3** | Mean Z-scores of the Stress Response subscale (SRS). \* $P < 0.05$ , \*\* $P < 0.01$ , and \*\*\* $P < 0.001$ .

$P = 0.064$ ]. Most participants thought that strangers were carrying the virus, agreed that washing or cleaning hands could prevent the virus and practiced hand washing frequently, and took the initiative to avoid strangers. The data also showed that there was a significant difference in wanting to have a physical investigation [ $F_{(2, 4,073)} = 33.537, P < 0.001$ ] among residents of the three areas. The residents of Wuhan city were the most doubtful about their health and more eager to have a general investigation. The residents of cities around Wuhan in Hubei province were less eager to have a general investigation, and the residents of cities outside Hubei province were the most eager. The statistical analysis results are shown in **Figure 4** below.

## DISCUSSION

The survey data show proof of a PTE effect at the initial stages of the COVID-19 outbreak (17, 34), but no ripple effect was observed. Specifically, the respondents showed PTE effects in their cognition and emotions (the degree of their cognitive and emotional responses increased along with geographical distance) but did not show PTE effects in their behaviors.

### Psychological Typhoon Eye Effect of Cognition

As the number of confirmed cases and deaths from the epidemic continued to rise daily, most residents truly felt the threat from

the virus, and participants in Wuhan, cities around Wuhan in Hubei province, and cities outside Hubei province generally believed that the NCP was horrible (18). In addition, participants from the three regions exhibited some significant differences in other aspects of their cognition of the epidemic, especially in places that differed from the usual perception, clearly showing psychological typhoon eye effects. For instance, residents of cities outside Hubei province thought they were most at risk of contracting COVID-19, and residents of Wuhan city and cities around Wuhan in Hubei province perceive lower risk of contracting COVID-19. Residents of Wuhan city perceived the least danger of the virus spreading and expressed the least support for isolating villages. Residents of Wuhan had the least cognition of protection consciousness and the lowest proportion of participants who scored highly (wearing masks, washing their hands frequently, and disinfecting regularly). Although Wuhan was the worst-hit area, with the highest number of people infected and the highest speed of transmission, among the study participants, the Wuhan residents had the lowest perception of whether they could be infected with the virus.

### Psychological Typhoon Eye Effect of Emotions

The psychological typhoon eye effect was the most obvious in the emotions of residents during the epidemic period, and this was reflected in multifarious negative emotions such as anxious thought, fearful thought, and depressed mood. Participants who

were farther from the center of the epidemic had a higher intensity of negative emotions than those who were closer to the center. The proportion of residents in cities outside Hubei province who responded positively to the item “it was easier to be nervous thought and anxious thought than usual” was higher than the proportion of residents of the other two regions who responded the same way. Compared to residents of the other regions, Wuhan residents showed the most stable state of mind; they had the lowest proportion of unprovoked fear. Residents outside Hubei province were the most likely to feel depressed, uneasy, and restless, and the Wuhan participants were the least likely. The residents who were closer to the center of the epidemic had more positive emotions and were more relaxed than the residents of the other two regions.

## Psychological Typhoon Eye Effect of Behaviors

During the transmission of COVID-19, residents were able to consciously take protective measures, such as washing their hands frequently and wearing masks. Regarding behavioral responses, participants were able to diversify their web-based messaging platforms to maximize the breadth and depth of their knowledge about COVID-19. Meanwhile, significant psychological typhoon eye effects were not found in the behavioral responses of residents. Residents outside Wuhan city paid more attention to the epidemic and authoritative information that was released. In addition, compared with the other two regions, residents from outside Hubei province had the highest average score for active self-adjustment; residents outside Hubei province were more inclined to look for information resources to deal with their negative emotions and more actively relieve stress.

The residents across the three areas show consistent behavioral responses to the pandemic, and these responses may have been more stable than their emotions and cognition. Therefore, a sustainable healthcare service for guiding cognition and emotions is urgently needed during the COVID-19 outbreak, and different measures should be adopted across various areas.

## Limitations

This study had several limitations (32). First, the questionnaire was a self-report questionnaire in the context of China’s culture, and the psychological symptoms and assessments were not confirmed via clinical evaluations. Second, the residents were just the young group (people) recruited in social media. Third, the study design was cross-sectional, which fails to provide valid information about the previous mental health of the subjects.

## CLINICAL IMPLICATIONS

The World Health Organization declared the COVID-19 outbreak a pandemic (35), and many countries have introduced social distancing measures (with some cities even closing themselves to public) to curb the transmission of the virus. These measures, which have ranged from mandatory quarantine to voluntary self-isolation, have socially isolated many people, thereby placing their mental and emotional health at risk (36).

Based on our findings related to the PTE effect of the pandemic, mental health intervention measures for residents residing in different areas or countries should be an important part of national disaster programs. Governments, media platforms, mental health services, and social support groups can also help alleviate negative cognition and emotions.

## Mental Health Intervention Measures for Residents of the Worst-Hit Areas

### Strengthening Emotional Guidance

The survey found that compared to residents of the two other regions, residents of Wuhan were more noncommittal about negative states, paid less attention to authoritative and positive events, and appeared to be in a more careless state. This might be related to long-term exposure to a dangerous environment, resulting in taking a dim view. Thus, we should quickly inform those near the center of the epidemic about the seriousness of epidemic prevention and control, strengthen their awareness of the crisis, and place the whole city on alert. In addition, more influential news media, especially the WeChat official account that most people paid attention to, should provide some credible scientific resources about how to correctly understand and view self-emotion and how to effectively adjust negative emotions.

### Strengthening Education About Protection Consciousness

The survey found that residents of Wuhan had insufficient awareness of virus protection and paid less attention to official information than residents of the other two areas. Therefore, relevant media needs to pay close attention to the situations of residents; do a good job as disseminators of the official “virus protection guide,” popular science, and protection knowledge; improve residents’ protection consciousness; enhance risk assessment and prevention awareness; urge residents to objectively and carefully understand the characteristics and dynamics of the epidemic situation; pay attention to the sources of infection risk; prevent residents from being inattentive and blindly optimistic; and encourage residents to develop good health habits.

### Strengthening Training on Effective Responses

The study found that compared to residents of the two other regions, people in Wuhan were less concerned about authoritative information, were more eager to thoroughly check their physical condition, and were less likely to adopt appropriate channels for psychological adjustment to reduce their stress. Obviously, these actions are not conducive to maintaining psychological balance in the face of an epidemic, and they tend to aggravate people’s negative emotions. Different behavioral responses to stressful events can also affect individuals’ psychological responses and stress states, especially in the subconscious context. Therefore, we should guide people near the center of the epidemic to acknowledge their objective environments, internal emotions and stress responses and adopt appropriate, reasonable, and effective response behaviors to attempt to solve problems. Furthermore, the government should establish psychological support institutions and strengthen

publicity and training to enhance the awareness and behavior of Wuhan citizens seeking psychological assistance.

### **Mental Health Intervention Measures for Residents Outside the Worst-Hit Areas Eliminating Unprovoked Fear and Building a Sense of Security**

The survey found that residents outside Wuhan were more worried, more uncertain about the risk, more afraid of being infected, and less confident than residents of the other two regions. We need to pay attention to this category of residents and provide emotional counseling (37, 38), reducing tension and improving logical thinking to help them to vent their tension and fear. Relevant information release platforms should guide them to examine whether their access to information is reliable to examine whether the source of their own insecurity and threats is true and to improve their information literacy and reasonable questioning ability to correctly assess the accuracy of information. For areas outside the center of the epidemic, it is suggested that the government should increase information transparency, provide timely disclosure of the latest status of the epidemic, offer timely refutation of rumors, and use simple and easy to inform people about the current status and how to address it.

#### **Timely “Disconnection” From Negative Information**

The survey found that compared to residents of the other two regions, residents outside Wuhan tended to pay more attention to information from the Internet, and their emotions were more easily affected. Many residents suffered from receiving negative and upsetting information and fell into a vicious cycle of “hypochondriac concerns - physical discomfort - anxiety aggravation”; the symptom characteristics were examined by consideration of an anxious mood, depressed mood, anxiety sensitivity (39). Although information is useful, people should not be too eager to read it, as this can make it difficult to eliminate negative emotions, and residents such as these will be more prone to worry, fear, and other negative emotions. Currently, what is needed is timely “separation” that can allow these individuals to decrease the amount of attention they give to the epidemic situation. The correct reporting principle was neither complete epidemic information nor no epidemic information, which could make residents work and rest regularly.

#### **Accurate Cognition of Stress and Acceptance of Self-Response**

During an epidemic situation, everyone experiences different degrees of psychological distress, and we should therefore provide early warnings in a timely way so that residents are ready to accept negative emotions and psychological problems. The relevant departments should work to calm and help residents during the epidemic so that they do not experience as much doubt and worry. The relevant departments should also guide residents to try to accept some negative emotions and their own reactions so that they are aware of psychological changes and can

become more accepting of the objective existence of a negative psychological state during the epidemic. This will allow residents to look at and recognize themselves to then solve problems and face psychological crises more rationally.

### **CONCLUSION**

The current research indicated that COVID-19 had affected the mental health and daily lives of the residents of three areas. Residents who were closer to the center of the epidemic were more relaxed, less anxious or panicked, paid less attention to authoritative and psychological adjustment information, sensed less danger, and experienced fewer emotional reactions in the earlier phase of COVID-19 than residents who were farther away. More attention should thus be paid to this group.

### **DATA AVAILABILITY STATEMENT**

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

### **ETHICS STATEMENT**

The study was designed in accordance with the tenets of the Declaration of Helsinki. Approval from the ethical authority of School of Educational Science, Huazhong University of Science and Technology was granted. Confidentiality and the statement confirming informed consent was managed by placing anonymous coding of one self-report questionnaires.

### **AUTHOR CONTRIBUTIONS**

YZ, GW, SX, FH, YB, ML, NL, and XC: conceived and designed the questionnaire. GL and JZ: recruitment and payment of participants. GW, YZ, and QX: analyzed the data. GW, SX, GL, and XC: wrote and revised the paper. All authors contributed to the article and approved the submitted version.

The restriction of numerous sectors of society and the uncertainty surrounding the development of the COVID-19 pandemic have resulted in adverse psychological states to college students isolated at home. In this study, we explored the mediating role of fatigue in the effects of epidemic rumination and resilience on depressive symptoms as well as how epidemic rumination and resilience may interact with one another. A large sample of Chinese college students ( $N = 1,293$ ) completed measures on epidemic rumination, resilience, fatigue, and depressive symptoms. Results indicated depressive symptomology was positively predicted by epidemic rumination while negatively predicted by resilience. In both cases, fatigue partially mediated these effects and positively predicted depressive symptoms. Unexpectedly, epidemic rumination and resilience interacted in a manner where the effect of rumination on fatigue became stronger as resiliency increased. Theoretical and practical implications are provided to further interpret the results.

**Keywords:** COVID-19, epidemic rumination, depression, fatigue, resilience

## INTRODUCTION

The heavy losses to the lives and property of people around the world from the global outbreak and spread of COVID-19 has induced severe psychological trauma to those affected. China was one of the earliest countries to be affected by COVID-19 and likewise one of the first to implement widescale measures to curb viral spread. In an effort to limit the spread among youth on college campuses, the Ministry of Education in China extended Winter recess and postponed the start of Spring semester. For Chinese college students, prolonged time at home with limited ability to go outside meant doing one's part to stop the spread of COVID-19. However, this came at the cost of abating their participation in normative social activities, such as meeting friends or participating in extracurricular activities. Such public health measures have led to a downstream torrent of negative mental health outcomes. Indeed, several studies have found that COVID-19 related stressors accrued a myriad of negative effects on mental health, such as inducing symptoms of both anxiety and depression [e.g., (1–3)].

Although few in number, these early studies have troubling implications for the general public knowing that depression has been linked to high rates of morbidity, recurrence, disability, and suicide (4), and has since become one of the major factors endangering human health (5). While

some evidence suggests that the physiological damage caused by depression may be short-lived, the psychological effects may be long-term (5). As is the case with many large-scale disasters, the negative mental effects COVID-19 induced on its general populace is rudimentary. Despite this, little attention has been given to the mental health status of younger individuals within the COVID-19 body of research (6). Because college students are often at the developmental stage in which they transition from adolescence to adulthood, this population may be particularly at risk. As the world continues its fight against the pandemic, it remains highly imperative to probe the antecedents of the onset of depressive symptoms amongst college students to design effective social interventions (7–9). Contributing to this significant gap in literature, we explored how resiliency and COVID-19 specific rumination may, respectively, mitigate and exacerbate fatigue, which in turn, increases the severity of depressive symptoms. Further, we examined whether resiliency and rumination interacted in a manner such that resiliency buffered the effect of rumination on fatigue.

## Epidemic Rumination and Depression

One's susceptibility to depression is partly contingent upon individual factors that can play a promotive role in the occurrence and development of the mental illness (10). Specifically, ruminative response style is argued to be a key risk factor for depression (11). Rumination is characterized by persistent and passive cognitive deliberation of negative stressors and events, ultimately aggravating preexisting depressive symptoms (12, 13) and crippling one's abilities for positive problem-solving (14–16). Those who exhibit greater rumination have been documented to experience more intense negative emotions (4, 17–19) and sense of hopelessness (20). Accordingly, rumination is largely in part considered a maladaptive response to stressors, given its large consumption of cognitive resources.

As rumination hinders adaptive problem-solving (21) and induces greater hopelessness (20), individuals may further lose the motivation to tackle the source of the issue, resulting in prolonged depressive symptoms (22). Early evidence of the role of rumination on stress consequences amid the COVID-19 pandemic has generally supported prior findings [e.g., (3, 23)]. However, these studies have measured general ruminative tendencies within the individual. Because it may be possible that individuals that otherwise do not engage in rumination during normative times developed ruminative tendencies specific to only COVID-19, we contend that a more target-specific approach may be necessary to better capture the cognitive responses to the novel virus. Following the definition of general rumination (24), we define *epidemic rumination* as ruminative tendencies specifically pertaining to the events surrounding COVID-19. Given evidence of the link between rumination and depression (15, 25), individuals with high levels of epidemic rumination may exhibit greater depressive symptomology (4, 17–19).

## Resilience and Depression

While epidemic rumination is a risk factor for depression, there are also those who show resiliency to life stressors. Resiliency refers to one's ability to actively adapt and cope with the impact of stress or trauma (26), showing adversity in the face of setbacks

(27, 28) and generally adept at maintaining or promoting positive mental health outcomes (29). Accordingly, those with greater resiliency generally tend to exhibit lower levels of depression (30–32). In the midst of the COVID-19 pandemic, a slew of recent studies has shown that resilient healthcare professionals experienced lower anxiety, posttraumatic stress, and depression (33, 34). Among the general populace, similar patterns emerged (30, 32, 35, 36). In other words, those who were able to adaptively cope with COVID-19 related stressors were better equipped to attenuate the onset of emotional distress consequences (37, 38). Thus, individuals able to remain steadfast and optimistic in spite of the current turbulent state of the world may be less likely to suffer from depressive symptoms.

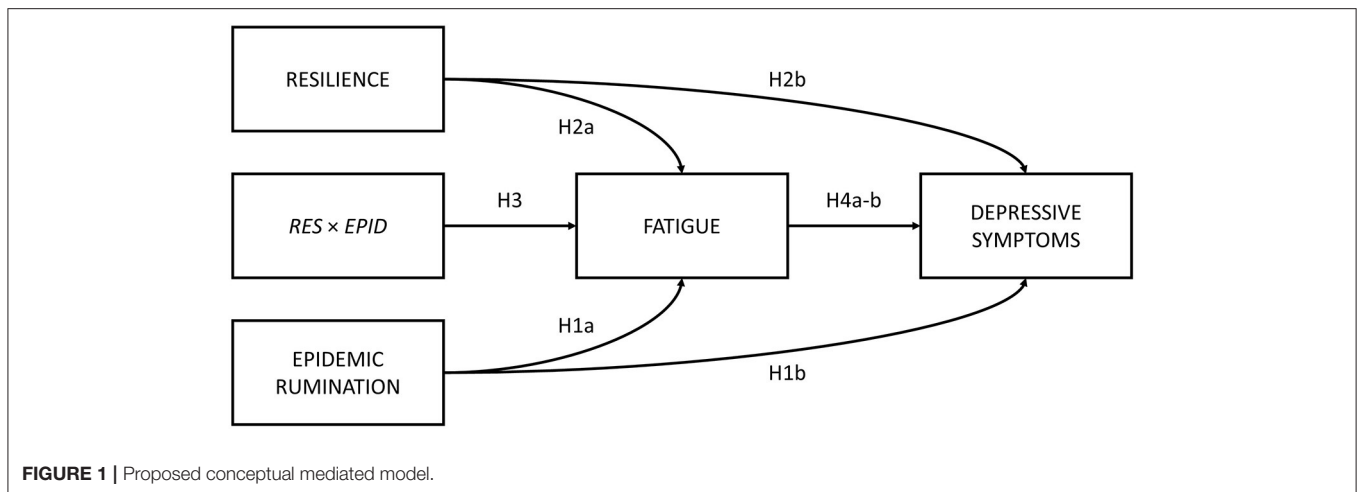

## The Mediating Role of Fatigue

With the prolonged nature and intensity of COVID-19, however, many individuals will naturally experience some form of fatigue, whether that be physical or psychological (39). This may be particularly the case for college students who are often not adept at handling sudden and large life stressors (40, 41), putting them at greater risk for developing depressive symptoms. As fatigue is a common byproduct of depleted psychological resources, risk factors [e.g., rumination; (42, 43)] and protective factors [e.g., resiliency; (44)] for said resources may, respectively, exacerbate and mitigate the onset of physical and psychological fatigue among individuals. Specifically, Luceño-Moreno et al. (34) found a strong negative relation between resilience and experience of emotional exhaustion among those impacted by COVID-19. In this regard, resilience may serve to not only directly reduce the experience of fatigue, but also serve to buffer the negative consequences of observed risk factors (e.g., epidemic rumination) (26, 45) through cognitive reappraisal (46). This may be especially critical given the rudimentary nature of fatigue in its risk to the negative consequences of life stressors (47), such as depression (48–50).

## The Present Study

The present study sought to first examine the roles of epidemic rumination and resilience on depressive symptoms. Secondly, the current study examined the mediating role of fatigue in the aforementioned relations. Lastly, we examined whether epidemic rumination and resilience interacted with one another in their effect on fatigue. We proposed a conceptual model (**Figure 1**) and the following hypotheses:

- Hypothesis 1.** Epidemic rumination is positively related to (a) fatigue and (b) depressive symptoms.
- Hypothesis 2.** Resilience is negatively related to (a) fatigue and (b) depressive symptoms.
- Hypothesis 3.** Epidemic rumination and resilience significantly interact such that resilience buffers the effects of rumination on fatigue.
- Hypothesis 4.** Fatigue is positively related to (a) depressive symptoms and mediates the effect of (b) epidemic rumination and (c) resilience on depressive symptoms.

## METHODS

### Participants

A large sample of 1,293 college students in China ( $M_{age} = 20.79$ ,  $SD_{age} = 1.67$ , 52% Female) were recruited for this study. A total of 464 (35.90%) participants were first years, 271 (21.00%) were second years, 310 (24.00%) were third years, and 248 (19.20%) were fourth year students.

### Procedures

Participants were invited to participate in an anonymous, online survey on how COVID-19 has impacted their psychological state and behaviors. As Winter recess was in session during the data collection period of this study due to delayed start of the Spring semester, participants were surveyed through an online survey platform (“SurveyStar,” Changsha Ranxing Science and Technology, Shanghai, China). After giving informed consent, participants were directed to the psychological measurements.

### Measures

#### Epidemic Rumination

Epidemic rumination was measured via a 10-item COVID-19 abridged version of the Ruminative Response Scale [RRS; (51, 52)]. Prior studies using the RRS in Chinese samples have shown good reliability and validity [e.g., (53, 54)]. The current scale was comprised of two dimensions: (1) reflective pondering (e.g., “I often think about why COVID-19 turned out the way it did”) and (2) brooding (e.g., “I often go someplace alone to think about my feelings”). Each item was scored from 1 (*not at all true*) to 5 (*definitely true*),  $\alpha = 0.76$ . Higher mean scores indicated greater levels of epidemic rumination. Confirmatory factor analysis (CFA) indicated acceptable fit, CFI = 0.92, TLI = 0.90, RMSEA = 0.08, SRMR = 0.05. See **Appendix** for all items.

#### Resilience

Resilience was measured via the Chinese version of the 10-item Connor-Davidson Resilience Scale (55), originally developed by Campbell-Sills and Stein (56). Prior use of this scale among Chinese participants showed good reliability and validity [e.g.,

(57)]. The scale was composed of ten items (e.g., “Able to adapt to change”),  $\alpha = 0.94$ . All items were scored from 0 (*never*) to 4 (*always*). Higher mean scores indicated higher levels of resilience.

#### Fatigue

Fatigue was measured via the Chinese version of the Fatigue Assessment Scale (58), originally developed by Michielsen et al. (59). This scale has previously been used with Chinese participants with good reliability and validity [e.g., (58)]. The scale was composed of twenty items (e.g., “I have problems thinking clearly”) and each item was scored from 1 (*never*) to 5 (*always*),  $\alpha = 0.86$ . Higher mean scores indicated greater levels of fatigue.

#### Depressive Symptoms

Depressive symptomology was measured via the Chinese version of the Center for Epidemiological Studies Depression Scale (60), originally developed by Radloff (61). Prior use of this scale among Chinese participants [e.g., (58, 62, 63)] have shown good reliability and validity. The scale was composed of twenty items and includes four dimensions: (1) depressed affect (e.g., “I felt lonely”), (2) positive affect (e.g., “I felt hopeful about the future”), (3) psychosomatic retardation (e.g., “I could not get ‘going’”), and (4) interpersonal relationships (e.g., “People were unfriendly”),  $\alpha = 0.95$ . Each item was scored from 1 (*not at all true*) to 5 (*definitely true*). Higher mean scores indicated greater levels of depressive symptoms.

## RESULT

### Descriptive Statistics

Means, standard deviations, and Pearson correlations are given in **Table 1**. As expected, epidemic rumination was positively related to fatigue and depressive symptoms, and negatively related to resilience. Resilience was strongly negatively related to both fatigue and depressive symptoms. Fatigue was strongly positively related to depressive symptoms.

## Epidemic Rumination and Resilience on Depressive Symptoms: The Mediating Effect of Fatigue

Structural equation modeling (SEM) through Mplus 8.3 (64) was used to analyze the mediating role of fatigue in the effects of epidemic rumination and resilience on depressive symptoms as well as the interaction between epidemic rumination and resilience on fatigue (Figure 2). The proposed model showed great fit (RMSEA = 0.05, SRMR = 0.04, CFI = 0.98, TLI = 0.98) based on field threshold standards (65, 66). Epidemic rumination was positively related to fatigue [ $\gamma = 0.11, t = 2.39, p = 0.017, 95\% \text{ CI} = (0.012, 0.176)$ ] while resilience was negatively related to fatigue [ $\gamma = -0.42, t = -11.52, p < 0.001, 95\% \text{ CI} = (-0.426, -0.290)$ ], supporting Hypotheses 1a and 2a. Moreover, epidemic rumination and resilience positively interacted in their relation to fatigue [ $\gamma = 0.07, t = 2.19, p = 0.029, 95\% \text{ CI} = (0.016, 0.154)$ ]. Fatigue was a strong positive correlate of depressive symptoms [ $\gamma = 0.58, t = 19.12, p < 0.001, 95\% \text{ CI} = (0.619, 0.801)$ ], supporting Hypotheses 4a-b that fatigue mediates the effect of epidemic rumination and resilience on depressive symptoms. Results also showed that even after controlling for fatigue, depressive symptomology was directly predicted by epidemic rumination [ $\gamma = 0.16, t = 5.15, p < 0.001, 95\% \text{ CI} = (0.110, 0.242)$ ] and resilience [ $\gamma = -0.23, t = -10.073, p < 0.001, 95\% \text{ CI} = (-0.426, -0.290)$ ], supporting Hypotheses

1b and 2b and suggesting that the mediation effect of fatigue was only partial.

The interaction effect is visually outlined in Figure 3 as a simple slopes plot with calculated gamma coefficients at  $-1 \text{ SD}$  and  $+1 \text{ SD}$  from the mean of resilience. For students with low resilience, the impact of epidemic rumination on fatigue was not significant ( $\gamma = 0.03, t = 1.18, p > 0.05$ ) compared to students with high resilience, where the impact of epidemic rumination on fatigue was significant ( $\gamma = 0.18, t = 5.54, p < 0.001$ ). While this interaction effect was significant, the direction of the contrasted with the hypothesis, and thus Hypothesis 3 was rejected.

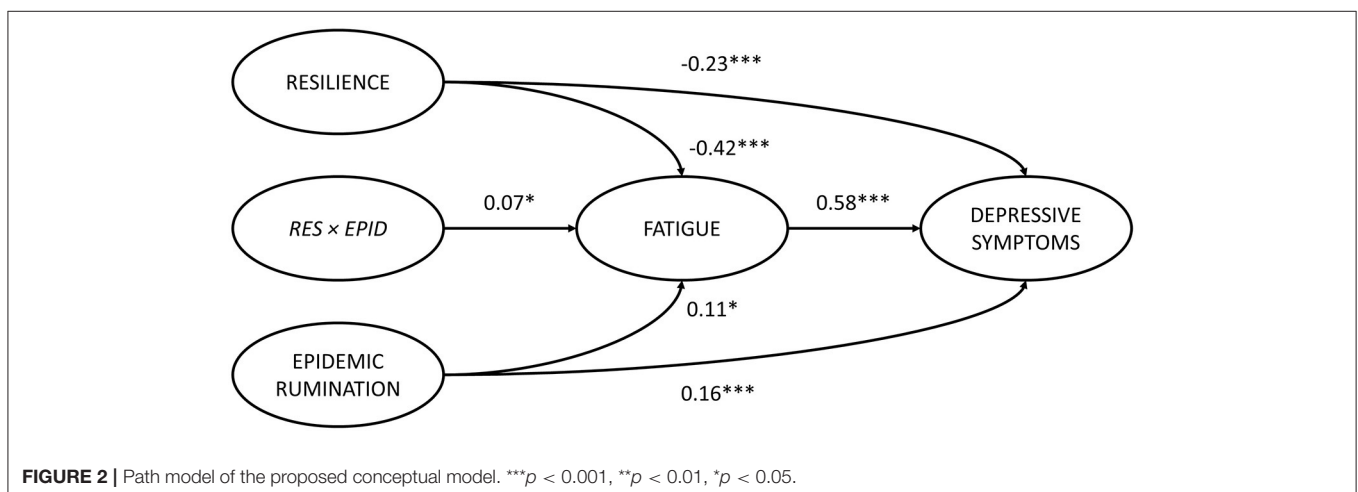

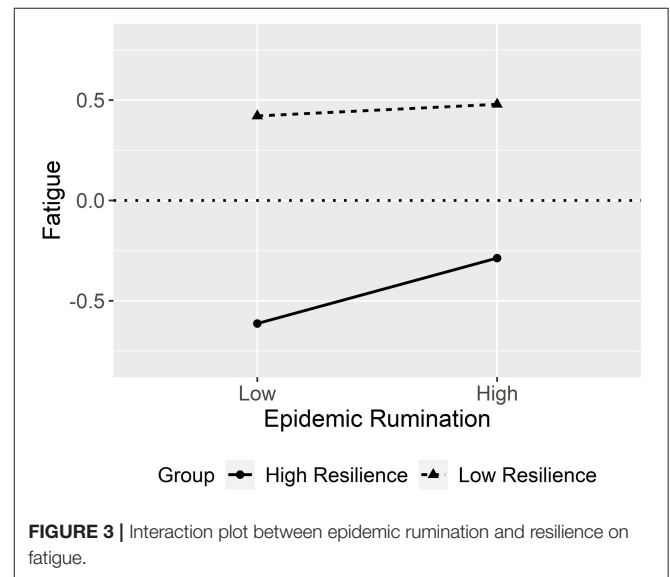

### Considering Alternative Models

Although results have generally provided strong support for our current model, several possible alternative models were also considered and tested given the cyclical nature of mental health outcomes and maladaptive behaviors (Table 2).

**TABLE 1** | Means, standard deviations, and correlations of the main study variables.

	<i>M</i>	<i>SD</i>	1	2	3	4
1. Epidemic rumination	2.97	0.54	–			
2. Fatigue	2.59	0.50	0.13***	–		
3. Depression	1.68	0.63	0.28***	0.65***	–	
4. Resilience	3.63	0.61	–0.14***	–0.40***	–0.74***	–

*N* = 1,293; \*\*\**p* < 0.001.

**TABLE 2** | Comparison of alternative models.

Model	Diagram	RMSEA	CFI	NNFI	SRMR
Proposed model		0.05	0.98	0.97	0.04
Alternative model I		0.05	0.97	0.96	0.05
Alternative model II		0.06	0.98	0.97	0.05
Alternative model III		0.10	0.91	0.98	0.12
Alternative model IV		0.10	0.91	0.88	0.11
Alternative model V		0.09	0.90	0.88	0.08
Alternative model VI		0.09	0.91	0.89	0.07
Alternative model VII		0.09	0.89	0.87	0.11
Alternative model VIII		0.08	0.90	0.88	0.08
Alternative model IX		0.13	0.90	0.87	0.09
Alternative model X		0.13	0.91	0.88	0.09
Alternative model XI		0.10	0.92	0.90	0.09
Alternative model XII		0.10	0.93	0.90	0.09

ER, epidemic rumination; F, fatigue; D, depressive symptoms; R, resilience.

Alternative Models I-II were direct derivatives of the proposed conceptual model but made strong assumptions that depressive symptoms were not directly preceded by resilience (Model I) and epidemic rumination (Model II). Both alternative models yielded comparable fits but ultimately did not allow for incorporating past findings that implicate direct effects of rumination [e.g., (15, 25)] and resilience on depressive

symptoms [e.g., (30, 32, 35, 36)]. Further, consistent with prior evidence of resilience as a moderating trait [e.g., (26, 67)], Alternative Models IV-VIII were also examined in which rumination was tested as a moderator at multiple paths. However, none of these competing models yielded comparatively good or better fits.

Lastly, four models that restructured the order of variables were considered. Although epidemic rumination may be a risk factor for fatigue and depressive symptoms, prior evidence suggests that possibility of the opposite trend. Specifically, fatigue may hinder self-control (47), possibly leading to greater rumination and subsequently depressive symptoms [(51, 68) Alternative Model IX]. Similarly, depressive symptoms and rumination may also be cyclical in which depressive symptoms may induce greater focusing on negative emotions (24) that lead to both fatigue and rumination (Alternative Model X). Further, while resiliency is often depicted as a stable individual trait, recent findings have alluded that one's resiliency may be malleable in response to varying degrees of risk [e.g., (69)], as also possibly evidenced by the negative correlations of epidemic rumination and fatigue on resilience. Thus, Alternative Models XI-XII were examined to test whether epidemic rumination posed a direct effect on resilience or indirect effect via fatigue. However, all competing models yielded poorer fits in comparison to the proposed model. Hence, the proposed model best yielded empirical support for the conceptual path model.

## DISCUSSION

Sudden public health emergencies risk serious social harm to the affected populace (70), particularly for college students who may be ill-equipped to adaptively manage the sudden stress of emergencies (71–73). This current research explored the effects of epidemic rumination and resilience on college students' depressive symptoms, the interaction between rumination and resilience, as well as the mediating role of fatigue. In this study, epidemic rumination was positively related to depressive symptoms, in line with several studies also documenting a positive link between the two constructs [e.g., (4, 17, 18, 58, 74)]. Similarly, resilience was negatively related to depressive symptoms, consistent with prior studies [e.g., (30, 31, 75)]. However, in examining the direct effects, fatigue was the strongest predictor of depressive symptoms, eclipsing the effect sizes of the two aforementioned predictors in comparison. This is not entirely unexpected, given that psychomotor retardation has long been a known sign of depression (76) and psychological and physiological exhaustion are close sister constructs. From the perspectives of the psychological resources theory (47) and cognitive load theory (77), fatigued individuals, depleted of psychological resources, may struggle in their fight against the onset of stress consequences when faced with prolonged negative emotional or psychological states, increasing the risk of depression (48, 49, 58, 78).

It is worth noting that in this study, the measurements used were meant to conceptually capture different components

of a similar construct; fatigue measured one's extent of mental and psychological tiredness and exhaustion compared to psychomotor retardation that captures the physiological symptomatology of depleted motivation in clinical depression. However, the two constructs remain fairly similar in their conceptualization and future research may seek to further parse them apart by specifying the target of the fatigue (i.e., fatigue over COVID-19 and its related events). For instance, the psychological and physiological consequences of prolonged exposure to COVID-19 information is popularly being referred to as the "COVID fatigue." It is currently unclear whether target-specific fatigue may yield different results. However, should there be strong theoretical or empirical reasoning to suggest that "COVID fatigue" may result in greater consequences, such as evidence of avoidant coping specific to COVID-19 stressors, then future research may be warranted to examine this link.

In predicting fatigue, both resilience and epidemic rumination were significant correlates. Resilience was a strong negative correlate of fatigue whereas epidemic rumination was a small positive correlate of fatigue. In both cases, the results generally supported prior findings [e.g., (79)]. What was interesting, and somewhat counterintuitive, however, was the positive interaction between epidemic rumination and resilience. This result was in direct contradiction to our hypothesized direction that high resiliency would buffer the effect of rumination on fatigue. One explanation may be that for those with very high levels of rumination, the negative effects were beyond the capacity of their ability to adequately cope. Indeed, while the conventional view has been that resilience serves as a protective role against difficulties, traumas, and tragedies (26, 67, 80), there has been a notable contention of scholars who have challenged this view, arguing that the benefits of resilience wanes at the highest levels of risk (69, 81, 82). For instance, Vanderbilt-Adriance and Shaw (69) suggested that the efficacy of protective factors can be lost when the counteracting risk surpasses a certain threshold. Thus, individuals who are highly resilient, but also ruminative, may continue to expend cognitive resources in spite of their inability to manage their stressors, exacerbating what may be an inevitable state of exhaustion. This may be in comparison to less resilient but ruminative individuals who may prefer the path of least resistance and simply let rumination work its course on inducing "normative" fatigue.

Although the interaction effect was notably small, fairly inconspicuous small effects may still yield long-term practical significant ramifications (83). Thus, future development and implementation of any interventions in building resilience may need to be more cognizant about possible unintended consequences toward those under high risk. Lastly, fatigue partially mediated the effects of epidemic rumination and resilience on depressive symptoms. This is significant in that mitigating physiological and psychological exhaustion may improve mental health outcomes. However, given that both epidemic rumination and resilience still yielded significant direct effects on depressive symptoms, targeted interventions may need to address several factors to observe large improvements in one's mental health outcomes.

## Significance and Implications of Research

While the current study did not directly examine the efficacy of any intervention strategies, the results provide several implications for what future studies may need to address. Firstly, it may be beneficial for college students to learn specific coping strategies. Given that COVID-19 is largely outside one's immediate control, certain active coping strategies that seek to address the source of the problem may not be practical or feasible. We also hesitate in advocating for any coping strategies that involve diverting one's attention from COVID-19 related contents as such endeavors may only serve to teach and promote avoidant coping. Thus, future research may seek to examine if strategies that address one's subjective response to stressors (e.g., cognitive reappraisal) prove fruitful in mitigating the onset of fatigue and depressive symptoms. Secondly, interventions that help college students to ensure adequate sleep, improve sleep quality, and engage in non-exhaustive exercise may hold potential benefits by reducing fatigue. Lastly, based on our findings that high resilience may not always yield desired outcomes, it may be necessary for interventions to first target reducing rumination prior to attempting to boost one's resilience.

## Limitations

Several limitations should be considered in interpreting the results. First, the cross-sectional and correlation study designs limit the extent to which causal inferences may be made. While alternative models were examined to compare contrasting theoretical paths and further justify the model examined, future studies should nonetheless seek to utilize longitudinal or experimental designs, as allowed, to further probe at the causality of the paths examined in this study. Secondly, the participants in the sample used were entirely from Chinese populations and may not generalize beyond this social ecology. Given that each country, and even the local clusters within geographical locations, may experience the COVID-19 pandemic differently, it is necessary for additional research to be conducted across cultures to examine the robustness of the model. Thirdly, all measures were examined via self-report scales. While statistical and process controls against common-methods bias were used (see **Appendix** for further details), future research may opt to incorporate mixed methods designs (e.g., quantitative with qualitative data, psychological with physiological measurements) to further enrich the findings from this study.

Fourthly, depressive symptomatology may not necessarily translate to clinical depression. As was shown in **Table 1**, the mean score of depressive symptoms was far below the midpoint of the scale and most participants did not report the highest levels of symptoms to typically constitute clinical depression. Thus, while the analyses used in this study examine *relations* between variables, and thus are not affected by the location of the means, future research may seek to pursue replication studies on clinically diagnosed samples. Lastly, the current study only examined fatigue as a mediating variable. As evidenced by prior studies, several other mediating variables may be relevant as well. Future studies may seek to examine a more comprehensive model in explaining the antecedents of depressive symptoms.

## CONCLUSION

The current study provides novel insight into examining the roles of epidemic rumination, resilience, and fatigue on depressive symptoms. It is imperative to continue monitoring the well-being of college students as they reach key developmental milestones amidst an uncertain social ecology. While focusing intervention strategies on fatigue may yield the largest, direct benefit, attention should also be given to mitigating ruminative tendencies as well as promoting resiliency. This may particularly be important given the current finding that only promoting one factor in the absence of the other may result in exacerbating fatigue for select individuals.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Jiangxi Normal University. The

patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

BY acted as the Principal Investigator and oversaw the study in its inception to completion. BY, XZ, ML, XW, and QY were responsible for data collection, writing the manuscript, and conceptualizing the models. HI contributed to the reconceptualization of the study models and rewriting of the paper in subsequent drafts after the initial submission. All authors contributed to the article and approved the submitted version.

## APPENDIX

### Addressing Common-Methods Bias

To control for common-method bias stemming from self-report measures, several steps were undertaken. To provide procedural control, participants' responses were anonymous and were free to withdraw from the study at any time. Further, it was stressed that there were no "right" or "wrong" answers to the measures. To provide statistical control, Harman's single-factor test was used. Exploratory factor analysis was run for all items of variables with rotated principal component and 13 factors were extracted with eigenvalues  $< 1$ . The first factor accounted for 38.58%, suggesting no significant common-method bias in the data (84).

### The Adapted COVID-19 Ruminative Response Scale

1. I often think about what causes COVID-19.
2. I often analyze the outbreak of COVID-19 and try to understand why I am depressed.
3. I often think about why COVID-19 turned out the way it did.
4. I often go away by myself and think about why I feel this way.
5. I often write down what I am thinking about and analyze it.
6. I often think about the COVID-19 epidemic, wishing it will get better.
7. I often wonder why I have these problems that others don't.
8. I often wonder why I can't handle things better.
9. I often analyze my personality to try to understand why I am depressed.
10. I often go someplace alone to think about my feelings.

doi: 10.3389/fpsyg.2020.561270

When labeling an infectious disease, officially sanctioned scientific names, e.g., “H1N1 virus,” are recommended over place-specific names, e.g., “Spanish flu.” This is due to concerns from policymakers and the WHO that the latter might lead to unintended stigmatization. However, with little empirical support for such negative consequences, authorities might be focusing on limited resources on an overstated issue. This paper empirically investigates the impact of naming against the current backdrop of the 2019–2020 pandemic. The first hypothesis posited that using place-specific names associated with China (e.g., Wuhan Virus or China Virus) leads to greater levels of sinophobia, the negative stigmatization of Chinese individuals. The second hypothesis posited that using a scientific name (e.g., Coronavirus or COVID-19) leads to increased anxiety, risk aversion, beliefs about contagiousness of the virus, and beliefs about mortality rate. Results from two preregistered studies [ $N_{(Study\ 1)} = 504$ ;  $N_{(Study\ 2)} = 412$ ], conducted across three countries with the first study during the early outbreak (April 2020) and the second study at a later stage of the pandemic (August 2020), found no evidence of any adverse effects of naming on sinophobia and strong support for the null hypothesis using Bayesian analyses. Moreover, analyses found no impact of naming on anxiety, risk aversion, beliefs about contagiousness of the virus, or beliefs about mortality rate, with mild to strong support for the null hypothesis across outcomes. Exploratory analyses also found no evidence for the effect of naming being moderated by political affiliation. In conclusion, results provide no evidence that virus naming impacted individual’s attitudes toward Chinese individuals or perceptions of the virus, with the majority of analyses finding strong support for the null hypothesis. Therefore, based on the current evidence, it appears that the importance given to naming infectious diseases might be inflated.

**Keywords:** psychology of naming, COVID-19, Wuhan Virus, coronavirus, pandemic, public messaging, China Virus, sinophobia

“Having a name matters to prevent the use of other names that can be inaccurate or stigmatizing.”  
—Tedros Ghebreyesus, Director-General, World Health Organization (WHO, 2020a).

“We’ve seen certain disease names provoke a backlash against members of particular religious or ethnic communities, create unjustified barriers to travel, commerce and trade, and trigger needless slaughtering of food animals. This can have serious consequences for people’s lives and livelihoods.”  
—Keiji Fukuda, Assistant Director-General, World Health Organization (WHO, 2020c).

## INTRODUCTION

In the face of a pandemic, one of the key decisions that scientists and policymakers face is how to name the infectious disease. While this decision might seem mundane relative to other urgent matters, international bodies, such as the World Health Organization (WHO) have expressed concern about potential unintended negative consequences of disease names (WHO, 2020a,b). The primary concern is that place-specific names, such as “Spanish Influenza” or “Middle East Respiratory Syndrome” will lead to the stigmatization of individuals associated with this region (WHO, 2020a). Thus, in 2015, the WHO released a report listing what they see as best practices for naming new human infectious diseases to “minimize the unnecessary negative impact of disease names” (Fukuda et al., 2015; WHO, 2020b). However, it generally takes significant deliberation for the WHO to officially sanction a name, by which point alternative names often have arisen in the public lexicon.

The 2020 pandemic is a perfect example of this name multiplicity, with several different monikers emerging. The first name that unofficially started floating around in the media since December 2019 is *Wuhan Virus*. This is a place-specific name derived from the likely emergence of the virus in Wuhan, China. As mentioned above, WHO guidelines warn against such place-specific names (Fukuda et al., 2015; WHO, 2020b), and this name has received negative media attention for its possible impacts on stigmatization and xenophobia (Board, 2020; Gabbatt, 2020). The second name to emerge was *Coronavirus*, a scientific but technically “inaccurate” name referring to the family of viruses. Nevertheless, this continues to be the most popular name in Google search trends (Google Trends, 2020). A third name, “COVID-19,” was released by WHO on February 11, 2020, in line with its guidelines (WHO, 2020b)<sup>1</sup>. Since then, the WHO, many governments, and media outlets have actively sought to instill this name in the public discourse. A fourth name considered is “China Virus” (WHO, 2020a). Similar to Wuhan Virus, this name has been criticized in the media for its potential to promote xenophobia and official briefings using this name have later been retracted (Trump and Donald, 2020). However, despite the rich media discussion, there is little empirical evidence on the psychological impacts of virus naming. To help address this question, we investigate the effects of names on people’s perceptions including sinophobia, anxiety, risk aversion, and mortality and contagiousness beliefs.

In the case of the current pandemic, the primary contrast is between the scientific names (COVID-19 or Coronavirus) and the place-specific names (Wuhan Virus or China Virus). Empirical research suggests that names play an important role in how we perceive phenomena (Wood, 1991; Waytz et al., 2014), although findings have been somewhat mixed. For example, in the health domain, studies have found that both drug (e.g., “opioid” vs. “narcotic”) and illness names (e.g., “gout” vs. “urate

crystal arthritis”) significantly impact patient and public reactions (Mangione and Crowley-Matoka, 2008; Petrie et al., 2018). However, in the domain of naming natural disasters, evidence has been inconclusive, with initial findings suggesting that female-named hurricanes led to significantly more deaths because they were erroneously perceived as less dangerous (Jung et al., 2014), but a reanalysis of the data found no support for this naming effect (Malter, 2014). Thus, the psychological effect of naming is very much an open topic for research.

The first research question this paper investigates is whether using a place-specific name leads to increased xenophobia toward individuals from that country. As discussed, the names Wuhan Virus and China Virus are generally shunned in media circles, and their use has been anecdotally linked to acts of violence against ethnically Chinese individuals living abroad (Al Jazeera, 2020; Board, 2020; Gabbatt, 2020). Psychologically, this is attributed to a process by which individuals associate their negative views toward the pandemic with a specific population (i.e., Chinese) and subsequently develop negative views about that population (Fukuda et al., 2015). We empirically test this possibility, exploring the effects of naming on *sinophobia*, the negative stigmatization of Chinese individuals. More specifically, if the above reasoning is correct, we would expect to find more negative views of Chinese people (i.e., *sinophobia*) when the pandemic is referred to by a place-specific name, i.e., Wuhan Virus or China Virus.

Moreover, we examine whether political affiliation moderates this naming effect. The theoretical rationale for such a moderation lies in political affiliation being related to ingroup favoritism, with conservatives showing stronger ingroup bias than liberals during times of threat (Perry et al., 2018). This ingroup favoritism could lead to increased *sinophobia*, specifically when the pandemic is referred to by place-specific names.

The second research question this paper investigates is the potential negative effect of using the official scientific name on attitudes toward the pandemic. Research has found that scientific concepts can lead to greater feelings of stress and increased aversion (Mallow, 1994). Further, scientific names are also generally not in the common lexicon and devoid of any human association, which could result in individuals feeling greater distrust of the phenomenon (Waytz et al., 2014). If this reasoning is correct, we would expect to find more negative perceptions of the pandemic when it is referred to with its scientific name, COVID-19 or Coronavirus, as compared to the place-specific names.

In sum, this paper tests two hypotheses with respect to naming: (a) that the place-specific names (Wuhan Virus/China Virus) lead to increased *sinophobia* relative to other names (Hypothesis 1) and (b) that the scientific names (COVID-19/Coronavirus) lead to more negative attitudes—in the form of increased levels of anxiety, risk aversion, and beliefs about contagiousness and mortality—relative to other names (Hypothesis 2). Also, we explore political affiliation as a potential moderator of this effect. Two separate studies were conducted during the early outbreak of the pandemic (April 2020) and at its later stages (August 2020). The entire set of study materials

<sup>1</sup>While COVID-19 is technically the name for the disease caused by the virus called SARS-CoV-2, WHO prefers to refer to the virus as “the virus responsible for COVID-19” or “the COVID-19 virus” to avoid the unintended hostility toward certain populations in Asia (Hong Kong is referred to “HKSAR” or Hong Kong Special Administrative Region).

and analysis plans for both studies were pre-registered before data collection (see [osf.io/9s4jk](https://osf.io/9s4jk)). Given the global nature of the pandemic, we collected data from three countries—US, Canada, and India—in Study 1 ( $N = 504$ ) investigating the names Wuhan Virus, COVID-19, and Coronavirus and two countries—US and India—in Study 2 ( $N = 412$ ) adding the name China Virus.

## STUDY 1

### Materials and Methods

In the first study, we obtained three samples from the United States of America (US), Canada, and India. All participants were recruited through the online surveying platform Amazon Mechanical Turk. Following the best practices in ensuring participant quality (Keith et al., 2017), we screened for participants who (a) had completed at least 50 previous surveys and (b) had a past participant approval rating of 95% and above.

A demographic breakdown across the total sample ( $N = 504$ ) shows a mean age of 36.09 ( $SD = 10.71$ ), 29.96% female, 43.06% Caucasian (38.69% Indian, 7.34% Black, 1.98% Chinese, 8.93% Other), and 52.18% having an undergraduate degree (14.09% lower qualifications and 33.73% higher qualifications).

The study procedure was identical across all three samples. Participants first read an article describing the spread of the pandemic and then answered questions relating to (a) state anxiety, (b) domain-specific risk aversion, (c) beliefs about contagiousness and mortality of the virus, and (d) attitudes toward Chinese individuals.

We manipulated one factor, virus name, across three levels: COVID-19, Coronavirus, and Wuhan Virus. We did so by using the respective name in the article (an example is shown in **Figure 1**) and in the following questions mentioning the virus (e.g., “Out of 100 people who are infected with the (COVID-19, Coronavirus, Wuhan Virus) how many do you think will die as a result of catching the virus?”). More details on the methods, manipulations, measures, pre-registered exclusions, and analysis plan are available on OSF (see [osf.io/9s4jk](https://osf.io/9s4jk)).

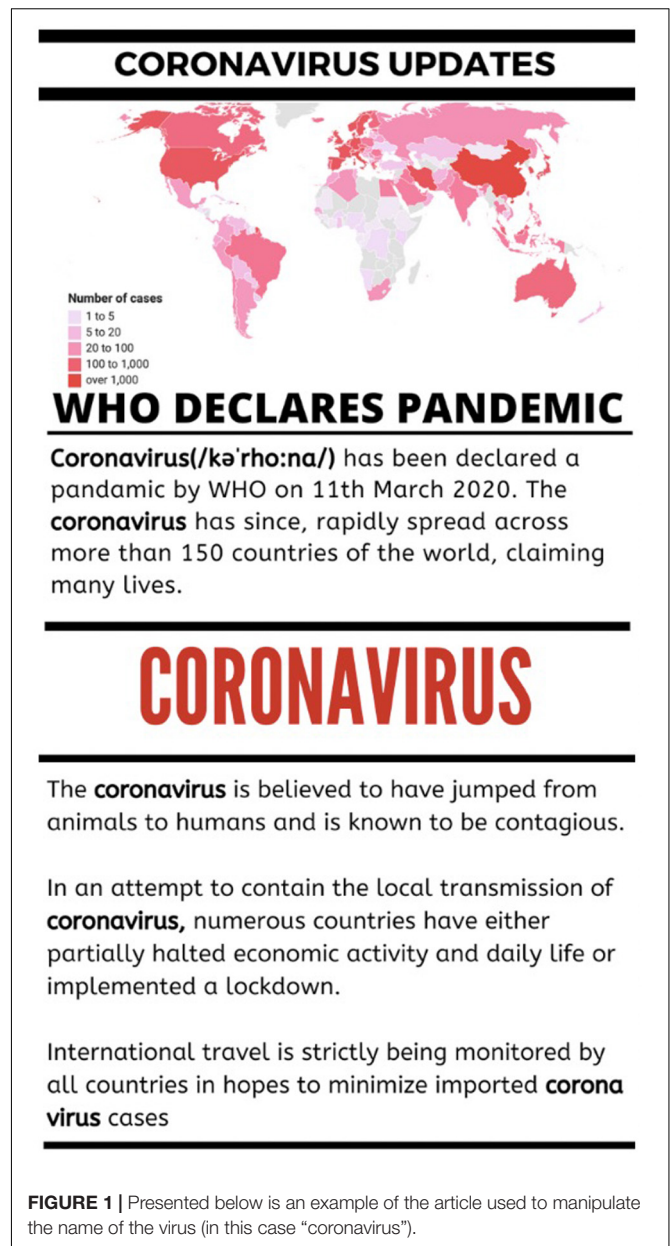

## Measures

### Anxiety

We measured state anxiety after reading the article using the PANAS-X fear subscale (Watson and Clark, 1999). Participants rated how well five different emotion words (nervous, scared, frightened, jittery, and shaky) characterized their current emotional state on a scale from 1 (“strongly disagree”) to 7 (“strongly agree”) [Cronbach's alpha ( $\alpha$ ) = 0.90].

### Domain-Specific Risk

We used an adaptation of the DOSPERT scale (Blais and Weber, 2006) with scenarios that relate specifically to the current pandemic to measure risk aversion. This scale (see **Appendix**) attempted to capture perceived risk related to different activities in the time of the pandemic. The scale demonstrated reasonable internal consistency ( $\alpha = 0.85$ ).

### Beliefs About Contagiousness and Mortality

We used two one-item measures developed by Fetzer et al. (2020) to measure beliefs about (a) how contagious the virus was and (b) how many out of 100 people infected would die from the virus. Answers ranged from 0 to 100 on both scales. Akin to the original paper, these responses were heavily skewed and thus all responses were logged (Fetzer et al., 2020).

### Sinophobia

To measure prejudice toward Chinese individuals, we adapted an explicit measure developed by Payne et al. (2010) to measure prejudice against black individuals. This included a measure of perceived warmth along with feelings of admiration and sympathy. Items were combined to form a single measure

of sinophobia ( $\alpha = 0.68$ ). We opted for an explicit measure, instead of an implicit measure, based on findings that explicit measures provide adequate assessments of prejudice (Axt, 2018). This measure was standardized with positive scores indicating sinophobia.

### Political Affiliation

Political affiliation was measured across all samples using a one-item five-point self-reported measure developed by McAdams et al. (2008), which asked participants: "How would you define yourself on the following scale in terms of your political orientation?" (1 = very liberal, 2 = liberal, 3 = middle of the road, 4 = conservative, and 5 = very conservative). This measure was then simplified into a categorical variable to create a clearer contrast between liberal (1) vs. middle of the road (2) vs. conservative (3).

### Education Level

Level of education was measured based on the highest level of qualification received by the participant: high school diploma, bachelor's degree, and postgraduate degree (master's/doctoral degree). This was coded as a categorical variable (1–3).

### Age and Gender

Demographic variables were measured using single items for age (18–100 +), gender (female = 0; male = 1), and education level (high school diploma = 1; bachelor's degree = 2; postgraduate degree = 3).

### Exclusions

Exclusions were applied in line with the OSF pre-registration. First of all, given the relatively subtle nature of the intervention, we excluded participants who failed an instructional manipulation check (Oppenheimer et al., 2009). Second, given the potential impacts on the outcome variables of interest, we excluded individuals who (a) had the virus, (b) were in physical contact with someone who had the virus, or (c) had close family and friends who had the virus. These exclusions did significantly cut the sample size (a total of 245 participants were excluded).

### Analysis Plan

We followed the analysis plan in line with the OSF pre-registration. We compared means across conditions (COVID-19 vs. Coronavirus vs. Wuhan Virus) using analysis of variance (ANOVA). We followed up with Bayesian analyses to evaluate the null hypothesis of no naming effect. Please note that all the Bayesian factors reported in this paper compare the likelihood of the data occurring under the alternative hypothesis vs. the null hypothesis ( $BF_{10}$ ). For example, a Bayes Factor of 10.00 indicates that the data are 10 times more likely to occur under the alternative hypothesis compared to the null hypothesis; alternatively, a Bayes Factor of 0.1 indicates that the data are 10 times more likely to occur under the null hypothesis compared to the alternate hypothesis (Jarosz and Wiley, 2014). These analyses were conducted using JASP with a standard unbiased Cauchy prior using the JASP default width of 0.5 (JASP Team, 2020). See Etz and Vandekerckhove (2018) and Wagenmakers et al. (2018)

for more information on interpretation for Bayes analyses. Finally, exploratory analyses, i.e., not formally pre-registered, explored the moderating effects of political affiliation.

## Results

Descriptive statistics and correlations are provided in **Table 1**.

### Sinophobia

We compared means across conditions for sinophobia using the three measures outlined by Payne and colleagues (Payne et al., 2010): warmth, admiration, and sympathy. We found no differences across conditions on sinophobia, with strong support for the null hypothesis [ $F(2, 501) = 0.78, p = 0.46, \eta = 0.00$ ; *Bayes Factor*<sub>( $BF_{10}$ )</sub> = 0.047]. In sum, in evaluating Hypothesis 1, there was strong evidence for the null hypothesis, i.e., place-specific naming did not increase sinophobia.

Next, we conducted exploratory analyses to see if any differences emerged depending on political affiliation (liberal vs. conservative;  $M = 1.96, SD = 0.89$ ). Analyses found no evidence of a significant interaction with condition with very strong support for the null hypothesis,  $F(4, 489) = 0.71, p = 0.59, \eta = 0.01$ ;  $BF_{10} = 0.000842$ . This suggests that political affiliation did not moderate sinophobic responses to different virus names.

### Anxiety, Risk Aversion, and Beliefs About the Virus

First, we compared means across the three naming conditions for anxiety, risk aversion and beliefs about contagiousness/mortality separately. Below, we report results pooled across the three samples (US, Canada, and India); note that similar patterns were seen within country samples (see **Table 2**). We found no main effect of naming on anxiety, with Bayesian analyses showing very strong support for the null hypothesis,  $F(2, 501) = 0.05, p = 0.95, \eta = 0.00$ ;  $BF_{10} = 0.023$ . Similarly, no significant differences emerged for the measure of domain-specific risk aversion with mild support for the null,  $F(2, 501) = 1.77, p = 0.17, \eta = 0.01$ ;  $BF_{10} = 0.119$ . Next, we detected a marginal effect on beliefs about contagiousness although Bayesian analyses still found weak support for the null,  $F(2, 501) = 2.66, p = 0.07, \eta = 0.01$ ;  $BF_{10} = 0.271$ . Finally, there was no support for an effect on

**TABLE 1** | Summary statistics and correlations for Study 1. Presented below are the means, standard deviations, and correlations for all variables across the entire sample.

mortality beliefs, with very strong support for the null,  $F(2, 501) = 0.03$ ,  $p = 0.97$ ,  $\eta = 0.00$ ;  $BF_{10} = 0.023$ .

## STUDY 2

The result of the first study provided consistent support for a null effect of virus naming on sinophobia and attitudes toward the virus. To further corroborate these results, which ran counter to our pre-registered hypotheses, a follow-up study was conducted. The aims of this study were twofold. First, the study sought to address whether the impacts of naming perhaps only emerge after increased exposure to all of the names by examining the same hypotheses at a second time point much later after the initial outbreak (August 2020). Additionally, given the null effects of the place-specific name “Wuhan Virus” on impacting sinophobia, we sought to investigate whether using a name more explicitly linking China with the pandemic, i.e., “China Virus,” might impact sinophobia. As in the previous study, all materials and analysis plans were pre-registered at [osf.io/9s4jk](https://osf.io/9s4jk).

## Materials and Methods

In the second study, we obtained samples from the US and India. All participants were again recruited through the online surveying platform Amazon Mechanical Turk with the same pre-qualifications as in Study 1 for ensuring participant quality. A demographic breakdown across the total sample ( $N = 412$ ) shows a mean age of 37.63 ( $SD = 12.48$ ), 37.62% female, 48.06% Caucasian (39.32% Indian, 7.04% Black, 1.21% Chinese, 4.37% Other), and 58.01% having an undergraduate degree (14.08% lower qualification and 27.91% higher qualification).

The study procedure was identical to Study 1 with the addition of another moniker (China Virus) as the fourth experimental condition and a different measure of coronavirus-specific risk perceptions. At the time of conducting this

second study, a scale for coronavirus specific risk perceptions had been validated by Dryhurst et al. (2020). Therefore, we decided to opt for the validated measure to provide consistent evidence across two scales and use a psychometrically valid scale. A forced response type manipulation check at the end of the survey asked participants to report the name of the virus as seen in the manipulation. A chi-square test indicated a significant relationship between the manipulation check and the manipulated names [ $\chi^2(12, N = 412) = 1059.12$ ,  $p < 0.001$ ], indicating that most people gave the correct response and that the manipulation was effective. After the study, participants were debriefed and thanked for their participation.

## Measures

All measures from Study 1 were included in this study and multi-item scales showed similar internal consistencies (anxiety,  $\alpha = 0.94$ ; sinophobia,  $\alpha = 0.68$ ).

### Coronavirus-Related Risk Perceptions

A modified version of a coronavirus related risk perceptions scale (Dryhurst et al., 2020) was included as an additional measure of risk perceptions. The scale had six items related to worries relating to the virus [e.g., “How likely is it that you will be directly and personally affected by (virus name) in the next 6 months?”] on a scale from 1 (“strongly disagree”) to 7 (“strongly agree”) ( $\alpha = 0.65$ ).

## Exclusions

Similar to the first study, we excluded 103 participants who failed an instructional manipulation check. However, in contrast to the first study, we did not exclude 149 individuals who (a) had the virus, (b) were in physical contact with someone who had the virus, or (c) had close family and friends who had

the virus<sup>2</sup>. This was to capture the reality of how widespread the virus had become by the time this second study was conducted (August 2020).

## Analysis Plan

The analysis plan remained unchanged from the first study and we compared means across conditions (COVID-19 vs. Coronavirus vs. Wuhan Virus vs. China Virus) using analysis of variance (ANOVA). Similar to Study 1, exploratory analyses explored the moderating effects of political affiliation.

## Results

Descriptive statistics and correlations are provided in **Table 3**. A comparison of means across each country sample is shown in **Table 4**. A summary of means across the two studies and four conditions is shown in **Table 5**.

### Sinophobia

Replicating the results of Study 1, but extended to the new China Virus condition, we found no differences across conditions on sinophobia, with strong support for the null hypothesis [ $F(3, 408) = 1.21, p = 0.30, \eta = 0.01, BF_{10} = 0.051$ ] (see also **Table 4**). Additionally, replicating the results of the first study, the interaction of political affiliation with condition was not significant, with very strong support for the null hypothesis,  $F(6, 399) = 0.56, p = 0.76, \eta = 0.01; BF_{10} = 0.002$ .

### Anxiety, Risk Aversion, and Beliefs About the Virus

Similar to Study 1, we first compared means across the four naming conditions for anxiety, risk aversion, and beliefs about contagiousness/mortality separately. Below, we report results pooled across the two samples (US and India). Note that similar patterns were seen within place-specific samples (see **Table 4**). We found no main effect of naming on anxiety, with Bayesian analyses showing “very strong” evidence for the null hypothesis,  $F(3, 408) = 0.77, p = 0.51, \eta = 0.01; BF_{10} = 0.028$ .

<sup>2</sup>We declared in our pre-registration that we would exclude infected individuals and therefore we ran the same set of analyses on the reduced sample as well. The results remained unchanged.

**TABLE 3 |** Summary statistics and correlations for Study 2. Presented below are the means, standard deviations, and correlations for all variables across the entire sample.

	M	S.D.	Min	Max	1	2	3	4	5
Anxiety	2.72	1.22	1	5	[0.94]				
Risk aversion	2.18	0.74	1	5	0.42***	[0.65]			
Contagiousness beliefs <sub>(logged)</sub>	2.16	0.98	0	4.62	0.20***	0.11*	–		
Mortality beliefs <sub>(logged)</sub>	1.84	0.98	0	4.60	0.33***	0.18***	0.38***		
Sinophobia	0	0.78	–1.68	1.78	–0.16***	–0.20***	0.03	–0.12*[0.68]	
Political affiliation	2.06	0.89	1	3	0.21***	0.12*	0.05	0.15**0.03	

Alpha coefficients for composite measures are provided in brackets. \*\*\* $p < 0.001$ , \*\* $p < 0.01$ , \* $p < 0.05$ .

Similarly, no significant differences emerged for the measure of the risk perceptions with strong support for the null,  $F(3, 408) = 0.59, p = 0.62, \eta = 0.00; BF_{10} = 0.022$ . Similarly, no effects were found on beliefs about contagiousness or mortality with Bayesian analyses, suggesting strong and moderate support for the respective nulls [Contagiousness:  $F(3, 408) = 0.58, p = 0.63, \eta = 0.00; BF_{10} = 0.022$ ; Mortality:  $F(3, 408) = 2.11, p = 0.10, \eta = 0.01; BF_{10} = 0.168$ ].

## DISCUSSION

Governments, policymakers, and international bodies must decide how to refer to an infectious disease. As such, significant amounts of effort and consideration go into the process of naming an infectious disease including guidelines being made and international conferences held (WHO, 2020b). Further, academic articles are written about best practices to “do no harm” (Fukuda et al., 2015; WHO, 2020a) and debates are sparked from global media to dinner tables as individuals condemn others for using “incorrect” and “inappropriate” names (Board, 2020; Gabbatt, 2020). However, how necessary are such debates? The present study found no evidence that the use of place-specific names leads to negative attitudes toward individuals from this location (i.e., sinophobia) and, further, Bayesian analyses found strong support for the null hypothesis. This is notable given that potential to cause xenophobia is one of the primary reasons given for not using place-specific names for infectious diseases (Fukuda et al., 2015; WHO, 2020a,b). Additionally, we found no evidence that naming alters anxiety, risk perceptions, or beliefs about the virus. These two empirical results, replicated across two studies at different time points, shed light on the limited impact of infectious disease naming in times of a pandemic and are further discussed below.

The null effect of using a place-specific name (“Wuhan Virus” or “China Virus”) on xenophobia is striking and contrary to the prevalent assumption in public policy discourse and the media (Board, 2020; Gabbatt, 2020; WHO, 2020a,b). In addition, the replication of this effect across two time points and different political affiliations lends robustness to the findings. This result does not imply that a negative association of China with the pandemic does not lead to sinophobia. Instead, it is evidence that the use of place-specific names is not sufficient to generate this negative association. To understand this better, we consider more closely how infectious disease names arise and situate the finding within the literature on racist language use.

The initial name for an infectious disease is typically one that is associated with its location of origin. A similar trend is seen across several infectious diseases, e.g., Spanish Flu, Middle-East Respiratory Syndrome, Zika, or Ebola. This is likely due to the origin being salient in the early outbreak, making it an easy name to generate for the public discourse (WHO, 2020a). There is also a broader tradition of naming phenomena by the place or person of origin that pervades much of our language, for example, names (e.g., O’Reilly, Tang, and Romanov), food (e.g., Kobe beef and English mustard), and species (e.g., Florida panther). For this article, the pertinent question is whether the act of naming

**TABLE 4 |** Effect of naming on individual perceptions and beliefs for Study 2. Presented below are the results of one-way ANOVAs run on each of the study variables across the two samples and the entire sample.

Sample	Statistics	Anxiety	Risk aversion	Contagiousness beliefs <sub>(logged)</sub>	Mortality beliefs <sub>(logged)</sub>	Sinophobia	No. of observations (N)

<sup>1</sup>(DOSPERT).

an infectious disease by its location (e.g., Wuhan) is enough to create a negative association with people from that location (e.g., Chinese individuals). The results of this paper provide empirical evidence that this may not be the case. Specifically, Bayesian analyses lend strong support to the null hypothesis that using a place-specific name (e.g., Wuhan Virus or China Virus) does *not* lead to increased sinophobia.

These findings speak to a broader literature on the use of racist language in public discourse. Increasing scholarly attention has been given to the impact of racist language since the rise of social media (e.g., Twitter), which gives racist individuals a platform to share and spread their views online (Chaudhry, 2015; Matamoros-Fernández, 2017). The defining element of racism is the act of discrimination against certain individuals or groups (Dovidio, 1986). Past research has documented the negative effect of discriminatory language both on the individuals being discriminated against and the broader society exposed to these terms (Gerstenfeld et al., 2003; Faulkner and Bliuc, 2016). Based on this, the current article suggests that with respect to the naming of infectious diseases, the sole use of place-specific names is not sufficient to incite racist attitudes among the public. Nevertheless, these findings do not speak to a

situation in which these terms are used to intentionally associate blame or discriminate against individuals from these locations. Moreover, this research does not consider the important element of how individuals from these locations (e.g., China) feel about the use of the terms and the potential negative psychological impact it might have on these individuals (Mays et al., 2007). Such research would be particularly important so that empirical research can inform social media sites on whether place-specific names should be considered harmful language and thus appropriately moderated (Chaudhry, 2015). In sum, while this research provides the first empirical evidence that infectious disease naming does not impact xenophobia, there are many important avenues for future research to explore.

A second empirical finding from this research is the lack of evidence for an effect of naming on anxiety, risk perceptions, or beliefs about the virus. Further, Bayesian analysis showed mild to strong evidence for the null hypothesis across all outcomes. This finding is one of the few cases showing a null effect of naming on psychological outcomes (cf. Malter, 2014). Instead, reviewing the psychology of naming literature, one would generally find evidence supporting an effect of naming (e.g., Wood, 1991; Jung et al., 2014; Waytz et al., 2014). This is potentially due

to a publication bias in psychology favoring significant results over null results (Ferguson and Brannick, 2012; Laws, 2013). A negative consequence of this bias is that it may lead to the false impression that the impact of naming is “always” significant and thus likely pervasive across many different domains. This in turn might have contributed to the strong media and policy discourse around the naming of infectious diseases (Board, 2020; Gabbatt, 2020; WHO, 2020a). Therefore, given the lay hypothesis that naming significantly impacts individual’s perceptions and responses to an infectious disease, the significant evidence in favor of the null hypothesis provided by this paper can be seen as an important contribution to research on the psychology of naming.

This research should be viewed in light of its strengths and limitations, which also point to future research directions. As a strength, the pre-registration of the study materials and analysis plan reduced researcher degrees of freedom, strengthening the paper’s conclusions relating to the main effects of naming (Nosek and Lakens, 2014). Also, the use of Bayesian testing of the null hypothesis helps in providing novel insights into what policymakers and researchers can *decrease* their focus on, as opposed to the general recommendations of what they should *increase* their focus on (Etz and Vandekerckhove, 2018).

Moreover, one important issue in research on the psychology of naming is tracking the impact of long-term exposure to the different names of an infectious disease. It is plausible that repeated exposure to place-specific names, such as “Wuhan Virus” might increase the chance that the negative associations with the pandemic are translated into negative attitudes toward individuals from Wuhan or China more broadly, especially in the light of significant economic impacts of the pandemic on individuals. This paper sought to partially address this issue by replicating the results in a second study conducted nearly 5 months after the initial study. This replication at least demonstrates that the effects are robust to increased exposure to all the names. Nevertheless, future research can explore more specifically the effects of increased exposure to a specific name.

A limitation of this research is its narrowed focus. Given that, to our knowledge, this is the first empirical study investigating the effects of naming during a pandemic, many different topics could have been chosen. We chose to focus on one topic that has gained a lot of media and policy attention, i.e., the potential for harm when naming an infectious disease (Fukuda et al., 2015; Board, 2020; Gabbatt, 2020; WHO, 2020a). However, there are still numerous topics to cover within this domain. Particular areas of interest based on this paper’s findings would be investigating if place-specific names have a negative psychological impact on individuals from those regions (e.g., China). It is plausible that the use of the name Wuhan or China Virus makes

Chinese individuals feel villainized or impacts *their* beliefs about the pandemic. Additionally, future research could investigate whether the tone/intention with which the name is used has an impact on the “harm” it causes. In this paper, we focused on a more prosaic use of the names, but it is possible that the name “China Virus” takes on another meaning when it is used by an individual seeking to incite sinophobia.

To conclude, this paper provided the first empirical test of the psychological effects of infectious disease naming. The key takeaway is that naming did not impact levels of sinophobia or anxiety, risk perceptions, and beliefs about the pandemic. Therefore, returning to the goal of “First Doing No Harm” (Fukuda et al., 2015), governments, media outlets, and international bodies can be more assured that their choice of name for an infectious disease is unlikely to lead to harmful xenophobia or negative psychological impacts, and thus they might be best served to focus their limited resources elsewhere.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study can be found in the online repositories. The names of the repository/repositories and accession number(s) can be found below: [osf.io/9s4jk](https://osf.io/9s4jk).

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Singapore Management University Ethics Committee. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

All authors contributed to the methodological design, data analysis, and writing of the manuscript.

## ACKNOWLEDGMENTS

We would like to thank the members of the Mindfulness, Attention, and Decision-Making Lab at the Singapore Management University including Amos Tai, Brian Tan Yeow Wee, Hong Xuan Tan, Megan Choy, Thanh Tuyen Ngyuen Tran, and Vanice Chow. We are also grateful to Singapore Management University, Lee Kong Chian School of Business, for funding this research.

## APPENDIX

Below is the *ad hoc* measure developed to assess domain specific risk perceptions (Blais and Weber, 2006). For each of the following statements, please indicate the risk you perceive the described activity or behavior to be given the current outbreak of (COVID-19/Coronavirus/Wuhan Virus).

The scale ranged from 1 “Not at all risky” to 7 “Extremely risky.”

Items:

1. Going to a supermarket to buy food
2. Commuting to work on a busy train
3. Traveling on a commercial airplane
4. Going to a bar where there have been no recorded cases of (COVID-19/Coronavirus/Wuhan Virus)
5. Going to the gym
6. Going for a walk in the park
7. Ordering lunch using food delivery
8. Walking past someone who has (COVID-19/Coronavirus/Wuhan Virus)
9. Sitting next to someone on the bus for 5 min who has (COVID-19/Coronavirus/Wuhan Virus)
10. Spending 30 min of close contact (e.g., conversation) with someone who has (COVID-19/Coronavirus/Wuhan Virus)

The coronavirus disease 2019 (COVID-19) health crisis is strongly affecting the psychological well-being of the general population. According to a very recent literature, the imposed lockdown and social distancing measures have generated a series of negative outcomes, including fear of the future, anxiety, and somatization symptoms. Few studies have investigated the impact of the COVID-19 pandemic on the well-being of parents and children, and still fewer studies have assessed the relationship between the psychological health of parents and children. The present study aimed at understanding the effect of parents' psychological distress and verbal aggression on behavioral and emotional symptoms of children during the COVID-19 lockdown. Using an online survey administered in the first weeks of the lockdown in Italy, we explored the mediating effects of parent verbal hostility and child emotional symptoms on the relationship between parent distress and child hyperactivity/inattention in a sample of 878 Italian parents (87.4% mothers; mean<sub>age</sub> = 40.58). Two hypotheses were proposed: (1) parent distress would significantly predict child hyperactivity/inattention, and (2) parent verbal hostility and child emotional symptoms would mediate the association between parent distress and child hyperactivity/inattention. The serial mediated model confirmed both hypotheses, suggesting that higher rates of psychological distress in parents were associated with higher levels of hyperactivity/inattention in children. Parent verbal hostility and child emotional problems were also found to positively mediate this relation. Our results may be used to improve sociopsychological interventions in the general population in the near future. They may also contribute to the clinical definition of therapeutic paths for parents and families.

**Keywords:** parent psychological distress, verbal hostility, emotional symptoms, hyperactivity and attention, COVID- 19

## INTRODUCTION

The coronavirus disease 2019 (COVID-19) health crisis is strongly affecting the psychological well-being of the general population. To prevent the spread of the virus, governments worldwide have imposed social distancing measures, closed schools, and enforced mandatory lockdowns, forcing individuals to deal with new and challenging situations (Brodeur et al., 2020). In Italy, a series of restrictions of increasing severity began on February 23, 2020, with a regional lockdown initiated in Lombardy (northern Italy), where the country's first case of COVID-19 was registered (Lizzerini and Putoto, 2020). Gradually, the measures became more stringent, culminating in a national lockdown on March 11, involving the closure of schools and prohibitions on general activities.

While many studies have assessed the impact of the pandemic on the general population (Mazza et al., 2020), few studies have assessed the effects of the lockdown on the parent-child relationship or parent and child well-being (Brown et al., 2020; Gassman-Pines et al., 2020; Griffith, 2020; Marchetti et al., 2020; Patrick et al., 2020). In addition to generating negative effects in the general population, the COVID-19 lockdown may also be creating a particularly stressful environment for parents, who may face concerns over their family's health, their children's isolation from teachers and peers, and their management of homeschooling and daily commitments (e.g., working remotely and meeting financial obligations; Fontanesi et al., 2020; Romero et al., 2020). Furthermore, although very few children have been infected with COVID-19 in Italy, children are not immune to the tragic impact of the pandemic, but may experience fear, isolation, uncertainty, worry, irritability, and inattention (Jiao et al., 2020).

Several studies have documented the damaging effects of psychological stress in children following negative events; such effects include drastic changes in emotional and behavioral patterns and sleep and eating habits, higher levels of anxiety and depression, and impaired social interactions (Hoven et al., 2005; Klein et al., 2009; Lai et al., 2015; Verrocchio et al., 2018). As suggested by the literature, these symptoms may be partly determined by the direct effect of experiencing a negative event; however, parents' mental health and parenting style behaviors may also play a key role in influencing children's adjustment during stressful situations (Pfefferbaum et al., 2015, 2016).

Parents' general mental health and psychological distress are well-established risk factors for psychological problems in children (Siegenthaler et al., 2012; Verrocchio et al., 2013; Patrick et al., 2020). The literature shows that maternal mental health is associated with poor behavioral, emotional, social, and cognitive outcomes in children (Glasheen et al., 2010; Verrocchio, 2016), whereas paternal depressive symptomatology contributes to negative emotional and behavioral outcomes in children (Weitzman et al., 2011). Overall, psychological distress has been found to be associated with adverse behavioral and emotional outcomes in children (Verrocchio et al., 2019); in particular – and regardless of parent gender – parents' mental health has been found to relate to emotional symptoms in

younger children and hyperactive behavior in children of all ages (Amrock and Weitzman, 2014).

Parenting style can be described as a constellation of practices toward children that create an emotional environment and influence child development and well-being. The role of parenting style behaviors on children's emotional and behavioral problems is widely cited in the literature (Rinaldi and Howe, 2012; Braza et al., 2015). In particular, maternal verbal hostility has been shown to be responsible for children's negative emotional arousal and internalizing symptoms (Smarius et al., 2019; Pozzi et al., 2020), and parental verbal aggression (i.e., yelling and bursts of rage) has been found to be associated with depression and anxiety symptoms in children and preadolescents (Möller et al., 2016). Furthermore, although parenting style tends to be relatively stable, some parenting style behaviors can be heightened or triggered by parents' compromised psychological well-being (Tavassolie et al., 2016), especially during stressful situations (Miki et al., 2019) such as the COVID-19 lockdown.

Aggressive maternal and paternal parenting behaviors have been shown to result in emotional problems in children, and these emotional problems may trigger the onset of inattention and hyperactive/impulsive symptoms (Eisenberg et al., 2001). Symptoms of emotional distress in children (e.g., irritability, sadness, and worry) are frequently accompanied by externalizing behaviors (e.g., restlessness, temper tantrums, and inability to concentrate) and may even predict attention-deficit/hyperactivity disorder (ADHD) symptoms over time (Brocki et al., 2019). In fact, recent studies have suggested that emotional problems may positively predict inattention symptoms and that high levels of physical (e.g., headaches and stomachaches) and internalizing symptoms – associated with emotional distress – are typically present before a diagnosis of ADHD (Han et al., 2020). Both internalizing and externalizing symptoms in children and preadolescents can have serious consequences for their interpersonal, cognitive, and psychological domains, such as impaired social competency, substance abuse, poor academic performance, and decreased mental health (Creavey et al., 2018; Gargano et al., 2018).

In light of these findings, it is reasonable to suggest that the present critical and unexpected situation of emergency may increase parents' mental distress; this may be reflected in a verbally aggressive parenting style, which may negatively influence children's psychological well-being. Understanding this relation and the outcomes is essential for properly addressing the needs of parents and children in the near future and for developing new interventions to help people cope with traumatic events. Italy was not only one of the first – and most severely affected – countries to suffer from the COVID-19 pandemic, but it is also subject to frequent natural disasters, earthquakes, and floods, resulting in displaced families who are forced to live in shelters and to reorganize their lives accordingly, with dramatic consequences for children's general well-being.

Although a wide range of maladaptive parenting practices may contribute to an undesirable parent-child relationship, the current study focused on the role of a single component of aggressive behavior in parents. Specifically, the present research aimed at understanding the relationship between

parent psychological distress, parent verbal hostility, and child behavioral and emotional symptoms during the COVID-19 lockdown. Although there is evidence of a bidirectional relation between parents and children, with children's characteristics eliciting certain parenting practices (e.g., Zadeh et al., 2010; Pearl et al., 2014), some studies have demonstrated that parental practices affect children's behavior much more strongly than the reverse (Choe et al., 2013). On this basis, we explored the mediating effects of parent verbal hostility and child emotional symptoms on the relationship between parent psychological distress and child hyperactivity/inattention in a sample of Italian parents. Drawing on the process-oriented model of developmental trajectories and child adjustment (Cummings et al., 2000; Miragoli and Verrocchio, 2008), which suggests that different factors and environments may encourage development along an adaptive or potentially maladaptive trajectory, we proposed two hypotheses: (1) parent psychological distress would significantly predict child hyperactivity/inattention behavior and (2) parent verbal hostility and child emotional symptoms would mediate the association between parent psychological distress and child hyperactivity/inattention behavior.

## MATERIALS AND METHODS

### Participants and Procedure

The study sample was part of a wider research project investigating the effect of the COVID-19 pandemic on the mental health of Italian parents and children. From April 3 to 14, participants completed an anonymous online survey on the Qualtrics platform, after reading and approving a consent form describing the aims of the study, participant rights, and the data treatment procedure. The survey took approximately 20 min to complete. Participants were randomly recruited through social media and snowball sampling and selected according to the following inclusion criteria: (a) being at least 18 years old and (b) being a parent to at least one child aged 3–13 years, with whom they were spending the lockdown. With respect to the latter criterion, we selected this age range for the children because we expected that the parents of these children would be experiencing a higher education-related burden during the lockdown, as younger children often require more parental assistance in their lessons and homework than do adolescents. The research protocol was approved in accordance with the Declaration of Helsinki and its revisions (General Assembly of the World Medical Association, 2014) by the local ethics committee (Board of the Department of Human Neuroscience, Faculty of Medicine and Dentistry, Sapienza University of Rome, n. 6.2020).

### Measures

The survey consisted of, first, a set of sociodemographic questions investigating parents' age, gender, marital status, work status, and level of education and the age and gender of the target child. Following this, the survey presented a series of standardized measures of parent psychological distress and verbal hostility

and child emotional symptoms and hyperactivity-inattention behavior during the COVID-19 lockdown.

Psychological distress of parents was assessed with the General Health Questionnaire-12 (Piccinelli et al., 1993; Piccinelli and Politi, 1993; Giorgi et al., 2014). This is a 12-item measure of somatic symptoms, depression, anxiety, insomnia, and social dysfunction. Participants were asked to evaluate how their distress had changed since the beginning of the lockdown on a scale from 0 to 3, with higher scores indicating a worse mental health condition (example item: "Have you felt constantly under strain?"). In the present sample, internal consistency was good ( $\alpha = 0.85$ ).

Verbal hostility of parents was assessed using three items (yells or shouts when child misbehaves, argues with child, and explodes in anger toward child) of the Italian short version of the Parenting Styles and Dimensions Questionnaire (Robinson et al., 1995, 2001; Confalonieri et al., 2009). Each item was rated on a five-point Likert scale ranging from 1 (*never*) to 5 (*always*). Participants were asked to evaluate the number of times they had used verbal hostility toward their child since the beginning of the lockdown. Total scores were created by summing the three-item scores. In this study, the Verbal Hostility subscale had acceptable internal consistency ( $\alpha = 0.76$ ).

Emotional symptoms and hyperactivity/inattention of children were assessed by parents using the Italian version of the Strengths and Difficulties Questionnaire-Parent Report (SDQ; Goodman, 2001; Marzocchi et al., 2002). The SDQ is a widely used brief behavioral screening instrument that assesses children's positive and negative attributes across five scales, each composed of five items: Emotional Symptoms, Conduct Problems, Hyperactivity/Inattention, Peer Problems, and Prosocial Behavior. For the present study, the Emotional Symptoms and Hyperactivity/Inattention subscales were used to assess emotion and behavioral problems. Participants were asked to evaluate – on a three-point Likert scale ranging from 0 (*not true*) to 2 (*certainly true*) – the presence of emotional and behavioral problems in their child during the lockdown. Example items of the two subscales used in this study include "Restless, overactive, and cannot stay still for long" and "Often unhappy, downhearted, or tearful." In the current study, the Emotional Symptoms and Hyperactivity/Inattention subscales had acceptable internal consistency ( $\alpha = 0.76$  and  $\alpha = 0.71$ , respectively).

### Data Analysis

Prior to the main analysis, we examined the data using frequencies and descriptive statistics. Data were screened for deviation from parametric assumptions and met the requirements without transformation. To test our hypotheses, we used Pearson correlations to investigate associations between parent psychological distress, parent verbal hostility, child emotional symptoms, and child hyperactivity-inattention experienced during the COVID-19 lockdown. Following this, we evaluated the association between child gender, age, and hyperactivity/inattention behavior in order to determine whether to include covariates in the hypothesis-testing model. Finally, we employed PROCESS Model 6 in SPSS 26.0 to examine Hypotheses 1 and 2. In addition, a 95% bias-corrected confidence interval

with 5,000 bootstrap samples was applied to determine the significance of the mediational effect.

## RESULTS

### Descriptive Statistics and Correlations

A total of 878 caregivers (87.4% mothers; mean<sub>age</sub> = 40.58 ± 6.41) who responded to the survey met the inclusion criteria and were included in the study. Descriptive data on the sample are summarized in **Table 1**. Means and standard deviations of all variables and the correlations between variables are displayed in **Table 2**. The results demonstrated significant and positive correlations between parent psychological distress during the COVID-19 lockdown, parent verbal hostility, child emotional symptoms, and child hyperactivity-inattention behavior, providing preliminary support for our hypotheses. Child gender and age were significantly related to hyperactivity/inattention behavior. Specifically, being male and younger was associated with higher hyperactivity/inattention behavior.

### Serial Mediation Model

There was a statistically significant direct effect confirming Hypothesis 1, that parent psychological distress during the COVID-19 lockdown would predict child hyperactivity-inattention behavior. Furthermore, indirect effects were also statistically significant, providing support for Hypothesis 2

(**Table 3; Figure 1**), that parent verbal hostility and child emotional problems during the lockdown would be positive serial mediators of the relationship between parent psychological distress and child hyperactivity-inattention.

## DISCUSSION

The present study examined the links between parent psychological distress, parent verbal hostility, and child emotional symptoms and hyperactivity-inattention during the COVID-19 lockdown, with an emphasis on the identification of potential mediating processes among these variables.

Throughout the pandemic, the psychological condition of parents and children has been an area of professional and institutional concern, worldwide. Nonetheless, despite the significant clinical interest in this topic, little effort has been devoted to its study. The present research thus extends our empirical knowledge of the relationship between parents' mental health and children's psychological well-being during a pandemic.

A primary goal was to explore the associations between parents' psychological distress and children's hyperactivity/inattention during the COVID-19 lockdown. The results showed that parents' psychological distress significantly predicted children's hyperactivity/inattention. This result was consistent with previous studies confirming that parents' psychological distress is a risk factor for the development of externalizing problems in children (e.g., Glasheen et al., 2010; Siegenthaler et al., 2012; Amrock and Weitzman, 2014). Furthermore, as expected on the basis of previous studies in the general population (e.g., Mayes et al., 2020), children's gender and age were significantly related to hyperactivity/inattention. Specifically, male gender and younger age were associated with higher hyperactivity/inattention. It is likely that the COVID-19 lockdown may be particularly stressful for parents, who may be facing concerns about the economic and physical health of their family; their children's isolation from peers and teachers; and the management, duration, and outcomes of their homeschooling (Fontanesi et al., 2020; Schmidt et al., 2020). These feelings and concerns may cause psychological distress, which is an emotional state characterized by depressive and anxious symptoms. Parents experiencing high psychological distress may be less attentive to and warm with their children. They may also transfer the burden of their emotional distress to their children, which could affect their children's adjustment. These results are in line with recent research suggesting that parental distress, a disadvantaged economic situation following the COVID-19 lockdown (i.e., loss of job or income), and social isolation represent important risk factors for child abuse and neglect, family violence, and a deterioration of the parent-child relationship (Brown et al., 2020; Gassman-Pines et al., 2020; Patrick et al., 2020).

The second aim of our study was to test parent verbal hostility and child emotional symptoms as mediators of the association between parent psychological distress and child hyperactivity/inattention. While the association between parent and child mental health in community samples is well-established

(e.g., Smith, 2004; Goodman et al., 2011), many authors have argued the need to study the mechanisms through which the psychological symptoms of parents and their children are associated (Powdthavee and Vignoles, 2008; Baiocco et al., 2019). Various processes – not yet fully understood – may be used to explain the association between parent psychological distress and child behavioral problems. Parenting practices have

long been cited as an important risk factor for child externalizing problems (Prevatt, 2003; Marmorstein and Iacono, 2004). Specifically, retrospective studies have demonstrated that verbal abuse during childhood is related to externalizing and internalizing disorders in adulthood, such as mood and anxiety disorders, eating disorders, substance abuse disorders, personality disorders, and schizophrenia, as well as to suicide risk

(Carr et al., 2013; Falgares et al., 2018). In a study of children aged 9–12 years, Donovan and Brassard (2011) showed that maternal verbal aggression was associated with depressive symptoms, delinquency, peer overt and relational victimization, and low self-esteem.

The results of the present study show that parent verbal hostility and child emotional problems during the COVID-19 lockdown were positive serial mediators of the relationship between parent psychological distress and child hyperactivity/inattention. The association between parent verbal hostility and child externalizing symptoms is consistent with the findings of previous studies (Pinquart, 2017); however, the present study also considered the interrelation between child emotional symptoms and hyperactivity/inattention, due to a substantial lack of evidence on this topic. Understanding the co-occurrence and temporal dynamics of hyperactivity/inattention and emotional symptoms may be significant for explaining the development of hyperactivity/inattention from childhood through adolescence and into adulthood. In addition, a closer exploration of these processes is warranted because the additional presence of emotional symptoms can significantly affect quality of life, academic performance, adult adjustment, and lifetime psychiatric comorbidities (Wehmeier et al., 2010; Seymour et al., 2012; Verrocchio et al., 2015). Our findings show that emotional symptoms of children significantly predicted their hyperactivity/inattention. Previous studies have confirmed that hyperactive/impulsive symptoms may be related to negative emotionality, irritability, a low frustration tolerance, and conduct problems (Martel and Nigg, 2006; Sobanski et al., 2010; Lin and Gau, 2017). Furthermore, our results are consistent with the findings of a study in which children whose parents frequently expressed negative affect and low warmth displayed underregulated emotion and were more prone to displaying externalizing behaviors, relative to children whose parents were warm and frequently expressed positive affect (Eisenberg et al., 2001).

The findings of the current study should be interpreted in light of a balanced consideration of the limitations and strengths of the research. No data on the effects of parents' psychological distress on children during the COVID-19 epidemic were available at the time of investigation. The use of a cross-sectional online survey enabled us to recruit as wide and representative a sample of the Italian population as possible, and it was considered the best way to obtain a timely picture of the national situation. However, the strengths of our study (i.e., the contribution to the knowledge base, the large sample size, and the use of validated psychological measures) should be measured against the study's limitations, which include the cross-sectional study design, which prevented us from detecting the direction of causality; the exclusive reliance on parent-report data on children; the possibility of social desirability bias; the sample restriction to only those participants with Internet access; participants' motivation to take the online assessment; and the low number of fathers enrolled.

Further longitudinal research in different countries involved in the COVID-19 pandemic and the use of observational measures and/or other informants of child emotional symptoms

and behavior are needed. Future research efforts should continue to explore the negative influences of parents' psychological distress during the COVID-19 lockdown on the well-being of children. For example, researchers could explore possible negative outcomes associated with specific types of parenting styles. Child development studies have demonstrated that warmth/hostility and restrictiveness/permissiveness are reliably related to child behavior, with a combination of high warmth/care and a moderate level of control providing the healthiest emotional and social outcomes (Burns and Dunlop, 1998). Research could also explore the individual and combined influence of parent psychological distress and parenting styles in the household, as well as the influence of specific parents' occupation (e.g., nurse or doctor). Another important question is whether certain children are more or less vulnerable, depending on their personal characteristics and temperament, as well as previous psychopathological diseases that can contribute to the development of specific vulnerabilities.

The knowledge contributed by the present study about the influence of parents' psychological distress on children's well-being during a pandemic may have two notable practical implications. First, our research could have relevant implications in the social care setting and, particularly, in the implementation of population-based projects aimed at reducing parents' psychological load. Second, the results are a useful starting point for identifying the aspects that can influence the parent-child relationship and children's distress and for directing interventions in the context of family therapy.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Board of the Department of Human Neuroscience, Faculty of Medicine and Dentistry, Sapienza University of Rome (id nr. 6.2020). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

MV, DM, and PR contributed to the concept and the design of the research project. LF, MV, and DM contributed to the analysis of the literature. CM and SG contributed to the administration of online survey and acquisition of data. DM and LF contributed to the analysis, interpretation and writing of data. The World Health Organization defined COVID-19 as a pandemic on March 11, due to the spread of the new SARS-CoV-2 coronavirus in all continents. Italy had already witnessed a very fast spread that brought the Government to place the entire country under quarantine on March 11, reaching more than 30,700 fatalities in 2 months. We hypothesized that the pandemic and related compulsory quarantine would lead to an increase of anxiety state and protective behaviors to avoid infections. We aimed to investigate whether protective behaviors might have been enhanced or limited by anxiety and emotional reactions to previous experience of stressful conditions. We collected data from 618 Italian participants, by means of an online survey. Participants were asked to rate their level of worry for the pandemic, and to complete two questionnaires measuring the anxiety level: the state-trait anxiety inventory (STAI-Y) and the Pre-traumatic stress reaction checklist (Pre-CI). Finally, the respondents were also asked to report about their compliance with protective behaviors suggested to avoid the spread of the virus (e.g., washing hands). Results show that respondents with higher levels of worry reported higher levels of anxiety and pre-traumatic reactions, with positive correlations among the three measurements, and that higher frequency of the three protective behaviors were put in place by respondents with higher levels of worry. Moreover, regression analysis showed that worry for COVID-19 was most predicted by age, anxiety levels, and Pre-traumatic stress. These results could be interpreted in an evolutionary framework, in which the level of worry leads persons to become more cautious (protective behaviors) maximizing long-term survival at the cost of short-term dysregulation (anxiety).

**Keywords:** COVID-19, anxiety, pre-traumatic stress reactions, protective behaviors, emotional worry

## INTRODUCTION

Beginning in the last months of 2019, a new coronavirus has spread worldwide triggering a viral pandemic in a few weeks, known as COVID-19, involving a respiratory syndrome with potentially severe complications (Cascella et al., 2020). This new coronavirus had been firstly isolated in Wuhan, China (Li et al., 2020b), but in a few weeks, the virus managed to infect the whole world being defined as a pandemic by the World Health Organization on March 11, 2020. This means that

all of us were suddenly exposed to daily information about the dramatic impact of the epidemic on global health. The new term “infodemic” was coined and referred to the great amount of information available online and by means of traditional and social media which is not always truthful or controlled by reliable sources. The worldwide consequences of the pandemic have been and will continue to be highly dramatic in terms of social, financial, and individual burden such as mortality (356,000 deaths at the present time), morbidity (about two million persons infected in 5 months), deprivation of personal freedom due to the recommended or imposed quarantine, and about one trillion dollars that has been estimated to be lost<sup>1</sup> (April, 2020). The cost in terms of psychological pressure has been heavy as well. It has been recently found, for instance, that healthy persons exposed to higher doses of media information about COVID-19 also reveal higher psychological distress (Yao, 2020).

In this scenario, Italy paid a very high price with more than 30,000 deaths from the end of February to mid-April, becoming the first and most afflicted country in Europe and in the world in that period. Preliminary epidemic data showed that male individuals had a higher likelihood to contract the virus compared to females (2/3 of the Italian infected patients were males) and, once infected, males were more likely to need hospitalization and to suffer from serious consequences than females (Onder et al., 2020). Moreover, COVID-19 was found to be more dangerous for older persons than for younger ones and for patients suffering from other chronic illnesses (Remuzzi and Remuzzi, 2020). A number of online studies proliferated worldwide with the aim to understand the impact of the epidemic on psychological variables such as depression and anxiety, as for instance, in China (Huang and Zhao, 2020; Lei et al., 2020; Li et al., 2020a), Iran (Moghanibashi-Mansourieh, 2020), Turkey (Özdin and Bayrak Özdin, 2020), Spain (Ozamiz-Etxebarria et al., 2020), and Italy (Mazza et al., 2020). All of these studies confirmed the psychological cost of the pandemic, compulsory quarantine, and excessive media exposure (infodemic).

## The Current Study

The general aim of this study was to investigate whether anxiety states and previous experiences of stressful conditions (pre-traumatic stress reactions) would influence the adoption of protective behaviors in order to avoid infection and to protect individual health (for a theoretical model see Freeston et al., 2020). In particular, we first investigated the possible effects of demographic differences on the anxiety level in the general Italian population. We hypothesized (1) that personal variables (gender, age, education, and occupation), as well as living in highly infected zones, could have an impact on the anxiety levels connected to COVID-19 infection. Then, because the quarantine period was made compulsory in Italy to all of the population since the 9th of March, we aimed at providing an overview of the daily protective habits of Italians, investigating the proclivity to adopt the behaviors suggested by the WHO (washing hands, opening windows, disinfecting living environments). Thus, we also hypothesized (2) that high levels of concern and worry for

COVID-19 could have an impact on the protective behaviors (Brooks et al., 2020; Li et al., 2020c) by enhancing an abnormal illness behavior (Lipowski, 1987) toward fueling hypochondriacal concerns or avoid behavioral recommendations. In fact, recent studies limited to parents and families, suggest that anxiety levels are connected to safety behaviors, but the health risks and fear connected to COVID-19 influence the rates of stress (Lauri Korajlija and Jokic-Begic, 2020; Spinelli et al., 2020). Most of the studies concerning previous pandemics had focused on either the cognitive aspects related to what the population knew about the illness and what people really did to prevent the spread of the pandemic (Barr et al., 2008), or on the affective aspects of the disaster, investigating post-traumatic stress disorder (PTSD), depression, or anxiety (Goodwin et al., 2011; Karademas et al., 2013). Finally, we explored (3) whether anxiety states determined by the current situation and individual predisposition to anxiety reactions (pre-traumatic stress reactions) might facilitate or inhibit the suggested protective behaviors. To our knowledge, the relationship between anxiety and protective behaviors during the COVID-19 lockdown has received very little attention, with respect to other psychopathological domains. It might constitute an important helpful evidence to understand whether and up to which extent the suggested guidelines to prevent the contagion can be affected by the psychological states (namely anxiety and stress) and by demographical differences (e.g., age, gender, and regional areas). Importantly, as it would be difficult to identify people meeting DSM-5 (American Psychiatric Association, 2013) diagnostic criteria for PTSD, because the pandemic is still ongoing, participants were asked to complete a questionnaire already used with Afghanistan veterans to measure their pre-traumatic stress reactions namely the Pre-CI scale. Previous studies have indeed shown that pre-traumatic stress reactions are a valid predictor of PTSD (Berntsen and Rubin, 2015).

## MATERIALS AND METHODS

### Data Sources and Procedure

Between March 26 and April 8, we used an online link to invite Italian participants to take part in a survey on the effects of COVID-19. During these 2 weeks, COVID-19 epidemic showed a great spread in Italy. On March 26, 62,013 persons were recorded as newly infected and 8,165 died because of COVID-19; on April 8, infected people raised at 95,262 and deaths to 17,669<sup>2</sup> on a total Italian population of 60,317,000 inhabitants. The survey was created and redistributed by using Qualtrics XM<sup>3</sup>. Participants completed the survey only after indicating their consent on a form that described the study aims, participant rights, and data treatment procedure. Participants were recruited through social media and snowball sampling. The survey took approximately 20 min to complete, and participation was voluntary, anonymous, and free. Due to both the lack of previous similar data available

<sup>2</sup><http://opendatadpc.maps.arcgis.com/apps/opsdashboard/index.html#/b0c68bce2cce478eaac82fe38d4138b1>

<sup>3</sup><https://www.qualtrics.com/it/?rid=langMatch&prevsite=en&newsite=it&geo=IT&geomatch=>

<sup>1</sup><https://unctad.org/en/Pages/Home.aspx>

when the online questionnaire was built and the need to obtain responses in a specific time window, the sample size was not specifically calculated *a priori*. At the beginning of the survey, the participants were informed that they would be asked to respond to a series of questions, specifying that all data would be treated anonymously and they were asked to agree with the informed content by clicking a button, otherwise they were redirected outside of the survey. The research was conducted in accordance with the ethical principles stated in the Declaration of Helsinki (World Medical Association, 2013), and approved by the Institutional Review Board of Psychology (IRBP) – Department of Psychological, Health and Territorial Sciences, Università degli Studi “G. d’Annunzio” Chieti-Pescara (id. nr. 20009).

The survey was composed of different sections. Here, we report data about socio-demographic information, anxiety level measured by using the STAI-Y questionnaire (Spielberger et al., 1983a), pre-traumatic stress reactions measured by using the Pre-Cl questionnaire (Berntsen and Rubin, 2015), affective worry (AW) measured by means of a list of questions adapted from a previous study (Liao et al., 2014), and protective behaviors constituted by three items about the daily behaviors recommended by the WHO in order to prevent the spread of COVID-19. When unavailable, the Italian translation was made *ad hoc* and validated by a bilingual person.

## Demographic Data

The survey was fully completed by 618 participants, including 441 females (71.36%) and 177 males (28.64%). The age of the sample ranged from 19 to 80 years old (means  $\pm$  SE:  $38.55 \pm 0.61$ ; SD = 15.26) and four age groups were created: group (a) 19–25 years old ( $N = 161$ , 26.01%); group (b) 26–35 years old ( $N = 164$ , 26.5%); group (c) 36–50 years old ( $N = 163$ , 21%); and group (d) 51–80 years old ( $N = 86$ , 26.4%). Education levels showed that 282 (45.7%) participants have a high school diploma (13 years of study), 235 (38%) have achieved the bachelor’s or master’s degree, and 101 (16.34%) have achieved a post-graduate degree. As regards with the current occupation, in our sample, 169 (23.35%) participants are students, 341 (55.18%) have a regular job, and 118 (17.47%) are retired or unemployed. These three classes were also grouped under two main categories: “unoccupied” ( $N = 265$ , 43%) and “occupied” ( $N = 353$ , 57%). Sixty-seven participants (10.8%) have declared to live in the so called “Redzones,” namely the Northern Italian regions with highest rates of deaths and infections (Lombardy, Veneto, Emilia-Romagna, and Piemonte) accounting for the 71.32% of all the COVID-19 cases in our Country.

## Measurements

### Anxiety

The Italian version of the State-Trait Anxiety Inventory, STAI-Y1 (Spielberger et al., 1983b; Pedrabissi and Santinello, 1989) was used to measure the current level of anxiety. The questionnaire is composed of 20 items investigating the general feelings of respondents on a 1–4 Likert scale. Ten items are focused on negative feelings and 10 items are focused on positive feelings. Responses on the positive items were reversed, so that higher scores to the STAI correspond to a higher level of anxiety (range:

from 1 to 80). The mean score of the whole sample was 48.92 ( $\pm 0.42$ ), Cronbach’s alpha for the present research is 0.94.

### Pre-traumatic Stress Reactions

The Pre-traumatic stress reaction Check List (Pre-Cl, Berntsen and Rubin, 2015) is a 20-item questionnaire investigating the psychological reactions to dangerous events, which at the moment of administration are still active. It has been shown to significantly correlate with the measurement of PTSD, as already found with Danish soldiers employed in Afghanistan (Berntsen and Rubin, 2015), showing its potential as a possible tool to predict the stress-related reaction in the population involved in the pandemic without the need to wait for the emergence of a PTSD diagnosis. It investigates the feelings of respondents in the last month on a 0–4 Likert scale. The final score ranges from 0 to 80, with higher scores corresponding to higher pre-traumatic reactions (e.g., intrusive involuntary images of possible future stressful events and their associated avoidance and increased arousal). As proposed by the authors who elaborated the questionnaire, pre-traumatic stress reactions are defined as disturbing future-oriented cognitions and imaginations which can be part of PTSD investigated by a temporal reversal of the past-directed items used in the diagnosis of PTSD. The advantage of this measure is that it can quantify a “sub-component” of a possible PTSD, during—not after—the traumatic event. Pre-Cl was translated in Italian and the mean score of the sample was 26 ( $\pm 0.66$ ). It could be of interest to underline that the mean Pre-Cl score measured in 211 soldiers was 22.85 (Berntsen and Rubin, 2015). For the present research, Cronbach’s alpha is 0.92.

### Affective Worry

Affective worry represents the emotional response to the risk of being infected with COVID-19. The levels of apprehension and concern for contracting the new coronavirus was measured by five items adapted from a study investigating the 2009 influenza AH1N1 pandemic in Hong Kong (Liao et al., 2014), and specifically translated in Italian: a 7-point Likert scale was used for three items, measuring (i) the level of concern to have contracted the new coronavirus with respect to a “seasonal flu” in case of flu-like symptoms, (ii) the level of concern to contract the new coronavirus in the next 1 month, and (iii) the level of concern to contract the new coronavirus in the next 1 month with respect to the overall population. A 5-point Likert scale was used to measure the level of concern to have contracted in the past 1 week the new coronavirus. A 10-point Likert scale was used to investigate the current level of concern toward the new Coronavirus. In all of the items, higher scores correspond to a higher level of concern. Cronbach’s alpha for the present research is 0.75.

### Protective Behaviors

The last part of the survey was aimed at quantifying the protective behavior acted by the respondents and corresponding to the recommendation suggested by the WHO in order to avoid the spread of the virus. In particular, participants were asked whether in the past 7 days they had (i) washed their hands more often than usual, (ii) cleaned and disinfected their house

**TABLE 1** | Characteristics of the sample.

Demographic variables	Pre-CI		STAI-Y		AW	
	<i>M</i>	<i>DS</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
<b>Gender</b>						
<i>Men</i>	19.78	14.25	44.14	9.76	18.71	5.10

more often than usual, and (iii) often opened home windows to maintain good ventilation. Moreover, in case of a positive response, participants were asked to state whether that behavior was carried out specifically to prevent the infection spread or for other reasons. For these three items, the responses were coded as one if the respondents declared to have carried out the behavior to prevent the Coronavirus spread, otherwise they were coded as 0.

## Statistical Analysis

Data were analyzed using IBM SPSS 26. *T*-tests and analysis of variance (ANOVA) were used to analyze the differences between subgroups in the study variables. Cohen's *d* was used as effect size index for the comparison between means and Tukey's HSD for ANOVA *post hoc* analysis. Pearson correlation analysis was used to assess the correlation between the study variables. Hierarchical linear regression model was used to evaluate the influences of personal factors and psychological variables on the affective worries. Predictors were personal factors (gender, age, and occupation), COVID-19-related experiences (living in a high infected density area), and psychological variables (Pre-Cl and STAI-Y).

## RESULTS

### Personal Variables and Anxiety

Table 1 shows the sociodemographic characteristics and scale scores of the sample. Female participants scored significantly higher than male participants to psychological scales of Pre-Cl ( $d = 0.60$ ), STAI-Y ( $d = 0.67$ ), and in the AW ( $d = 0.38$ ). ANOVA *post hoc* results showed that Pre-Cl and STAI-Y scores ( $p < 0.05$  and  $p < 0.01$ , respectively) were significantly higher in less educated participants and students ( $p < 0.01$  and  $p < 0.01$ , respectively), which was to be expected because a large number of participants with a high school diploma were college students (35%). Surprisingly, living in a highly COVID-19 infected areas (*redzones*) did not affect the psychological scales scores. Pearson correlation analysis showed that trait anxiety (STAI-Y) was largely associated with Pre-Cl ( $r = 0.708$ ,  $p < 0.01$ ) and moderately with AW ( $r = 0.434$ ,  $p < 0.01$ ) that, in turn, was moderately associated with Pre-Cl ( $r = 0.397$ ,  $p < 0.01$ ) (data not shown; available at request to the corresponding author).

### The Effects of Concern for COVID-19 on Protective Behaviors

Table 2 shows the characteristics of suggested protective behaviors. People who carry out protective behaviors due to concern about COVID-19 infection showed higher levels of AW. In particular, people who wash their hands more frequently due to the fear of being infected showed significantly higher levels of AW than other participants ( $d = 1.04$ ), a moderate effect was also found in participants who disinfected or cleaned their house due to COVID-19 ( $d = 0.63$ ). Participants who open their windows to refresh their house to prevent the infection of COVID-19 showed moderately higher levels of Pre-Cl ( $d = 0.26$ ) and trait anxiety ( $d = 0.32$ ), and higher levels of AW ( $d = 0.56$ ). Table 3

**TABLE 3 |** Hierarchical regression analysis for personal and psychological variables predicting affective worry (AW).

	B	SE	$\beta$	R	R <sup>2</sup>
<i>Step 1</i>					
Gender	0.78	0.42	0.07	0.20	0.04***
Age	0.04	0.01	0.11**		
Education	-0.41	0.26	-0.06		
<i>Step 2</i>					
Redzones	0.45	0.58	0.03	0.23	0.05*
Occupation	1.50	0.40	0.15***		
<i>Step 3</i>					
STAI-Y1	0.15	0.02	0.30***	0.49	0.24***
Pre-Cl	0.07	0.02	0.20***		

The tabled values for beta reflect Bs after Step 3, \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

Gender: 1, male; 2, female; Redzones: 1, living in a Redzone; 0, not living in a Redzone; Occupation: 1, working, 0, student/not unoccupied.

shows the hierarchical regression model for predicting AW from sociodemographic and psychological variables. Being older ( $B = 0.04$ ,  $\beta = 0.11$ ,  $p < 0.01$ ), and having an occupation during the lockdown ( $B = 1.50$ ,  $\beta = 0.15$ ,  $p < 0.001$ ) were significantly associated to AW, even though they predicted only less than 1% of its variance. Trait anxiety ( $B = 0.15$ ,  $\beta = 0.30$ ,  $p < 0.001$ ) and Pre-Cl ( $B = 0.70$ ,  $\beta = 0.20$ ,  $p < 0.001$ ) showed higher association with AW by explaining 24% of its added variance.

## DISCUSSION

A number of studies published in the last weeks (Liao et al., 2014; Asmundson and Taylor, 2020; Huang and Zhao, 2020; Lei et al., 2020; Mazza et al., 2020; Moghanibashi-Mansourieh, 2020; Ozamiz-Etxebarria et al., 2020; Özdin and Bayrak Özdin, 2020) showed increased anxiety and stress levels due to the COVID-19 pandemic and lockdown. The present study was aimed at investigating the behavioral impact of emotional responses to such a stressful event. As expected, the results of the present study confirm gender and age differences on psychological reactions to COVID-19 consistent with another recent Italian report (Mazza et al., 2020). Women and younger adults scored significantly higher to trait anxiety (STAI-Y), pre-traumatic stress levels (Pre-Cl), and AW than men and older participants. These results are in line with previous investigations showing overall higher levels of anxiety (McLean et al., 2011; Li and Graham, 2017) and vulnerability to experience post-traumatic reaction in women than in men (Sareen et al., 2013). Furthermore, younger adults are likely to be more exposed to "infodemia" because they can be more exposed to social media and the Internet (Siliquini et al., 2011) and, therefore, more vulnerable to increased anxiety and stress attributable to this massive and uncontrolled exposition to pandemic information (Yao, 2020). Another possible explanation for this latter result is that younger participants may have a lower psychological buffer because of a lower educational level since younger age, student status, and education all experienced more anxiety than the other subgroups. Surprisingly, living in

a “redzone” (i.e., in a highly infected area with higher mortality rates) did not influence emotional reactions or behavioral habits. This may be due to the fact that less than 11% of our sample lived in a “redzone” or that the local impact of the infection were less powerful than the “infodemic” influence on psychological states. Overall, within our sample, only gender is related to the AW, whereas age, educational level, occupation, and gender are related to both anxiety and stress reactions. This pattern of results is partially confirmed by the regression model showing that 24% of the total variance of AW is explained by older age, having a job during the lockdown, and stress.

Our aim was also to assess the effect of these psychological traits on the daily behavior suggested in order to prevent the spread of the virus. To this aim, we took into account three specific behaviors (frequent hands washing, house disinfection, and opening windows), and asked participants whether they complied with these behaviors in the last weeks with the specific aim to prevent the pandemic. The results showed that hand washing and house cleaning/disinfecting are not influenced by either anxiety or stress levels, while participants with higher scores in both anxiety and stress scales are more prone to open the windows to ventilate the living environments. Furthermore, all of the three protective behaviors (hand washing, house disinfecting, and opening the windows) are influenced by the AW: participants with a higher level of worry about the COVID-19 declared to carry out each behavior more than the participants with a lower level of AW. The present data suggest that the anxiety connected to the fear of COVID-19 infection can be the motivation to engage in the recommended protective behaviors.

It is also relevant to note that our sample scores are relatively higher in the STAI-1Y scale. In fact, 63% of participants reported a score higher than 40, which researches suggest to be the clinical cut-off score for moderate symptoms, and the 14% scored higher than 60, which is the cut-off score for severe clinical anxiety symptoms (Pedrabissi and Santinello, 1989; Barisone et al., 2004). It is possible to suggest that, in line with other studies (Marchetti et al., 2020; Mazza et al., 2020), the general population’s levels of anxiety and stress symptoms have risen due to COVID-19 fear and uncertainty.

A final remark has to be made concerning the measured stress. As specified, we measured the stress level by means of the Pre-Cl, a scale previously used with Afghanistan soldiers before, during, and after their war experience (Berntsen and Rubin, 2015). This scale has been shown to significantly predict the PTSD symptoms in that population, and we used this scale in order to have a rapid frame of a possible PTSD in the general population, at least in Italy, once the medical emergency will be controlled (namely, after the traumatic period). These results may be intended as a snapshot of a possible escalation of PTSD in the world, although caution is needed about the possibility to generalize this conclusion. In fact, it should be highlighted that an online survey was the only tool available to collect data during the quarantine. Nevertheless, due to the specific methodology used, one of the limitations is the uncontrolled representativeness of the sample (e.g., higher proportion of younger than older respondents, as well as of women rather than men). Similarly, some of the psychological scales used in the present study are not specifically validated for the online testing, and in particular, the Pre-Cl

is a scarcely used test, which has been employed with Danish soldiers and it was not used in circumstances similar to those here described. For the same reason, even if it has been shown that in the military sample Pre-Cl scores significantly correlate with PTSD (Berntsen and Rubin, 2015), we could hypothesize a generalization of such a correlation to the sample tested here, but further studies are needed in order to confirm this possibility. Finally, due to the impossibility to assess a previous diagnosis of anxiety and related disorder [e.g., obsessive compulsive disorder (OCD)], our results, while promising, can be subjected to two biases. Firstly, we investigated some behaviors that are salient for people with OCD, and this could have had an impact on some participants’ answers. Then, the participants with previous diagnosis of anxiety disorders may have found themselves in an uncomfortable situation while participating in the survey, and that may have raised the levels of anxiety. Due to these reasons, future research should investigate the effect of lockdown and COVID-19 related behavior specifically in clinical samples.

We can conclude that targeted interventions by governments and institutions in support of the psychological wellbeing of the general population are desirable. The present results suggest that a particular attention should be focused on the part of population who had shown to be more prone to anxiety and stress, namely women, younger people, and students, who could be exposed to a real post-traumatic stress disorder.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The study was designed and carried out in accordance with the World Medical Association Declaration of Helsinki and its subsequent revisions, and approved by the Institutional Review Board of Psychology – Department Of Psychological, Health And Territorial Sciences, University “G. d’Annunzio” of Chieti-Pescara. The participants provided their online informed consent to participate in this study.

doi: 10.3389/fpsyg.2020.567522

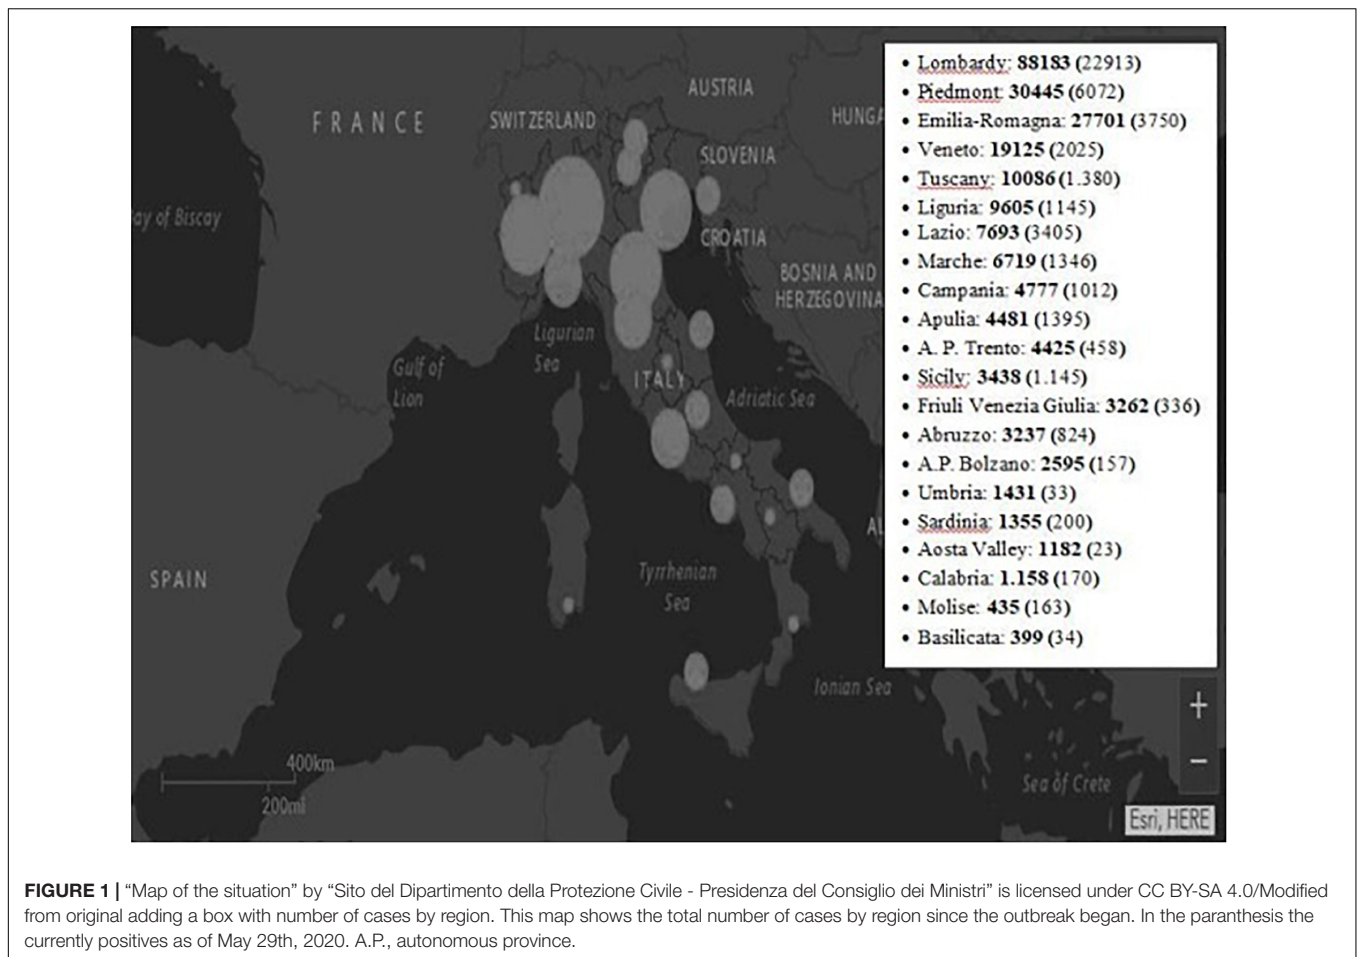

The new Coronavirus (COVID-19) has been declared a global pandemic by the World Health Organization (WHO). The sudden outbreak of this new virus and the measure of lockdown adopted to contain the epidemic have profoundly changed the lifestyles of the Italian population, with an impact on people's quality of life and on their social relationships. In particular, due to forced and prolonged cohabitation, couples may be subject to specific stressors during the epidemic. In addition, living with a chronic health condition may add specific challenges to the ones posed by the epidemic itself. The present cross-sectional study aimed to provide a picture of the challenges as well as the resources for both individual and relational well-being of Italian individuals in a couple relationship ( $N = 1921$ ), with a specific attention to the comparison between individuals living with and without a chronic disease. Results showed that people with a chronic disease had lower psychological well-being and more fears and worries about the COVID-19. People with a chronic disease perceived fewer resources than healthy people. Moreover, the challenges are shown to be associated with less psychological well-being and high pessimism about the future. Instead individual, relational, and social resources play a protective role during the pandemic for both healthy and chronically ill people.

**Keywords:** COVID-19, chronic illness, stress, psychological well-being, relational well-being

## INTRODUCTION

The new Coronavirus (COVID-19) has been declared a global pandemic by the World Health Organization (WHO). In Italy, since the first official case of COVID-19 (February 20th, 2020), a rapid spread of the contagion was reported, making Italy, and especially the North of the country, one of the countries with the highest COVID-19 infection and victim rates (**Figure 1**). Since March 11th, a strict lockdown was adopted by the Italian government to contain the epidemic: Group activities, social gatherings, outdoor activities were prohibited or strongly limited, businesses

**FIGURE 1 |** “Map of the situation” by “Sito del Dipartimento della Protezione Civile - Presidenza del Consiglio dei Ministri” is licensed under CC BY-SA 4.0/Modified from original adding a box with number of cases by region. This map shows the total number of cases by region since the outbreak began. In the parenthesis the currently positives as of May 29th, 2020. A.P., autonomous province.

that were not regarded as essential were forced to close or - whenever possible- opt for smart-working, etc. Such measures have drastically changed people’s day-to-day life. These changes were essential to contrast the spreading of coronavirus and protect the health system, though they inevitably produced some unintended consequences on people’s lives. Indeed, they profoundly affected people’s quality of life, generating not only changes in lifestyles, social relationships and in the perception of others, but also in the level of stress (Franceschini et al., 2020; Landi et al., 2020; Rossi et al., 2020). In addition to physical and psychological health risks, isolation and loneliness, closure of businesses, organization of home-schooling, economic vulnerability, and job losses were some among the many stressors derived from this emergency (e.g., Crayne, 2020; Di Crosta et al., 2020; Pietrabissa and Simpson, 2020). In fact, pandemic causes psychological consequences on those individuals who are infected by the virus (e.g., Duan and Zhu, 2020), on health professionals (e.g., Barello et al., 2020; Giusti et al., 2020; Vagni et al., 2020a), but also on the non-infected community, because they impact several aspects of social life more generally. In fact, people’s quality of life was profoundly touched by the sudden outbreak of this new virus and by this measure of lockdown (Casagrande et al., 2020; Favieri et al., 2020; Mazza et al., 2020; Zeppegno et al., 2020). Previous studies on COVID-19 reported

an influence of both the disease and quarantine measures on psychological well-being (Brooks et al., 2020; Liu S. et al., 2020; Rossi et al., 2020; Xiao et al., 2020), highlighting an increase in anxiety and depressive symptoms and in the perception of lack of control in the general population together with a general decrease in levels of well-being and perception of health in general (Lima et al., 2020).

In this scenario, having a partner, and sharing this emergency with him/her, may be an important protective factor for people’s well-being, as the couple relationship has proved to promote both physical (Koball et al., 2010; Horn et al., 2013) and psychological health (Donato and Parise, 2015; Pagani et al., 2015; Donato et al., 2018a; Pagani et al., 2020). Nonetheless, the couple itself may be subject to specific stressors during the epidemic. Forced and prolonged cohabitation, with no physical space nor time alone to unloading one’s stress and negative emotions, may have put some extra pressure on the couple’s daily life, especially if partners are already engaged in coping with additional stressors (Randall and Bodenmann, 2009).

In particular, living with a chronic health condition may add specific challenges to the ones posed by the epidemic itself (Mazza et al., 2020). Based on currently available information and clinical expertise, people of any age who have serious underlying medical conditions might be at higher risk for severe consequences from

COVID-19, thus people living with a chronic disease may have feared to be particularly susceptible to the virus or particularly at risk once infected. Several public and private agencies, in fact, resolved to provide specific guidelines for chronic disease patients in order to respond to their FAQs (e.g., the COVID-19 hotline specific for diabetes patients set up by the Italian Health Ministry). In addition, both the congestion of the health system over several weeks after the virus outbreak and the closing of outpatient services may have made chronic disease patients' management of the chronic condition as well as their daily life particularly difficult and challenging. The stress pile-up that this segment of the population may have lived with particular intensity might have lasting consequences on their well-being well after the end of the epidemic, which may reverberate on the sanitary system in the long run. On the other hand, people living with a chronic disease may have developed important competences for managing their health as well as stressful health circumstances (Bertoni et al., 2015; Graffigna et al., 2017), which may represent relevant resources to navigate the epidemic period.

The present study aimed to provide a picture of the challenges as well as the resources for both individual and relational well-being of Italian individuals in a couple relationship, with a specific attention to the comparison of individuals living with and without a chronic disease.

Stress is generally recognized as challenging for both individual and relational well-being (Donato and Parise, 2015; Pagani et al., 2015; Donato et al., 2018b; Pagani et al., 2020). In particular, according to Chinese survey data (Liu D. et al., 2020) and the United States Centers for Disease Control and Prevention (Centers for Disease Control and Prevention, 2020), the outbreak of COVID-19 has undoubtedly been a stressful event. The pandemic situation can be highly stressful for individuals at different levels. Changes in the domain of work (job uncertainty, smart-working, work overload), economic worries, and social distancing, on the one hand, and forced cohabitation, on the other hand, may be especially challenging for people's well-being (Godinic et al., 2020). In addition, fear of contagion is particularly critical for well-being (Mertens et al., 2020; Venkatesh and Edirappuli, 2020), generating anxiety for one's own personal health and for the health of significant others. Further, the pandemic situation could generate not only concerns for one's own personal and relational condition, but also concerns for the consequences of COVID-19 at a more global level (i.e., concerns for the world future, concerns for the general community). In light of this, in the present study we focused our attention on three challenges to well-being: global stress, fear of contagion, and worries about the epidemic consequences.

Besides challenges, it is important to identify also those resources that may help individuals to cope with the situation (e.g., Lenzo et al., 2020). In particular, we considered individual, relational, and social resources, which may protect individuals' well-being. At the individual level, a central concept in understanding how individuals cope with difficulties is their sense of coherence (Antonovsky, 1987). Sense of coherence can be conceptualized as a global orientation that influences the extent to which individuals perceive the world as comprehensible, manageable, and meaningful. Sense of coherence has been found

to be linked to well-being and mental health (Anderson, 1998; Eriksson and Lindström, 2007). In a situation in which the foundations of what makes life meaningful and comprehensible have been put at risk, sense of coherence may help maintain well-being. Moreover, individuals in a couple relationship can count not only on their individual coping (Vagni et al., 2020a), but also on dyadic coping strategies. Dyadic coping describes the interpersonal process partners use to jointly cope with stress (Bodenmann, 1997) and is an important factor in maintaining both individual and relational well-being (Donato, 2014; Donato et al., 2015; Pagani et al., 2019).

At the relational level, the capacity to work together as a couple against stress could be a key process in contrasting the negative impact of COVID-19 on partners' life. Also, at the social level, an important resource could be social support. Social support is an exchange of emotional, informational, or practical assistance with significant others aimed at enhancing the well-being of the recipient (Shumaker and Brownell, 1984). The psychosocial literature, in general, has highlighted the consequences for well-being of being the recipient of supportive acts. In a moment in which social distancing has been imposed as a means of prevention from contagion, perceiving the closeness and the support from one's family and friends could be protective for well-being. At this regard, we considered both individual (in terms of both psychological well-being and view of the future) and relational well-being (in terms of satisfaction for one's couple relationship).

In light of these premises, the study had two main goals: (1) To test whether healthy and chronically ill individuals differed in terms of the above challenges and resources. We could expect participants with a chronic disease to be subject to more challenges (i.e., higher levels of stress, fear of contagion, and worries about the epidemic consequences) than participants without a chronic disease. We made no specific predictions with regard to resources (i.e., individual and dyadic coping, family and friend support), as we could expect that, on the one hand, people living with a chronic disease may have developed important competences for managing their health as well as stressful health circumstances, such as a special awareness of their own health, on the other hand, however, their well-being could be more compromised than the one of their healthy counterparts due to their disease. Beyond the higher risk for severe consequences from COVID-19 for people with serious underlying medical conditions, these comparisons might allow us to reveal possible differences between people with and without a chronic health condition also in the psychosocial impact of the COVID-19 epidemic. In addition, we wanted to test whether the impact of a chronic disease on the challenges and resources experienced by individuals in couples depended on whether or not they lived in the North of Italy. The Northern regions of the country, in fact, were those more severely impacted by the epidemic. On the other hand, however, the Northern regions of Italy are also well-known to have the most efficient organization of sanitary services. (2) To analyze the moderating role of health condition (healthy vs. chronically ill) in the associations of the above challenges and resources with participants' individual and relational well-being (i.e., to test whether healthy and chronically

ill individuals differed in these associations as a function of their health condition). This analysis would allow us to identify common and/or specific factors to either contain or promote in order to protect participants' psychosocial well-being. We might expect a stronger impact of stress, fear of contagion, and worries on the well-being of participants with a chronic disease than in participants without a chronic health condition. As far as resources are concerned, in light of the reasons listed above we made no specific predictions.

## MATERIALS AND METHODS

### Participants and Procedure

The present study is part of a broader longitudinal research project, titled "The Family at the time of COVID19," developed by the Family Study and Research University Centre of the Università Cattolica del Sacro Cuore (Milan, Italy) in collaboration with the Human Highway Society. A web-based cross-sectional survey, broadcasted through different platforms and mainstream social-media, was used to collect data. The survey took place from March 30th to April 7th, the period of the national lockdown with constantly growing contagion rates. A brief presentation informed the participants about the aims of the study, and an electronic informed consent was requested from each participant before starting the investigation. The survey took approximately 30 min to be completed. A short questionnaire collected information on some demographic and COVID-19 related information. Standardized questionnaires to evaluate psychological dimensions were administered. To guarantee anonymity, no personal data, which could allow the identification of participants, were collected. Due to the aim of the current research, having at least 18 years was the only inclusion criterion adopted. The study was conducted in accordance with the Ethics Committee of the Department of Psychology of the Università Cattolica del Sacro Cuore. Participants could withdraw from the survey at any moment without providing any justification, and no data were recorded. For the purpose of the present study, we selected people reporting to be in a couple relationship ( $N = 1921$ ). The main demographic characteristics of the sample are shown in **Table 1**.

### Measures

The instrument used was a self-report questionnaire composed of the following scales, in addition to socio-demographic data.

#### Fear of Contagion

In order to assess the level of fear of being infected by the coronavirus, participants were asked to express their agreement on a 7-point Likert scale (1 = "not at all" and 7 = "very agree") to the *ad hoc* item "Are you worried about getting sick of COVID-19 (the disease caused by coronavirus infection)?"

#### Worries About the Epidemic Consequences

To assess the level of concern about the consequences of the situation connected to the spread of coronavirus, participants were asked to express their agreement on a 7-point Likert

**TABLE 1 |** Demographic characteristics of the sample.

Variables	Overall sample ( $N = 1921$ )	Healthy participants ( $N = 1446; 76.9\%$ )	Participants with a chronic disease ( $N = 434; 23.1\%$ )
<b>Gender</b>			
Female	1281 (66.7%)	952 (65.8%)	300 (69.1%)
Male	640 (33.3%)	494 (34.2%)	134 (30.9%)
<b>Age</b>			
18–24 years	12 (0.6%)	9 (0.6%)	3 (0.7%)
25–34 years	269 (14%)	224 (15.5%)	40 (9.2%)
35–44 years	656 (34.1%)	527 (36.4%)	114 (26.3%)
45–54 years	617 (32.1%)	458 (31.7%)	144 (33.2%)
55–64 years	272 (14.2%)	176 (12.2%)	92 (21.2%)
Over 65 years	95 (4.9%)	52 (3.6%)	41 (9.4%)
<b>Italian zone</b>			
Northern Italy	886 (46.6%)	660 (46.2%)	209 (48.3%)
All other zones	1017 (52.9%)	770 (53.8%)	224 (51.7%)
<b>Relationship</b>			
Marriage	1442 (75.1%)	1063 (73.5%)	349 (80.4%)
Cohabiting	479 (24.9%)	383 (26.5%)	85 (19.6%)
<b>Being a parent</b>			
Yes	1417 (73.8%)	1058 (73.2%)	327 (75.3%)
No	504 (26.2%)	388 (26.8%)	107 (24.7%)
<b>Educational qualification</b>			
Degree or Ph.D.	316 (32.7%)	540 (37.4%)	118 (27.3%)
High school diploma	525 (54.4%)	772 (53.4%)	236 (54.5%)
Secondary school diploma	118 (12.2%)	129 (8.9%)	74 (17.1%)
Primary school license	6 (0.6%)	4 (0.3%)	5 (1.2%)

scale (1 = "not at all" and 7 = "extremely") to the *ad hoc* single item "How concerned are you about the current coronavirus situation?"

### Stress

To measure their level of stress, participants were presented with a series of statements describing potential sources of stress related to different areas (personal, family or work-related). They were then asked to indicate their degree of stress related to each of these statement on a 5-point Likert scale (1 = "not at all" and 5 = "extremely"). Item examples were "Losing one's job"; "Managing family life". The Cronbach's alpha was 0.87.

### Individual Coping

Individual coping resources were assessed in terms of participants' sense of coherence, that is the confidence that one's environment is predictable and that things will work out as well as it can reasonably be expected (Antonovsky, 1979). Sense of coherence was measured through the Sense of Coherence Scale (SOC; Antonovsky, 1979; Barni and Tagliabue, 2005), which is composed of 13 items rated on a 7-point scale. Items examples are: "Are you surprised by the behavior of people whom you thought you knew well?"; "How often do you have feelings that you're not sure you can keep under control?"; "How often do you have the feeling that there's little meaning in the things you do in your daily life?". We computed a global index of the scale by

averaging the 13 items and its Cronbach's alpha was 0.79. Higher scores represent higher sense of coherence.

### Dyadic Coping

Dyadic coping is the way partners cope together against stress and was measured by the Dyadic Coping Questionnaire (DCI; Bodenmann, 1997; Donato et al., 2009). We used a selection of 8 items from the original 41-items scale, rated on a 5-point scale ranging from 1 = "never" to 5 = "very often," that measures positive and negative partner dyadic coping responses (e.g., "My partner proposed practical solutions to the problems that this situation caused"; "My partner accused me of not managing stress well enough"). In the current study, we used the total score that was computed by averaging the 8 items after reversing the negative items: Higher scores represent more supportive dyadic coping responses. The Cronbach's alpha was 0.71.

### Family Support

To assess the level of family support, we used the subscale of "The multidimensional scale of perceived social support" (Zimet et al., 1988) focused on the area of family. The four items of this subscale were rated on a 5-point Likert scale (1 = "not at all" and 5 = "very much"). Items examples are: "I can really talk to my family of my problems"; "My family really tries to help me make decision". The Cronbach's alpha was 0.93. Higher scores refer to a higher level of support from the family.

### Friends' Support

To assess the level of friends' support, we used the subscale of "The multidimensional scale of perceived social support" (Zimet et al., 1988) focused on the area of friends. The four items of this subscale rated on a 5-point Likert scale (1 = "not at all" and 5 = "very much"). Items examples are: "I can count on my friends when things go wrong"; "I have friends with whom I can share joys and sorrows". The Cronbach's alpha was 0.92. Higher scores stand for a higher level of support from friends.

### Psychological Well-Being

To measure their level of psychological well-being, participants were presented with a series of statements describing possible psychological and physical conditions. They were then asked to indicate their degree of these statement on a 6-point Likert scale (1 = "never" and 6 = "always") referring to their last week. Item examples were "I felt calm and peaceful"; "I felt discouraged and sad"; "I felt full of energy". The Cronbach's alpha was 0.65. Higher scores represent a higher level of psychological well-being.

### Pessimistic View of the Future

Pessimistic view of the future was measured through the "Dark Future Scale" (Zaleski et al., 2019) which is composed of 5 items rated on a 5-point Likert scale (1 = "absolutely wrong" and 5 = "absolutely true"). Items examples are: "I fear that the problems that worry me now will continue for a long time"; "I am terrified by the thought that I may have to face crises or difficulties in life". The Cronbach's alpha was 0.89. Higher scores refer to a more pessimistic view of the future.

### Relational Well-Being

Relational well-being was measured through one *ad hoc* item. This item ("Overall, how do you rate the relationship with your partner during this period?"), measuring global perception of couple relationship satisfaction, was administered on a 10-point scale (1 = "very negative" and 10 = "very positive"). Higher scores refer to higher relational well-being.

### Data Analyses

Data were analyzed using the software IBM SPSS version 22.0 (SPSS Inc. Chicago, IL, United States). Significance threshold was set at  $p = 0.05$ . In particular, descriptive statistics were used to summarize the overall and groups' (i.e., healthy vs. chronically ill) sample characteristics concerning the main variables of the study (Table 2). In order to explore differences among healthy people and people with a chronic disease from different regions of Italy, a series of 2 (Italian zones: Northern Italy vs. Rest of Italy)  $\times$  2 (Health status: No chronic disease vs. chronic disease) factorial ANOVAs were conducted for the study variables. Finally, a series of hierarchical multiple regression analyses was conducted to test the associations of the challenges (i.e., fear of contagion, worries about the epidemic consequences and stress) and resources (i.e., individual coping, dyadic coping, family support and friends' support) with the three outcomes of interest (i.e., psychological well-being, pessimistic view of the future, and relational well-being) as well as the moderating role of health condition in the associations between each predictor and each outcome.

## RESULTS

### Differences Among Healthy People and People With a Chronic Disease and Among Italian Zones for the Study Variables

A series of two-way factorial analysis of variance (ANOVA) was conducted for each measure. The dependent variable were: Psychological well-being, pessimistic view of the future, and relational well-being, while between-subject factors were: Health status that is the presence or absence of a chronic disease (two levels: 0 = no chronic disease; 1 = presence of a chronic disease), and Italian areas (two levels: 1 = northern Italy; 2 = rest of Italy).

#### Fear of Contagion

The ANOVA showed a significant main effect of Health status [ $F(1,1790) = 16.71, p < 0.001, \eta_p^2 = 0.09$ ]. There was also a statistically significant interaction between the effects of having or not a chronic disease and the Italian areas on fear of contagion [ $F(1,1790) = 3.77, p = 0.04, \eta_p^2 = 0.05$ ]. In particular, only in the central and southern Italy there was a significant effect of health status: People with a chronic disease who lived in central and southern Italy, had significantly more fear of contagion ( $M = 5.15, SD = 0.11, p < 0.001$ ) than healthy people who lived in the same areas ( $M = 4.57, SD = 0.06, p < 0.001$ ). In the Northern Italy there was not a significant effect of Health status (Healthy people:  $M = 4.57, SD = 0.07, p = 0.14$ ; People with a chronic disease:

**TABLE 2** | Descriptive statistics of all study variables by overall sample and groups.

Areas	Variables	Groups						
		Overall Sample ( <i>N</i> = 1921)		Healthy people ( <i>N</i> = 1446)		Chronic disease ( <i>N</i> = 434)		Scale range
		<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	
Challenges	Fear of contagion	4.67	1.70	4.57	1.69	4.96	1.71	1–7
	Worries about the epidemic consequences	6.08	1.15	6.05	1.16	6.16	1.12	1–7
	Stress	3.47	0.84	3.44	0.85	3.54	0.85	1–5
Resources (individual; dyadic; and social)	Individual coping (SOC)	4.75	1.15	4.79	1.16	4.65	1.12	1–7
	Dyadic coping	3.59	0.71	3.59	0.70	3.59	0.72	1–5
	Family support	3.36	0.97	3.39	0.96	3.23	0.97	1–5
	Friends' support	3.91	0.88	3.93	0.86	3.82	0.95	1–5
Outcomes	Psychological well-being	3.61	0.88	3.68	0.86	3.43	0.88	1–6
	Pessimistic view of the future	3.49	0.87	3.43	0.87	3.65	0.84	1–5
	Relational well-being	7.86	1.87	7.88	1.85	7.80	1.97	1–10

$M = 4.78$ ,  $SD = 0.12$ ,  $p = 0.14$ ). No significant main effect of Italian areas was found.

### Worries About the Epidemic Consequences

There was a statistically significant main effect of Italian areas [ $F(1,1859) = 7.69$ ,  $p = 0.01$ ,  $\eta_p^2 = 0.06$ ]. In particular, people who lived in northern Italy showed lower levels of worries about the epidemic consequences ( $M = 6.02$ ,  $SD = 0.05$ ) compared to people who lived in the rest of Italy ( $M = 3.19$ ,  $SD = 0.04$ ). The main effect of Health status [ $F(1,1859) = 3.44$ ,  $p = 0.06$ ], and the interaction were not significant [ $F(1,1859) = 1.11$ ,  $p = 0.29$ ].

### Stress

There was a statistically significant main effect of Italian areas [ $F(1,1859) = 9.14$ ,  $p = 0.01$ ,  $\eta_p^2 = 0.06$ ]. In particular, people who lived in northern Italy showed lower levels of stress ( $M = 3.42$ ,  $SD = 0.03$ ) compared to people who lived in the rest of Italy ( $M = 3.56$ ,  $SD = 0.03$ ). There was also a statistically significant main effect of Health status [ $F(1,1859) = 5.06$ ,  $p = 0.03$ ,  $\eta_p^2 = 0.06$ ]. In particular, people with a chronic disease showed more stress ( $M = 3.55$ ,  $SD = 0.04$ ) than healthy people ( $M = 3.44$ ,  $SD = 0.02$ ). The interaction was not significant [ $F(1,1859) = 0.10$ ,  $p = 0.75$ ].

### Individual Coping (SOC)

There was a statistically significant main effect of Health status [ $F(1,1859) = 5.27$ ,  $p = 0.03$ ,  $\eta_p^2 = 0.06$ ]. In particular, people with a chronic disease showed lower levels of individual coping, as measured in terms of sense of coherence ( $M = 4.65$ ,  $SD = 0.05$ ), than healthy people ( $M = 4.80$ ,  $SD = 0.03$ ). The main effect of Italian areas [ $F(1,1859) = 1.59$ ,  $p = 0.21$ ], and the interaction were not significant [ $F(1,1859) = 0.22$ ,  $p = 0.64$ ].

### Dyadic Coping

The main effect of Italian areas [ $F(1,1694) = 0.36$ ,  $p = 0.55$ ], Health status [ $F(1,1694) = 0.03$ ,  $p = 0.87$ ] and the interaction were not significant [ $F(1,1694) = 0.03$ ,  $p = 0.86$ ].

### Family Support

There was a statistically significant main effect of Italian areas [ $F(1,1859) = 5.08$ ,  $p = 0.02$ ,  $\eta_p^2 = 0.06$ ]. In particular, people who lived in northern Italy showed lower levels of family support ( $M = 3.25$ ,  $SD = 0.04$ ) compared to people who lived in the rest of Italy ( $M = 3.37$ ,  $SD = 0.04$ ). There was also a statistically significant main effect of Health status [ $F(1,1859) = 10.01$ ,  $p = 0.03$ ,  $\eta_p^2 = 0.06$ ]. In particular, people with a chronic disease showed lower levels of family support ( $M = 3.23$ ,  $SD = 0.05$ ) than healthy people ( $M = 3.39$ ,  $SD = 0.02$ ). The interaction was not significant [ $F(1,1859) = 2.76$ ,  $p = 0.10$ ].

### Friends' Support

There was a statistically significant main effect of Health status [ $F(1,1859) = 2.33$ ,  $p = 0.02$ ,  $\eta_p^2 = 0.06$ ]. In particular, people with a chronic disease showed lower levels of friends' support ( $M = 3.82$ ,  $SD = 0.04$ ) than healthy people ( $M = 3.94$ ,  $SD = 0.02$ ). The main effect of Italian areas [ $F(1,1859) = 2.33$ ,  $p = 0.13$ ] and the interaction were not significant [ $F(1,1859) = 1.91$ ,  $p = 0.17$ ].

### Psychological Well-Being

There was a statistically significant main effect of Health status [ $F(1,1859) = 28.76$ ,  $p < 0.001$ ,  $\eta_p^2 = 0.06$ ]. In particular, people with a chronic disease showed lower levels of psychological well-being ( $M = 3.42$ ,  $SD = 0.04$ ) than healthy people ( $M = 3.69$ ,  $SD = 0.02$ ). The main effect of Italian areas [ $F(1,1859) = 2.60$ ,  $p = 0.11$ ] and the interaction were not significant [ $F(1,1859) = 0.01$ ,  $p = 0.93$ ].

## Pessimistic View of the Future

There was a statistically significant main effect of Health status ( $F(1,1859) = 21.42, p < 0.001, \eta_p^2 = 0.06$ ). In particular, people with a chronic disease showed a more pessimistic perception of the future ( $M = 3.66, SD = 0.04$ ) than healthy people ( $M = 3.44, SD = 0.02$ ). The main effect of Italian areas [ $F(1,1859) = 0.52, p = 0.47$ ] and the interaction were not significant [ $F(1,1859) = 0.06, p = 0.80$ ].

## Relational Well-Being

There was a statistically significant main effect of Italian areas [ $F(1,1859) = 5.86, p = 0.02, \eta_p^2 = 0.06$ ]. In particular, people who lived in northern Italy showed lower levels of relational well-being ( $M = 7.74, SD = 1.98$ ) compared to people who lived in the rest of Italy ( $M = 7.96, SD = 0.07$ ). The main effect of Health status [ $F(1,1859) = 0.66, p = 0.42$ ] and the interaction were not significant [ $F(1,1859) = 0.13, p = 0.72$ ].

## Testing the Moderator Effect of Health Status in the Association of Challenges and Resources With Individual and Relational Well-Being

A series of hierarchical multiple regressions were conducted for each outcome (psychological well-being, pessimistic view of the future and relational well-being) to examine (a) the effect of challenges (fear of contagion, worries about the consequences of the epidemic, and stress) and resources (individual: Individual coping; relational: dyadic coping; social: family support and friend support) and (b) the moderating effect of health status in the association between predictors and outcome. To reduce multiple collinearity between variables, the continuous predictors were standardized (Jaccard et al., 1990; Aiken et al., 1991; West et al., 1996; Cohen et al., 2003). Health status was dummy coded (0 = no chronic disease; 1 = presence of a chronic disease) and interaction terms were computed by multiplying the moderator with each of the seven predictors. In the first step, all predictors were included (Challenges: fear of contagion, worries about the epidemic consequences, stress; Resources: individual coping, dyadic coping, family support, friend support). In the second step, interaction terms between each predictor and health status were entered in the analysis. Simple slopes analyses were used to explore significant interactions. In order to control for Type 1 error inflation due to the large number of predictors, a Bonferroni correction for multiple comparisons was employed. Means were considered significantly different when the statistical test's  $p$ -value was less than 0.006.

## Psychological Well-Being

The regression model was significant [ $R^2 = 0.391, F(8,1640) = 131.36, p < 0.001$ ]. In particular, as reported in **Table 3**, among challenges, worries about the epidemic consequences and stress had a negative and significant effect on psychological well-being. On the contrary, the effect of fear of contagion was not statistically significant. Among people's resources, individual coping, dyadic coping, and family support

had a positive and significant effect on psychological well-being. On the contrary, the effect of friends' support was not statistically significant. The effect of health status was negative and statistically significant. This means that people with a chronic disease reported lower psychological well-being than healthy people. No interaction effects were found.

## Pessimistic View of the Future

The regression model was significant [ $R^2 = 0.332, F(8,1640) = 101.989, p < 0.001$ ]. In particular, as reported in **Table 4**, among challenges, worries about the epidemic consequences and stress had a positive and significant effect on participants' pessimistic view of the future, that is the higher participants' fear of contagion, worries and stress the more pessimistic their view of the future. On the contrary, the effect of fear of contagion was not statistically significant. Among people's resources, individual coping had a negative and significant effect on the pessimistic view of the future, which means that the higher participants' individual coping the more optimistic their view of the future. On the contrary, the effects of dyadic coping, friends' and family's support were not statistically significant. The effect of health status was positive and statistically significant. This means that chronically ill people reported a more pessimistic view of the future than their healthy counterparts. The only significant interaction was between Health status and fear of contagion. The

CI, confidence interval. \* $p < 0.006$  ( $p$ -value after the Bonferroni's correction).

simple slope analyses showed a significant positive effect of fear of contagion on the pessimistic view of the future only for people with a chronic disease (healthy people:  $b = 0.05$ ,  $p = 0.09$ ; people with chronic disease:  $b = 0.17$ ,  $p < 0.001$ ; **Figure 2**). No other significant interaction effects were found.

### Relational Well-Being

The regression model was significant [ $R^2 = 0.414$ ,  $F(8,1640) = 144.56$ ,  $p < 0.001$ ]. In particular, as reported in **Table 5**, the effect of predictors concerning challenges were not statistically significant. Among people's resources, dyadic coping and friends' support had a positive and significant effect on relational well-being. The effect of individual coping and family support were not statistically significant. The effect of health status was not statistically significant. The only significant interaction was between Health status and fear of contagion. The simple slope analyses showed a significant positive effect for both healthy people and people with chronic disease, though this association was stronger for healthy individuals than for chronically ill ones (healthy people:  $b = 0.70$ ,  $p < 0.001$ ; people with chronic disease:  $b = 0.50$ ,  $p < 0.001$ ; **Figure 3**). No other significant interaction effects were found.

## DISCUSSION

The present study aimed to provide a picture of the challenges (in terms of stress, fear of contagion, and worries about the epidemic consequences) as well as resources (in terms of individual and dyadic coping as well as social support from family and friends) of Italian individuals involved in a couple relationship. In particular, we analyzed the psychosocial impact of COVID-19 epidemic by comparing healthy people and people with a chronic disease, to underline potential differences between these groups, given the higher risks of contagion and related consequences for

unhealthy individuals. In addition, the role of the Italian zones in the above differences was taken into consideration, as the highest number of contagions and deaths due to COVID-19 was registered in Northern Italy. Finally, the study analyzed whether the associations of the above challenges and resources with participants' individual and relational well-being differed as a function of their health status.

With regard to the first aim of the present study, results have shown that fear of contagion, worries about the pandemic, and the total stress score were higher for people with a chronic disease than for healthy people, although moderate to high levels of these variables were observed for both healthy and chronically ill participants. These results highlight that the COVID-19 epidemic was particularly demanding for people with a chronic disease, in line with recent studies on fear of COVID-19 contagion in people with an oncological disease (Romeo et al., 2020). In fact, for cancer patients, the fear of being infected adds up to the cancer condition, with an explosion of traumatic effects. Focusing on the challenges for healthy and chronically ill people allowed us to detect the different impact of COVID-19 on these populations, showing that people with a chronic disease are more compromised by the situation both physically and psychologically. For these people, in fact, concrete challenges are added at least on two levels. First, the concrete higher risk of being infected by the virus. Secondly, given the impact of the pandemic on ordinary hospital activities, chronically ill people may fear not to be able to manage their own disease and symptoms due to the difficulties in maintaining routine medical treatments or in contacting their own physician. These demands may actually add to the stress and worries of participants living with a chronic disease.

The present findings, moreover, showed an interplay between the health status of participants and their zone of living. More specifically, people with a chronic disease who lived in the central

and southern regions of Italy, reported higher levels of fear of contagion than chronically ill people living in the North. Also, the level of stress was higher for people resident in central and southern Italy, despite the study by Casagrande et al. (2020) showed a high level of distress in northern regions. These results, considering the lowest impact of contagion in these zones, were actually unexpected. We could assume that this result may be linked to the fact that southern parts of Italy were impacted by

the epidemic at a later time than the North, when the dramatic news about the huge rate of infections and casualties in this region spread out, fomenting serious worries in the rest of Italy, especially in light of the fact that the North was renowned for its higher economic and healthcare system resources as compared to the rest of the country. In fact, the Italian healthcare system has been always decentralized and managed by regional governments and this causes a significant North-South economic divide in

favor of the wealthier regions of the North (Cersosimo and Nisticò, 2013) and this situation was further amplified by the outbreak of the COVID-19 (Armocida et al., 2020).

With regard to the area of resources, people with a chronic disease perceived lower individual and social resources than healthy participants, despite having moderate to high levels of these variables. Considering individual resources, people with a chronic disease showed lower levels of sense of coherence compared to the healthy individuals. Seems that the COVID-19 situation, combined with the challenges for the chronically ill population discussed above, decreases in this group the perception of the world and of what is happening around them as understandable, manageable, and meaningful. This is especially critical, considering that individual coping resources were found to be important protective factors in the context of COVID-19 emergency stress (Vagni et al., 2020b). Specific attention should therefore be devoted to sustain chronically ill individual's coping competences.

With regard to social resources, family and friends' support levels were high for both groups, but lower for chronically ill participants. It could be that living with a chronic disease, with all the demands that this imposes on individuals' daily lives, may impair chronically ill people's social lives. Some evidence exists, for example, that individuals living with a chronic disease experience more loneliness than healthy individuals, even though their social network size and emotional support exchanges does not differ as a function of disease status (Penninx et al., 1999).

Furthermore, it was observed that the level of dyadic coping was moderate to high in both groups and it was independent of the health status. According to the literature on dyadic coping,

we could assume that partners cope together in facing a common stressor as shown both on healthy population (Bodenmann, 2005; Donato et al., 2009; Donato and Parise, 2012; Donato et al., 2015; Pagani et al., 2019) and in people with a chronic disease (Bertoni et al., 2015; Rapelli et al., 2020). This specific dyadic skill in both healthy and unhealthy participants emphasizes, firstly, the interdependence of partners' stress and coping experience and, secondly, the coping process with external stressors as in the case of COVID-19. Given that dyadic coping is a relational competence that partners develop with both minor and major stressors (Bodenmann, 1997; Donato, 2014), both groups may have plenty of occasions to exercise their dyadic coping. Furthermore, we could recognize that Italian couples showed good resources in their couple relationship. The maintaining of a high-quality romantic relationship during times of stress—such as in the case of the COVID-19 pandemic—is very challenging (e.g., Neff and Karney, 2004), as demonstrated also by the divorce rates during COVID-19 lockdown in China and future longitudinal research should examine how partners may adapt to this situation in the long run.

Finally, as far as well-being is concerned, people with a chronic condition showed lower levels of psychological well-being and higher levels of a pessimistic view of the future (Ramírez-Maestre et al., 2019; Rapelli et al., 2020). Besides, relational well-being was similar between the two subgroups and, as previously demonstrated in the literature, a high-quality romantic relationship could be a useful resource to face daily stress (Donato et al., 2009; Donato and Parise, 2012; Donato et al., 2015; Pagani et al., 2019) and also to cope with the pandemic-related stress (Balzarini et al., 2020; Donato et al., in press).

With regard to the second aim of the study, tests of the associations of challenges and resources with individual outcomes showed that worries about the epidemic consequences and stress were negatively associated with psychological well-being, conversely resources area were positively associated with it.

With reference to the resource portfolio of partners, participants' sense of coherence, that is how meaningful and integrated people view life and the world around them, was positively associated with psychological well-being. This finding confirms what previously found for healthy people (Eriksson and Lindström, 2007) as well as for people afflicted with serious illnesses and disabilities (Anderson, 1998). For example, in chronic patients, sense of coherence was associated with hope and lower symptoms of anxiety and depression (Möllerberg et al., 2019). In a salutogenic perspective, these results suggest that during a pandemic situation it is important to take into consideration also the individual coping strategies and to promote them in order to cope with stress.

Furthermore, dyadic coping and support from family and friends were positively associated with psychological well-being, in line with the literature that explored the supportive role of relationships and their positive effect on well-being among healthy and unhealthy populations (Falconier and Kuhn, 2019).

In particular, dyadic coping was associated with different positive outcomes (Hilpert et al., 2016; Parise et al., 2019), suggesting that having a supportive partner especially during an emergency situation like a global pandemic may alleviate stress, help sharing common difficulties, and improve partners' psychological well-being. In fact, when an external and shared stressor, like the COVID-19, outbreaks, relying on the partner and on couple skills becomes essential. Moreover, social support could be considered as a crucial protective factor, especially during the COVID-19 epidemic, as previous studies reported that the presence of a social support could help managing a stressful and traumatic event, like for example an illness (Cutrona et al., 2018).

In an opposite direction were the results on participants' view of their future, in fact worries about the epidemic consequences and stress were positively related to a pessimistic perception of future, the more people reported worries about the COVID-19 situation and the higher their levels of stress, the more pessimistic was their view of the future. Moreover, the significant interaction effect showed that the fear of contagion increased a pessimistic view of the future only for people with a chronic condition. This finding confirms a central role in this emergency situation of fear and uncertainty about the epidemic progression on mental health (Casagrande et al., 2020), as demonstrated also in past virus outbreaks (e.g., Pappas et al., 2009), for people suffering for a chronic disease. In fact, in this population the risk of contagion was higher and the consequences more dangerous. These results indicate that the fear of contagion may crystallize in the present the person with chronic disease, so that the perception of a (good) future is unthinkable. Conversely, higher levels of individual resources protected against a pessimistic perception of the future. In fact, the perception of having a good individual coping was negatively associated with the pessimistic perception of the

future, as the person may perceive control over the situation even if it is stressful and a sense of competence in coping with it.

With regard to participants' relational well-being, interestingly, the significant interaction showed that the association of fear of contagion with relational well-being of participants was positive and significant for both healthy and chronically ill participants, though it was weaker for people with a chronic disease. This result seems to suggest that during COVID-19, when social relationships were reduced due to strict isolation and social distancing, the more people were afraid of an external threat like the virus, the more they perceived their couple relationship as satisfactory. This apparently counter-intuitive finding could have at least two explanations: first, people may need close support and to perceive it positively to cope with the threat of the virus; secondly, the unusual closeness and time spent together as a couple due to the lockdown could allow participants to increase their marital quality. Furthermore, if, on the one hand, fear of contagion precludes the perception of an optimistic future for chronically ill people as previously discussed, on the other hand, it reveals its "generative" effect by activating relational resources and becoming an occasion to test the strength of the couple's relation, both for the sick and the healthy participants (Donato et al., in press). In fact, the fear of contagion seems to strengthen the couple's bond, the partners are more united to fight a common enemy (the virus) and therefore more satisfied with their relationship.

With reference to resources, dyadic coping and friends' support were significantly associated with participants' relational well-being and in a positive direction. In time of COVID-19 in fact, perceived good support from the partner or friends (but not from family) was associated with a positive perception of participants' relational well-being. In light of the importance of the quality of the couple relationship for people's physical and mental health (Donato and Parise, 2015; Pagani et al., 2015; Donato et al., 2018b; Pagani et al., 2020), these findings highlight several key avenues professionals could take in order to sustain and promote both healthy people's and chronically ill individuals' couple relationships.

The results of the present study also underline the importance of taking a privileged look in the category of subjects with chronic disease, most affected by the current health emergency. In particular, the present findings have implications for the development of target interventions for the most vulnerables' needs, which take psychological and social (as well as medical) aspects into consideration. In particular, interventions could pay attention to activities devoted to reduce stress and enhance individual and dyadic coping skills of chronic patients as well as promote social support (e.g., through the activation of online groups).

To the best of our knowledge, our study is the first to explore the psychosocial effects of the COVID-19 emergency in the Italian population focusing on participants in couples, with and without a chronic disease. Furthermore, another strength of the study was the focus on both challenges and resources: in an effort to respond to the pandemic it is essential to know what are the most relevant challenges people live as well as the available resources to activate. Resources, moreover, were

analyzed in terms of individual, relational, and social ones: in accordance with Bronfenbrenner's (1979) ecological systems theory, in fact, individuals are embedded within interconnected systems pertaining to the person, his/her relationships, as well as the social and cultural environment in which they live in and taking into account all this different levels, beyond the individual one, is another strength of the present study. The validity and implications of the present findings should be considered in light of some limitations. First, the present study had a cross-sectional design, which means no conclusions can be drawn with respect to the causality of the observed relationships and directionality of relations between variables. Future research should adopt a longitudinal design in order to help address these issues. Second, this study is based on the comparison between two unequally sized groups (unhealthy vs. healthy participants), as it was not primarily designed to make such comparison, and no information about the type of chronic disease of our sample was collected. Future research should use comparable samples and collect more information on participants' chronic conditions. In addition, pre-COVID measures of variables were not possible in the current study. A final limitation has to do with the exclusive reliance on quantitative approach.

Further research could rely on qualitative measures in order to deeply capture the complexity of the experience of living with a chronic disease during a pandemic.

Again, future longitudinal studies could clarify the changes over time and the direction of the associations. Finally, in future research, the directions identified in this study connected to the importance of resources, at an individual, relational, and social level, to face a critical event might be expanded and better analyzed: In fact, the assumption of a salutogenic perspective could promote a better understanding of the situation considering both risks and protective factors and could be useful also for clinicians who have to sustain people with chronic disease. In fact, not only high levels of stress, but also low levels of individual and relational resources could be

harmful. To conclude, the COVID-19 epidemic had an impact on different levels and the present results highlight how focusing on both the challenges to face and the resources to sustain may help highlight important avenues for intervention. From a psychological point of view, although chronically ill individuals are especially challenged during this situation and perceive less resources, their resources may be a relevant leverage to use for sustaining their psychosocial well-being in the aftermath of the pandemic.

Burnout has been recognized as a serious health problem. In Portugal, before COVID-19 Pandemic, there were strong indicators of high prevalence of burnout in physicians and nurses. However, the Portuguese Health Care Service was able to efficiently respond to the increased demands. This study intends to understand how psychosocial variables might have been protective factors for burnout in physicians and nurses in Portugal. Specifically, we considered several psychosocial variables that have been found to be protective factors for burnout in previous research and we compared their predictive and unique impact in the prediction of burnout. These variables are perceptions of justice (distributive, procedural, justice from colleagues, justice from patients, and their families), professional identification, meaningful work and empathy. We also included workload, as a risk factor, and controlled other variables that can be confounds for burnout, such as socio-demographic variables, ideological variables (religiosity, political orientation), and specific variables related with COVID-19 pandemic. The sample of the present study is composed by 229 physicians (aged between 23 and 70 years old,  $M = 36.54$ ;  $SD = 10.72$ ; 48% male and 52% female) and 268 nurses (aged between 22 and 69 years old,  $M = 34.96$ ;  $SD = 9.52$ ; 27% male and 73% female). An online survey was created using Qualtrics and participants were recruited via Facebook and LinkedIn. The data were collected during 29 days (between the 45th and the 74th days after the first diagnosed case of COVID-19 in Portugal). The results showed that workload was a significant risk factor, except for disengagement in physicians. The most consistent protectors across samples were procedural justice (for both dimensions of burnout, both in physicians and nurses) and professional identification (for disengagement, both in physicians and nurses; for exhaustion only in physicians). This study suggests that decreasing workload and promoting procedural justice and professional identification are key factors that might be simultaneously and independently addressed in interventions for reducing the risk of burnout or preventing it from occurring in the first place.

**Keywords:** burnout, organizational justice, professional identification, social identity, empathy, meaningful work, workload, health care workers

## INTRODUCTION

Burnout has been defined as a psychological syndrome of exhaustion, cynicism, and inefficacy resulting from ongoing occupational stressors (Leiter and Maslach, 2003), and that can take place in any kind of occupation (Leiter and Schaufeli, 1996).

Burnout has been recognized as a serious health problem and, particularly, the high incidence of burnout in physicians (West et al., 2018, for a review) and nurses (Woo et al., 2020, for a review) has been recognized as a threat, not only to the professionals themselves but also to their patients and the organizations in which they work. Indeed, burnout has been found to be associated with decreased mental and physical health of health care workers; lower quality care, threats to patient safety, and lower patient satisfaction; and reduced productivity, increased turnover and increased costs of the health care system (for a review in physicians see West et al., 2018; for a review in nurses see Bakhamis et al., 2019).

In Portugal, before COVID-19 Pandemic, there were strong indicators of high prevalence of burnout in physicians and nurses. In a study with a national sample of 9,176 of Portuguese physicians, it was found that 66% of them were in a high level of emotional exhaustion (Vala et al., 2017). In a sample of 1,262 nurses, also at a national level, about 50% had a high level of burnout (Marôco et al., 2016).

However, as stated by the President of the Order of Physicians (Guimarães, 2020), the Portuguese Health Care Service (Serviço Nacional de Saúde—SNS), was able to efficiently respond to the increased demands of the COVID-19 Pandemic. This may be considered somehow surprising. Indeed, despite the high levels of burnout already present in health care workers (Vala et al., 2017), they had to deal with the increased stress caused by the Pandemic (Bavel et al., 2020), and specifically as health care workers they faced additional stressors, such as increased workload, high risks of contagion and, many of them, isolation from their own families (Guimarães, 2020).

Research has shown that perceptions of justice, social identification, meaningful work and empathy are associated with burnout. However, that same research have been conducted under separate theoretical frameworks and the impact of these different predictors have not been tested together. Moreover, those same studies have not consistently included other variables related with work, socio-demographic variables and ideological variables, that can also impact on burnout.

The present paper has two main goals. The first goal is to identify the core psychosocial variables might have been protective factors for burnout in physicians and nurses in the first 2 months of the COVID-19 pandemic in Portugal, comparing their predictive and unique impact in the prediction of burnout. The variables considered were perceptions of justice (distributive, procedural, justice from colleagues, justice from patients, and their families), professional identification, meaningful work, and empathy. We also controlled for workload as a risk factor, and for other variables that can be confounds for burnout, such as socio-demographic variables (age, sex, income), ideological variables (religiosity, political orientation), and specific variables related

with COVID-19 pandemic. The second goal is to understand how these variables might relate theoretically to explain burnout.

In the next section we will briefly review the literature related with each of the theoretical variables considered.

## Burnout

Burnout was first described by Freudenberger (1974) and mostly developed by Maslach (1976) in collaboration with other researchers (Schaufeli et al., 2009). It has been conceived as a cumulative reaction to ongoing occupational stressors and defined originally as a three-dimensional psychological syndrome of exhaustion, cynicism, and inefficacy (Leiter and Maslach, 2003): the exhaustion component refers to feelings of being overextended and depleted of one's emotional and physical resources; cynicism component (also known as depersonalization or disengagement) refers to a negative, callous, or excessively detached response to various aspects of the job, that is self-protective of exhaustion, and can result in the loss of idealism and the dehumanization of others; the inefficacy refers to feelings of incompetence and a lack of achievement and productivity at work.

Later on, a two-dimensional approach emerged with exhaustion and cynicism as the two core dimensions of burnout, with inefficacy being considered as a possible consequence of burnout (e.g., Bakker et al., 2004). This is the approach we will be using in the present study (Oldenburg Burnout Inventory, OLBI, Bakker et al., 2004), with the two dimensions of burnout named as exhaustion and disengagement. The exhaustion dimension refers to feelings of physical fatigue and overload in relation to work (Demerouti and Bakker, 2008). The dimension of disengagement refers to the distance from work and negative attitudes toward own work (Bakker et al., 2004).

## Workload

The workload refers to overload, when job demands exceed human limits (Maslach et al., 2001). It is one of the core risk factors for burnout development when it is a chronic job condition and not an occasional emergency (Leiter and Maslach, 2003).

Both the Six Areas of Work Life Model (Leiter and Maslach, 2003; Brom et al., 2015) and the Job Demands—Resources Theory (Demerouti et al., 2001), consider workload a key variable to explain burnout.

## Justice Perceptions

Since the genesis of the Social Justice theories (Stouffer et al., 1949; Adams, 1965), perceived justice has been found to be an important predictor of satisfaction and well-being. More recently, organizational justice has been identified as an important predictor of health (Elovainio et al., 2002b) and of burnout (Maslach et al., 2001). Several dimensions of justice have been considered: distributive, procedural and interactional.

Distributive justice refers to the perception that the resources that are allocated to people are “deserved” or not, according to their contributions (Adams, 1965). If the reward obtained is proportional to the contribution, the situation is considered as just; if not, it is considered as unjust. The judgment of fairness

may be comparative, with another person or with the same person in the past, or may be done in absolute terms.

Procedural justice refers to the fairness of the means by which distributions, or decisions about them, are made (Thibaut and Walker, 1975). Apart from the possibility of “having a voice” (Thibaut and Walker, 1975) in this process, a fair procedure has to be based on accurate information; and the patterns and criteria for decision-making have to be consistent (across people and time) and there should be a possibility of reversing decisions (Leventhal, 1980).

Interactional justice (Bies and Moag, 1986) refers to the respectful and proper manner by which authorities communicate procedural details and justify their decisions using honest and truthful information.

Not much studies have assessed and compared the unique impact of these three dimensions of organizational justice in burnout. With the intention of contributing to fill this gap, Moliner et al. (2005) found that distributive, procedural and interactional justice were all negatively associated with both cynicism and exhaustion but when considered together only procedural justice was a significant predictor of both dimensions of burnout. We believe that one reason for this might have been the high correlation between procedural and interactional dimensions. In this case, it is recommended to aggregate the measure in one procedural/interactional dimension, so that it is possible to avoid the costs of multicollinearity (Colquitt, 2012). This aggregation of the procedural and interactional justice in only one dimension is also in agreement with the Group Value Model (Tyler and Lind, 1992; Tyler, 1994) that includes both procedural and interactional aspects of justice in the conceptualization of a unique dimension named simply “procedural justice.”

The impact of justice perceptions on well-being can also be conceptualized as a buffer (Bobocel and Hafer, 2007) that serves to protect individuals of major stressors and decreases the impact of demands (a moderator hypothesis between workload and justice concerns).

In the present study we included other dimensions of justice that we think are particularly relevant for physicians and nurses, such as justice of colleagues, patient justice and family patient's justice. Previous studies in physicians (Smets et al., 2004) showed that perceived injustice from colleagues was associated with exhaustion, and perceived injustice from patients was associated with both exhaustion and depersonalization. As far as we know, no previous studies have addressed the impact of perceived patient family justice on burnout. However, it was found that aggressive behavior (incivilities) from patients and their families, which can be considered as a proxy of perceived injustice, was associated with burnout (Campana and Hammoud, 2013).

## Professional Identification

Since the first studies that experimentally showed the impact of intergroup categorization (Tajfel et al., 1971), the concept of social identity and its implications for intergroup relations and well-being started to get attention from researchers.

Tajfel (1978) defined social identity as “that part of an individual's self-concept which derives from his [or her]

knowledge of his [or her] membership of a social group (or groups) together with the value and emotional significance attached to that membership” (p. 63). People belong to a variety of groups, and they may differ in the strength of the sense of membership, which is conceptualized as social identification (Turner et al., 1987). This strong sense of membership with a social group (that at the organizational level may be either the organization or the work team), has shown to be an important protector of health and well-being (Jetten et al., 2012) and an important protector for burnout (Avanzi et al., 2015, 2018).

The relation between social identification and burnout has been conceptualized in two different ways: social identity mediating the relation between procedural justice and well-being (self-esteem, the group-value model, Tyler et al., 1996) and social identification predicting a reduction in workload which in turn reduces burnout (Avanzi et al., 2018).

Because, in Portugal it is very common that physicians and nurses work in more than one organization, in this study, instead of identification with organization, we considered a measure of identification with the profession.

## Meaningful Work

Hackman and Oldham (1976) defined meaningfulness of the work as “the degree to which the employee experiences the job as one which is generally meaningful, valuable, and worthwhile” (Hackman and Oldham, 1976, p. 256). Although more recent conceptualizations of meaningful work have been proposed (Pratt and Ashforth, 2003; Steger et al., 2012) they incorporate the essence of this definition.

Meaningful work has mostly found to be an important protector of well-being at work (Duffy et al., 2012; Steger et al., 2012; Yaseen, 2013) and burnout (e.g., Borritz et al., 2005; Fouché et al., 2017), including burnout in physicians (Rasmussen et al., 2015) and nurses (Tei et al., 2014). However, recently Jones and Griep (2018) showed that meaningful work can also be a risk factor for burnout because it may lead employees to continue increasing their efforts beyond their limits.

## Empathy

Empathy is generally considered to be a two-dimensional construct with an affective dimension and a cognitive dimension (Mehrabian, 1997). The affective dimension refers to the capability to share another person's emotional state (Eisenberg and Strayer, 1987), and the cognitive dimension of empathy, refers to the ability to understand (not necessarily share) another's emotional state (Davis, 1994).

Both emotional and cognitive empathy of physicians and nurses have been found to be beneficial for the quality of care and for patient satisfaction (Wilkinson et al., 2017; Samra, 2018, for reviews). However, there is less agreement about the benefits of empathy for health care workers, with two competing hypothesis, that empathy might be either a protective or a risk factor for burnout (Zenasni et al., 2012). The results are indeed not conclusive. In a recent systematic review of 10 studies correlating empathy and burnout in health care professionals (Wilkinson et al., 2017), eight of the studies provided empirical support for a negative relationship between empathy and burnout, one study

provided support for a positive relationship between burnout and empathy, and one study reported contradictory evidence with positive and negative correlations between different subscales of the empathy and burnout measures.

In this study we will try to contribute to address this issue and we will consider affective and cognitive empathy as distinct dimensions of empathy.

## Control Variables

We controlled for several variables that may affect the proposed relationships but that were not of direct theoretical interest. We controlled for respondents' age and gender because both variables have been found to affect burnout in physicians and nurses (e.g., Maslach and Leiter, 2017; West et al., 2018). We also controlled for the participants' years of professional experience because their predictive role in burnout in these professionals has been demonstrated previously (e.g., Marôco et al., 2016; Meira et al., 2017).

Income was also included because it is an important predictor of well-being (Lucas and Schimmack, 2009).

We controlled for religion and political orientation of the participants because religion is an important predictor of well-being (Koenig, 2012) and is usually associated with a more right wing political orientation (Correia et al., 2018).

Finally, questions related to COVID-19 pandemic (trust in policies, tasks changed and isolation the family) that might have been additional stressors for the health care professionals were also included as control variables.

In sum, in the present study we expect workload to be a risk factor for both dimensions of burnout both in physicians and nurses; we expect justice perceptions and professional identification to be protectors of burnout. We do not make specific predictions for meaningful work and empathy, because previous studies have found they may be either protector or risk factors. Furthermore, we will test if all the previous associations continue to be significant over and above the control variables.

## MATERIALS AND METHODS

### Participants

Table 1 presents the descriptive statistics for control variables and Table 2 presents the descriptive statistics for the theoretical variables.

The sample of the present study was composed by 229 physicians (aged between 23 and 70 years old,  $M = 36.54$ ;  $SD = 10.72$ ; 48% male and 52% female) and 268 nurses (aged between 22 and 69 years old,  $M = 34.96$ ;  $SD = 9.52$ ; 26.9% male and 73.1% female).

About 58.5% of physicians and 58.2% of nurses worked in the public sector, 7.9% physicians and 21.6% nurses worked in the private sector and 33.6% physicians and 20.1% nurses worked in both sectors.

The average number of years of participants exercising their profession was around 11 years ( $M = 11.23$ ;  $SD = 10.65$ , for physicians;  $M = 11.72$ ,  $SD = 9.24$ , for nurses). The participants were from all regions in the country, but mostly

from Metropolitan Area of Lisbon (43.7% physicians; 46.3% nurses), Center (15.3% physicians; 19.4% nurses) and North (17.9% physicians; 13.4% nurses) (Table 3).

A total of 43.2% physicians and 39% nurses were isolated from their nuclear family due to the COVID-19 pandemic and about 82.5% physicians and 60.4% nurses have changed their functions due to this pandemic. Most participants considered

that the policies adopted by their country to combat the COVID-19 pandemic were adequate (physicians:  $M = 4.50$ ,  $SD = 0.72$ ; nurses:  $M = 4.44$ ,  $SD = 0.72$ ).

## Procedure

This study received Ethical approval by the Portuguese Order of Psychologists (OPP—Ordem dos Psicólogos Portugueses), in the framework of an initiative to support scientific research in health psychology and behavior change (Via Verde de Apoio OPP para a Investigação Científica em Saúde Psicológica e Mudança Comportamental).

An online survey was created using Qualtrics and participants were recruited via Facebook and LinkedIn<sup>1</sup>. The link for the study was also available at the website of the Portuguese Order of Psychologists.

At the beginning of the survey, the participants were informed about the general purpose of the study. Participants were informed that the study was non-invasive, there were no physical, financial, social, legal or other risks connected with the study and the results would be analyzed anonymously. It was also explained that they could withdraw from the study by closing the web browser without their responses being recorded.

The contact of the person responsible for the project was given in case they wished to obtain additional information or had any questions about the study.

After providing informed consent and agreeing to participate, they were presented with the main measures. In the last block of the survey, participants were asked to provide demographic and professional information and questions related to the Pandemic COVID-19.

At the end, the participants were debriefed and the theoretical variables of the study were indicated. The participants were thanked for their participation, and the contact of the person responsible for the project was again provided.

The average completion time of the survey was 10 min. The data were collected during 29 days (between the 45th and the 74th days after the first diagnosed case of COVID-19 in Portugal, in most of this time the country was in lockdown).

## Measures

### Burnout

We used the Portuguese adaption (e.g., Sinval et al., 2019), of the Oldenburg Burnout Inventory (OLBI, Bakker et al., 2004). The OLBI has sixteen items and consists of two dimensions with eight items each: exhaustion (e.g., “There are days when I feel tired before I arrive at work,” physicians  $\alpha = 0.83$ ; nurses  $\alpha = 0.81$ ) and disengagement (e.g., “It happens more and more often that I talk about my work in a negative way,” physicians  $\alpha = 0.86$ ; nurses  $\alpha = 0.83$ ). Responses were given on a five-point scale, 1 = “totally disagree” to 5 = “totally agree.”

<sup>1</sup>We did not address specific groups of nurses and physicians. We addressed nurses and physicians individually and, in many cases, they shared the link with other professionals. Although the link of the questionnaire was available in the Portuguese Order of Psychologists, this happened only in the last days of the collection of data, and the specific location on that website is not specifically intended to be consulted by physicians and/or nurses.

### Justice Perceptions

Distributive justice was assessed with three items (e.g., “In general, the rewards I receive are fair,” physicians  $\alpha = 0.82$ ; nurses  $\alpha = 0.82$ ) taken from the five item distributive justice scale developed and validated by Rego to the Portuguese population (2000). The items were answered in a scale from 1 = “totally disagree” to 5 = “totally agree.”

Procedural justice was assessed with three items (e.g., “My organization has a mechanism that allows employees to appeal decisions”) taken from the four item scale of procedural justice scale of Rego (2000) and with three items (e.g., “My superior treats me with respect and consideration”) taken from the five item scale of interactional justice developed and validated by Rego (2000). An aggregated index of procedural justice was composed with the mean of the items used to measure procedural justice and interactional justice (physicians  $\alpha = 0.88$ ; nurses  $\alpha = 0.88$ ). We thus avoided multicollinearity issues, due to the high correlation between procedural and interactional justice (physicians  $r = 0.68$ ; nurses  $r = 0.66$ ).

Justice of colleagues was measured using two items (e.g., “My colleagues appreciate my work,” “My colleagues acknowledge my work,” physicians  $\alpha = 0.82$ ; nurses  $\alpha = 0.84$ ).

Patients justice was measured using two items (“My patients recognize my work,” “My patients acknowledge my work”). Justice of patient family members was assessed using two items (“My patients’ relatives recognize my work,” “My patients’ relatives acknowledge my work”). For these items, a five-point response scale was used: 1 = “totally disagree” to 5 = “totally agree.” Because there was a very high correlation between patient justice and family patients justice (Table 4, physicians  $r = 0.75$ ; Table 5, nurses  $r = 0.76$ ), and to avoid multicollinearity issues, we calculated an aggregated index of patient and family patient’s justice (physicians  $\alpha = 0.92$ ; nurses  $\alpha = 0.91$ ) to use on the regression analysis.

### Professional Identification

This construct was measured with one-item measure (“I identify with my profession”) and the responses were given on a five-point scale ranging from 1 (“totally disagree”) to 5 (“totally agree”). This item was adapted from the one item measure of organizational identification used by Postmes et al. (2012) (“I identify with the organization I work for”).

### Meaningful Work

Meaningful Work was evaluated with two items (“The work I do serves a greater purpose,” “I know my work makes a positive difference in the world”; physicians  $\alpha = 0.77$ ; nurses  $\alpha = 0.72$ ) taken from The Work and Meaning Inventory (WAMI) (Steger et al., 2012): with a five-point response scale ranging from 1 = “totally disagree” to 5 = “totally agree.”

### Empathy

Empathy was measured using the Portuguese Adaptation of the Basic Empathy Scale short version (BES-A) (Pechorro et al., 2018). This version is a translation and validation of a shorter version (Salas-Wright et al., 2012) of the Basic Empathy Scale (BES) (Jolliffe and Farrington, 2006). This BES-A version has

For all measures, scores were computed by averaging across items, with higher scores indicating stronger endorsement of the construct. For sex, 1 indicates "male" and 2 "female." \* $p < 0.05$ ; \*\* $p < 0.01$ , \*\*\* $p < 0.001$ .

seven items, with three items for the affective dimension (e.g., “After being with a friend who is sad about something, I usually feel sad,” physicians  $\alpha = 0.78$ ; nurses  $\alpha = 0.80$ ) and four items for the cognitive dimension (e.g., “I can often understand how people are feeling even before they tell me,” physicians  $\alpha = 0.81$ ; nurses  $\alpha = 0.69$ ). The items were answered on a five-point response scale: 1 = “totally disagree” to 5 = “totally agree.”

### Workload

Workload was evaluated with one item taken from The Areas of Worklife Scale (AWS) (“I have enough time to do what’s important in my job”—recoded) (Leiter and Maslach, 2003), on a five-point response scale: 1 = “totally disagree” to 5 = “totally agree.”

### Control Variables

Income was measured with an item adapted from the European Social Survey (2018): “Which of the following descriptions is closest to your current income?” with a four statements response scale, 1 = “It is very difficult to live with my current income”; 2 = “It is difficult to live on my current income”; 3 = “My current income is enough to live”; 4 = “My current income allows me to live comfortably.”

Religiosity was measured with an item adapted from the European Social Survey (2018): “Regardless of whether you belong to a particular religion, how religious would you say you are?” with a five-points answer scale ranging from 1 “not religious at all” to 5 “very religious.”

Political Orientation was measured with an item adapted from the European Social Survey (2018). (“In politics people sometimes talk of ‘left’ and ‘right.’ Where would you place yourself on this scale, where 1 means the left and 5 means the right?”).

Three items referring to specific factors related to COVID-19 Pandemic were used. Trust in policies to combat the COVID-19: “To what extent do you consider that the measures to deal with this pandemic in your country are adequate?” from 1 “nothing” to 5 “very much”; task changes: “Has the COVID-19 pandemic changed your functions?” Yes/No answer; and isolation from family: “Are you isolated from your nuclear family due to COVID-19?” Yes/No answer).

## RESULTS

### Preliminary Analysis

The descriptive statistics for all variables are given in **Tables 1, 2**. Physicians ( $M = 3.07$ ,  $SD = 0.65$ ) and nurses ( $M = 3.10$ ,  $SD = 0.60$ ) had significantly higher levels of exhaustion than disengagement ( $M = 2.69$ ,  $SD = 0.71$ , for physicians;  $M = 2.76$ ,  $SD = 0.70$ , for nurses), [physicians  $t(228) = 9.28$ ,  $p < 0.001$ ; nurses  $t(267) = 8.41$ ,  $p < 0.001$ ].

First, we examined the pattern of correlations between the variables under study separately for physicians and nurses. **Table 4** (physicians) and **Table 5** (nurses) depict correlations between study variables.

For physicians, significant negative correlation for exhaustion and disengagement were found with the following variables: income, trust in policies (COVID-19), justice of colleagues, distributive justice, procedural justice, and professional identification. A positive significant association between workload and exhaustion and disengagement was obtained. Cognitive empathy, meaningful work, patient justice, and family patient justice were significantly and negatively correlated with disengagement. Being a man was a risk factor for disengagement.

For nurses, we found a negative significant correlations for both exhaustion and disengagement with income, trust in policies (COVID-19), meaningful work, justice of colleagues, patient justice, family patient justice, distributive justice, procedural justice, and professional identification. Furthermore, exhaustion was positively associated with affective empathy, and negatively associated with age, years of professional experience and task changes (COVID-19). A significant negative association between disengagement and religion was obtained. Being a woman was a risk factor for exhaustion. A positive association was also found between both exhaustion and disengagement with workload.

### Main Analysis

To clarify the relationships between our variables, multiple regression analyses were performed for each burnout dimension (exhaustion and disengagement) regarding each professional group. The variables were ordered in two blocks: control variables—Step 1 = sex, years of professional experience<sup>2</sup>, income, religiosity, political orientation, isolated from family, task changes, trust in policies to deal with COVID-19; and theoretical predictors—Step 2 = workload, cognitive empathy, affective empathy, meaningful work, justice of colleagues, patient and family patient’s justice, distributive justice, procedural justice, professional identification.

Therefore, we will study the explanatory power of theoretical predictors of exhaustion and disengagement in addition to that of control variables. For both subsamples, the results of Model 2 is presented in **Table 6**.

In physicians, 36% of the variance in exhaustion was predicted by workload (beta = 0.24;  $p < 0.001$ ), affective empathy (beta = 0.12;  $p < 0.05$ ), procedural justice (beta =  $-0.30$ ;  $p < 0.001$ ) and by professional identification (beta =  $-0.22$ ;  $p < 0.001$ ). Higher workload and affective empathy significantly predicted higher exhaustion. Higher procedural justice and professional identification significantly predicted lower exhaustion.

For nurses, 42% percent of the variance in exhaustion was predicted by years of professional experience (beta =  $-0.12$ ;  $p < 0.05$ ), income (beta =  $-0.16$ ;  $p < 0.01$ ), trust in policies (COVID-19) (beta =  $-0.13$ ;  $p < 0.05$ ), workload (beta = 0.31;  $p < 0.001$ ), affective empathy (beta = 0.15;  $p < 0.01$ ) and procedural justice (beta =  $-0.15$ ;  $p < 0.05$ ). Higher workload and affective empathy significantly predicted higher exhaustion. Age, higher income, higher trust in policies (COVID-19) and higher procedural justice significantly predicted lower exhaustion.

<sup>2</sup>We did not include age in the regression to avoid multicollinearity issues due to its’ high correlation with years of professional experience.

For physicians, 42% of the variance in disengagement was predicted by sex ( $\beta = -0.15$ ;  $p < 0.01$ ), procedural justice ( $\beta = -0.39$ ;  $p < 0.001$ ) and professional identification ( $\beta = -0.31$ ;  $p < 0.001$ ). Being a male, a perception of higher procedural justice and professional identification significantly predicted lower disengagement.

Finally, 52% of the variance in disengagement in nurses was predicted by income ( $\beta = -0.10$ ;  $p < 0.05$ ), religiosity ( $\beta = -0.10$ ;  $p < 0.05$ ), workload ( $\beta = 0.11$ ;  $p < 0.05$ ), meaningful work ( $\beta = -0.15$ ;  $p < 0.01$ ), justice of colleagues ( $\beta = -0.10$ ;  $p < 0.05$ ), patient and family patient's justice ( $\beta = -0.12$ ,  $p < 0.05$ ), distributive justice ( $\beta = -0.12$ ;  $p < 0.05$ ), procedural justice ( $\beta = -0.27$ ;  $p < 0.001$ ) and professional identification ( $\beta = -0.28$ ;  $p < 0.001$ ). High income, religiosity, meaningful work, justice of colleagues, patient and family patient's justice, distributive justice, procedural justice, and professional identification significantly predicted lower disengagement. Higher workload significantly predicted higher disengagement.

Given the results consistently found the unique impact of procedural justice and professional identification as burnout protectors (except for exhaustion in nurses), and workload as a core risk factor (except for disengagement in physicians), we tested three possible models of the relation between these variables. We used Hayes's (2013) Multiple Mediation macro

(5,000 iterations; bias corrected) and we included the significant predictors found in the regression analysis (Table 6) as covariates.

Based on the group-value model, we first tested the possible indirect effect of procedural justice on exhaustion through professional identification in physicians and disengagement (both for physicians and nurses). None of the indirect effects of procedural justice on burnout through professional identification was significant (exhaustion in physicians:  $\beta = -0.02$ , CI 95% [-0.06, 0.00]; disengagement in physicians  $\beta = -0.04$ , CI 95% [-0.09, 0.00]; disengagement in nurses,  $\beta = -0.01$ , CI 95% [-0.05, 0.03].

We also tested a model where professional identification has an indirect effect on burnout through workload (Avanzi et al., 2018). None of the indirect effects of professional identification on burnout through workload were significant (exhaustion in physicians:  $\beta = -0.01$ , CI 95% [-0.03, 0.04]; exhaustion in nurses:  $\beta = -0.03$ , CI 95% [-0.09, 0.02]; disengagement in physicians  $\beta = 0.00$ , CI 95% [-0.01, 0.03]; disengagement in nurses,  $\beta = 0.00$ , CI 95% [-0.01, 0.02].

Finally, we tested the possibility of procedural justice buffering the impact of workload on burnout. The buffer effect of procedural justice on the relation between workload and burnout was only obtained for disengagement in nurses ( $\beta = -0.11$ , CI 95% [-0.18, -0.03]). In this sample, when procedural justice was lower, higher workload is significantly associated with

**TABLE 6 |** Regressions: predicting burnout in physicians ( $N = 229$ ) and nurses ( $N = 268$ ).

higher disengagement (beta = 0.16, CI<sub>95%</sub> [0.07, 0.26]), but when procedural justice was higher, workload did not affect disengagement (beta = -0.01, CI<sub>95%</sub> [-0.10, 0.08]).

For physicians we did not obtain support for the buffer effect of procedural justice on workload, neither for exhaustion (beta = -0.02, CI<sub>95%</sub> [-0.10, 0.05]), nor for disengagement (beta = -0.09, CI<sub>95%</sub> [-0.18, 0.00]).

## DISCUSSION

This paper aimed to test and compare the unique and predictive impact of workload, empathy, meaningful work, perceptions of justice, and professional identification on burnout (exhaustion and disengagement) of physicians and nurses in times of COVID-19 pandemic. These variables have been shown to be important predictors of burnout, but have not been considered together in a same study. Furthermore, we also controlled for individual variables, that could impact on that relations: demographic, ideological, and related with COVID-19 pandemic.

The results of correlations generally confirmed the ones of previous research. However, the testing and comparison of the unique impact of each of these variables revealed that the predictors considered are not equally important. We obtained a pattern of results that shows some predictors are common to both dimensions of burnout both in physicians and nurses, and a specificity of some of the predictors for each of the dimensions of burnout and that differ between physicians and nurses.

Workload was positively associated with both dimensions of burnout both in physicians and nurses (e.g., West et al., 2018; Dubale et al., 2019), and even when all variables were considered, workload remained a significant risk factor except for disengagement in physicians.

Justice perceptions were found to be differently associated with burnout, all of them as protective factors when significant. Procedural justice, distributive justice and justice of colleagues were negatively associated with both dimensions of burnout both in physicians and nurses. Justice of patients and family patient justice were negatively associated with exhaustion (nurses) and disengagement (physicians and nurses). These results confirm the research previously conducted by Moliner et al. (2005) demonstrating the protective role of justice in burnout. Furthermore, procedural justice was a unique and significant protector for the two dimensions of burnout in physicians and nurses. This is in line with the research that shows the importance of procedural justice for good functioning in organizations and well-being (e.g., Elovainio et al., 2002a).

Professional identification was correlated negatively with both dimensions of burnout both in physicians and nurses. These results support the hypothesis of professional identification as protective factor of burnout, as demonstrated in the study by Avanzi et al. (2018), and it remained a significant and unique protective factor for distancing (both in physicians and nurses) and for exhaustion in physicians, but not for exhaustion in nurses, confirming the important role of social identity for the protection against burnout.

For the disengagement of nurses, more dimensions of justice besides the procedural one remained significant protective factors when all variables were considered, namely distributive justice, justice of colleagues, and patient and family patient's justice.

Meaningful work was negatively associated with exhaustion (nurses) and disengagement (physicians and nurses). These results support our hypothesis and confirm previous research on the premise of meaningful work as protective factor for burnout (e.g., Borritz et al., 2005) in physicians (e.g., Rasmussen et al., 2015) and nurses (e.g., Tei et al., 2014). However meaningful work only remained a significant predictor of disengagement in nurses.

For empathy the results support the hypothesis of empathy as risk factor, specifically affective empathy for exhaustion in nurses, and cognitive empathy as protective factor for disengagement in physicians. When all the variables were considered, affective empathy emerged as risk factor for exhaustion, both in physicians and nurses.

Income was a risk factor for both dimensions of burnout in nurses, which might be explained by the lower incomes of nurses in Portugal and by the fact that, for people with lower incomes, income is more strongly related with well-being than for people with higher incomes (Lucas and Schimmack, 2009). Indeed, income is a resource that helps individuals to overcome inconveniences and hassles, that allow individuals to obtain paid help for less enjoyable activities, such as chores, and also to engage in enjoyable activities (for a review, see Tay et al., 2017). Future studies should try to further investigate these associations.

Given the results consistently found the unique impact of procedural justice and professional identification as burnout protectors (except for exhaustion in nurses), and workload as a core risk factor (except for disengagement in physicians) we tested three possible models of the relation between these variables.

The first analysis was based on the group-value model. We tested the possible indirect effect of procedural justice on burnout through professional identification. However, our data did not support for the application of the group-value model to predict burnout in the present sample of physicians and nurses.

The second analysis was based on the model where professional identification has an indirect effect on burnout through workload (Avanzi et al., 2018). Again, our data did not support for the this model.

The third analysis, tested the possibility that procedural justice could act as a buffer and be a moderator of the impact of workload on burnout. Only for disengagement in nurses it was found that high procedural justice may decrease the impact of workload on burnout.

This study has important implications for interventions because it suggests several focus that might be simultaneously and independently addressed: decreasing workload and promoting procedural justice and professional identification, seem to be central to interventions for reducing the risk of burnout or preventing it from occurring in the first place. The fact that these factors are related with organizational issues goes in the same line that burnout intervention may be done at the level of the working conditions (Maslach and Leiter, 2015) and not mainly at the level

of the treatment of the individual (Maslach et al., 2001) as it still happens (e.g., Hue and Lau, 2015; Castanheira, 2020).

This study has of course some limitations. Some of the constructs were assessed with few items, because we had many variables and the measurement of all of them with the entire scales would result in a very long questionnaire that would certainly discourage participants from answering. However, the measures of internal consistency of the shortened scales were very good.

A second limitation is related with the samples, that were convenience samples and the data were collected in a specific period of the pandemic. Nevertheless, the sample showed good variability in most of the sociodemographic, ideological and occupational variables, which supports its' heterogeneity and therefore the possibility of generalizability of these results for similar samples.

One third limitation refers to the correlational design of this study, that limits the nature of the conclusions that can be drawn about the causal relations among variables. Nevertheless, considering psychosocial variables as predictors and burnout as an outcome is in line with previous research that tried to find the predictors of burnout (e.g., Demerouti et al., 2001).

A fourth limitation refers to the fact that all predictors and outcome variables were self-reported, which might lead to possible overestimation of the associations between them due to shared method variance.

Future studies should try to replicate these results with other samples of physicians and nurses and may also explore if the protective factors that we found in this study extend to other occupations in contexts and times less affected by the specificities of adapting to a Pandemic.

We strongly believe that this paper can contribute to encourage research to focus on the variables that are the stronger predictors of burnout and to stimulate the test of models that consider how these variables might relate. According to our results, the core variables seem to be procedural justice, professional identification and workload, and act independently of each other. With the continuation of the pandemic and the persistence of the increased stress on the health care systems, we recommend that procedural justice and professional identification should receive special attention of interventions in the Health Care Services. However, we do not intend to devalue the importance of recommending the reduction of the workload to which these professionals are subject to. We think the study

of protective factors is important, but they should not devalue the relevance and responsibility of organizations to reduce risk factors, namely workload.

## DATA AVAILABILITY STATEMENT

The datasets presented in this article are not publicly available because the participants of this study did not agree for their data to be shared publicly. However, the datasets can be available under request directed to Isabel.correia@iscte-iul.pt.

## ETHICS STATEMENT

This study received Ethical approval by the Portuguese Order of Psychologists (OPP – Ordem dos Psicólogos Portugueses), in the framework of an initiative to support scientific research in health psychology and behavior change (Via Verde de Apoio OPP para a Investigação Científica em Saúde Psicológica e Mudança Comportamental). The participants provided their electronic informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

IC planned the study and selected the variables and the instruments. IC and AA contributed to the writing of all parts of the manuscript. AA put up the questionnaire in the Qualtrics platform and recruited the participants via Facebook and LinkedIn. Both authors contributed to the article and approved the submitted version.

## FUNDING

AA received funding from the Fundação para a Ciência e Tecnologia (FCT) reference number UIDB/03125/2020.

## ACKNOWLEDGMENTS

We would like to thank Jorge Vala and Helena Carvalho for comments on a previous version of the manuscript.

Psychiatry* 11:579563. doi: 10.3389/fpsy.2020.579563

**Objective:** We aimed to determine the prevalence of burnout among hospital healthcare workers in Libya during the coronavirus disease (COVID-19) pandemic and civil war.

**Methods:** A cross-sectional study was conducted from April 18 to May 2, 2020 among Libyan healthcare workers. Data on participant characteristics were collected with a specifically designed questionnaire. Burnout was assessed with the abbreviated Maslach Burnout Inventory (aMBI) comprising three subscales: emotional exhaustion (EE), depersonalization (DP), and personal accomplishment (PA), with each sub-scale score range from 0 to 18. For EE and DP, scores of 10 to 18 were regarded as “moderate to severe burnout.” PA was scored inversely, where a score  $\leq 10$  indicated severe burnout.

**Results:** The study yielded a sample size of 532 participants. Of these, 357 (67.1%) reported emotional exhaustion (EE Score  $\geq 10$ ), 252 (47.4%) reported depersonalization (DP score  $\geq 10$ ), and 121 (22.7%) reported a lower sense of personal accomplishment (PA score  $\leq 10$ ). Verbal abuse was experienced by 304 participants (57.1%) and physical abuse in 93 (17.5). Gender was associated with high emotional exhaustion and high depersonalization. Being 35 years or older was associated with high depersonalization. Professional specialty was significantly associated with high emotional exhaustion and depersonalization. Fear of COVID-19 infection was associated with high emotional exhaustion and high depersonalization.

**Conclusion:** The rising prevalence of mental disorders and inadequate availability of health services facilities during the COVID-19 pandemic and civil war demonstrated the need for healthcare policies to address the well-being of healthcare workers to decrease the risk of loss, suicide, and medical negligence.

**Keywords:** coronavirus disease, medical staff, professional burnout, COVID-19, psychiatric illness, pandemic, war exposure

## INTRODUCTION

In December 2019, a novel coronavirus designated as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was identified as the cause of severe viral pneumonia in Wuhan, a city in Hubei Province, China (1). This virus was recognized as a global pandemic on February 11, 2020 (2). By August 14, the World Health Organization recorded over twenty million cases of coronavirus disease (COVID-19), including more than 756,000 deaths (3, 4).

Since the emergency of the first case of COVID-19 was detected in Libya on March 24, followed by a substantial increase in the number of cases. By August 14, more than 6,611 cases were confirmed, with the death toll exceeding 132 (5).

Research indicates that frontline healthcare staff involved in the management and diagnosis of COVID-19 are at risk of experiencing psychiatric disturbances and deteriorating mental health (6). This may be a result of various challenges, such as shortages of personal protective equipment, scarcity of appropriate medications, risk of infecting family members, expectations of inadequate assistance, and fear of contracting the virus. Along with the financial difficulties that physicians are facing in many countries, these factors place healthcare workers under considerable pressure, threatening their mental well-being (7, 8).

Several studies have identified a correlation between mental health issues and the COVID-19 pandemic in healthcare workers. A recent study conducted in China from January 29, 2020, to February 3, 2020, to assessed the mental health status of physicians and nurses, and found that they demonstrated a high prevalence of anxiety, depression, and insomnia (6). Further, a study conducted in Singapore from February 19, 2020, to March 13, 2020, observed increased psychological distress, anxiety, and depression among healthcare workers during COVID-19 (9).

However, there is little data available on physician burnout during the pandemic. Burnout is defined as a medical condition of physical and mental fatigue associated with work or care-providing activities (10, 11). Burnout involves cognitive fatigue, depersonalization, and a diminished sense of success (12). Since physicians endure an extremely taxing working environment, burnout syndrome among healthcare workers has attracted major interest in recent years.

Research supports that physicians are at higher risk of burnout due to exposure to emotional pressure beyond the level experienced in most other professions (13). Furthermore, burnout has been linked to decreased efficiency and diminished work satisfaction among physicians (14). Subsequently, irritability and dissatisfaction may impact individual's sense of well-being and willingness to function fully at work, negatively affecting the ability of physicians to care for patients (15). In addition, physician burnout has been linked to increased risk of medical errors, which also has a harmful effect on patient outcomes (16). Worryingly, burnout has been associated with suicidal risk and elevated levels of depression (17–20). The condition has also been linked to physiological issues, such as increased risk of cardiovascular diseases (21, 22), and inflammation biomarker elevation (23).

A further exacerbating factor for Libyan physicians is that since 2011, Libya has suffered from several civil wars and financial crises that can potentially lead to conflict-related traumatic events and higher rates of mental disorders (24, 25). In addition, due to the absence of a formal psychiatric training program, Libya lacks adequate mental healthcare facilities; currently having 0.2 psychiatrists and 0.05 psychiatric nurses per 100,000 people (26, 27).

Therefore, we believe that healthcare workers in Libya are at greater risk for burnout syndrome and lower quality of life during the COVID-19 pandemic. We aimed to determine the prevalence of, and factors associated with, burnout syndrome among Libyan healthcare workers during the COVID-19 pandemic in a time of civil war.

## METHODS

This was a cross-sectional study.

### Participants

Healthcare professionals working in Libyan hospitals were recruited for the study from April 18, 2020, to May 2, 2020. Data were collected via a questionnaire that was distributed among 20 major hospitals in printed and electronic format, via mobile messages and emails. Inclusion criteria were as follows: participants must have worked in late March and April, and must have worked in either surgery, internal medicine, intensive care, or emergency departments. Exclusion criteria were as follows: having patients with mental illnesses or severe chronic diseases such as advanced diabetes, hypertension, and tuberculosis. Participants with missing data, incomplete Abbreviated Maslach Burnout Inventory (aMBI), or those with a history of mental illness were excluded from the analysis.

### Measures

The questionnaire contained two sections. The first section was developed specifically for the study and comprised participant demographic characteristics, marital status, years of work experience, work shifts, number of working hours per week, illicit drug use and smoking history, employment status, educational level, perspectives on COVID-19, social stigmatization, the effects of the civil war, internal displacement, transportation-related issues, physical and verbal abuse of physicians.

The second section contained the English version of the Abbreviated Maslach Burnout Inventory (aMBI), which is a nine-item scale developed for and most commonly used in the detection of burnout among physicians (28–31). The aMBI comprises three subscales: emotional exhaustion (EE, emotional depletion due to job demand and continuous work-related stress), depersonalization (DP, impersonal response toward the recipient service), and personal accomplishment (PA, the degree of personal competence, achievement, and job satisfaction). Each subscale contains three items. Responses are based on a seven-point Likert scale, ranging from 0 (“never”) to 6 (“every day”). For EE and DP, a higher score indicates greater burnout, and for PA, a higher score indicates a greater sense of accomplishment. Therefore, high EE and DP scores, and a low PA score indicated

a higher level of burnout. Overall burnout was taken as the sum of EE and DP scores.

The scores of each subscale ranged from 0 to 18. For EE and DP, scores of 0 to 9 were categorized as “no to low burnout” and scores of 10 to 18 were regarded as “moderate to severe burnout.” This was the inverse for PA because higher PA scores indicate less burnout. For PA, a score  $\leq 10$  indicates severe burnout. The score for each item was summed for each physician.

The aMBI is a reliable tool to measure burnout among physicians and has been validated in several previous studies (32–37). The Cronbach's alpha coefficient scores for each subscale were as follows: emotional exhaustion  $\alpha = 0.89$ , depersonalization  $\alpha = 0.76$ , personal accomplishment  $\alpha = 0.72$ , and overall burnout  $\alpha = 0.81$ .

## Statistical Analysis

Data did not follow normal distribution according to Shapiro-Wilk test. Confirmatory factor analysis of the Abbreviated Maslach Burnout Inventory (aMBI) was assessed using structural equation modeling (SEM) as previously published (38), and the models were tested using IBM<sup>®</sup> SPSS<sup>®</sup> Amos<sup>™</sup> 24 (IBM Corp., Armonk, NY, USA). This yielded several measures as follows:  $\chi^2$  minimum fit test as in inferential testing of the model. The root means square error of approximation (RMSEA) determine the lack of fit due to reliability (39), where it provides fit per degree of freedom of the model with 0.05 or less desirable as indicating good fit model. Adjusted goodness of fit index (AGFI) and the goodness of fit index (GFI) adjust for the number of estimated with a range from 0 to 1 with 0.9 or more as a desirable indicator of good fitting model. Also, comparative fit index (CFI) will be used to assess fit related to null modeling using noncentrality parameters (40). CFI range from 0 to 1 with 0.9 or more as an indicator of good fitting model. The standardized root mean square residual (RMR) was used as the average of the differences between sample correlations and

estimated population correlations, with a value range from 0 to 1; where  $<0.08$  indicative of fitting model (41).

Differential item functioning (DIF) using multiple indicator multiple cause (MIMIC) model was performed on latent factors (EE, DP, PA) of the best fitting model on the “online vs. paper” variable to see if there were statistically significant coefficients between the two methods of data collection which may necessitate splitting of the samples or whether both ways yield similar valid results.

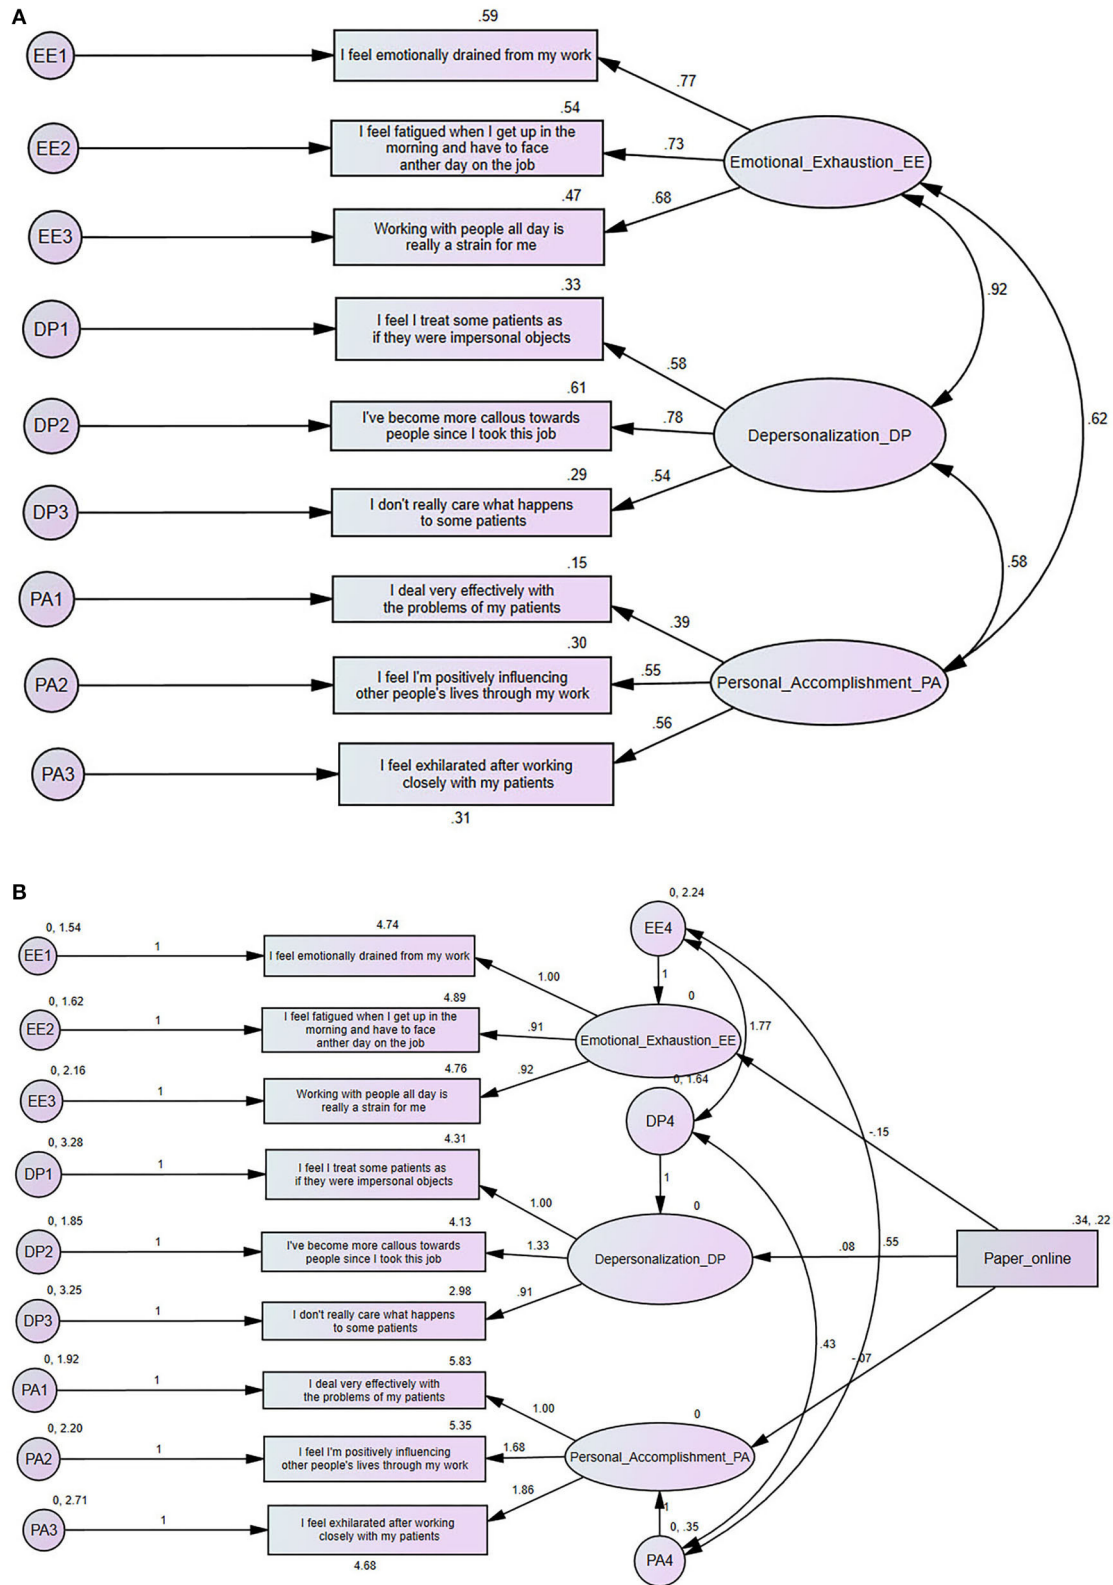

Baseline characteristics and working conditions for men and women were compared using the Mann-Whitney U test for continuous variables and the chi-square test for categorical variables. Fisher's exact test was used to compare the burnout subscales with the demographic data. Phi ( $\phi$ ) was used to measure the strength of association of two dichotomous variables, while Cramer's V was used to measure the strength or association of more than two nominal variables. The aMBI level of internal consistency was determined by a Cronbach's alpha among study participants. A Spearman's rank-order correlation test was conducted to assess the relationship between emotional exhaustion, depersonalization, and personal accomplishment scores and study variables. Data entry and statistical analysis was performed using SPSS version 25.0 (IBM Corp., Armonk, NY, USA).

## Ethical Considerations

The study was approved by the Bioethics Committee at the Biotechnology Research Center in Libya. All participants provided consent before participating in the study.

## RESULTS

A total of 532 out of 600 (88.66%) participants completed the questionnaires [353 (66.4%) online, 179 (33.6%) papers]. The mean age was 33.08 (SD = 7.25). The sample comprised 294 (55.3%) males and 238 (44.7%) females. Participants with

**FIGURE 1 | (A)** Standardized parameter estimates for the factor structure of the Abbreviated Maslach Burnout Inventory (aMBI). **(B)** Multiple indicator multiple cause (MIMIC) structural equation model for differential item functioning (DIF) based on paper or online method.

**TABLE 3** | Scores of participants according to the abbreviated Maslach Burnout Inventory.

Subscale	Mean $\pm$ SD	Range (min–max)	Percentile		
			25th	50th	75th
Emotional exhaustion	11.25 $\pm$ 4.81	0–18	8	12	15
Depersonalization	8.5 $\pm$ 5.06	0–18	4.25	9	12.75
Decreased personal accomplishment	12.74 $\pm$ 3.74	0–18	11	13.5	15
Emotional exhaustion + depersonalization	19.76 $\pm$ 8.99	0–36	12	21	27

SD, standard deviation.

incomplete questionnaire data were excluded from the analysis. Only responses from internal medicine (223; 41.9%), intensive care (64; 12%), emergency medicine (111; 20.9%), and surgical departments (134; 25.2%), and their subspecialties were included. The participants' baseline characteristics are presented in **Table 1**. A chi-square test for association was conducted between gender and subjects' basic characteristics. There was a statistically significant association between gender and marital status, living conditions, employment status, years of work experience, department, smoking, and physical abuse ( $p < 0.05$ ). We used the validated English version of aMBI, and the scale was tested for internal consistency, as determined by a Cronbach's alpha of 0.76 for emotional exhaustion,  $\alpha = 0.66$  for depersonalization,  $\alpha = 0.71$  for personal accomplishment, and overall burnout  $\alpha = 0.801$ .

### Confirmatory Factor Analysis

CFA was performed on aMBI items, and parameters were calculated by using maximum likelihood. Minimum was achieved,  $\chi^2 = 170.35$ , degree of freedom (df) = 24,  $p \leq 0.001$ . While (GFI = 0.93, AGFI = 0.87, CFI = 0.88, RMSEA = 0.11, and RMR = 0.22). The results are summarized in **Table 2** and **Figure 1A** provides an overview of the model. Testing measurement invariance was performed between paper and online collection method to see if there is any difference. Overall model, we found  $\chi^2 = 190.82$ , df = 48,  $p < 0.001$ . We found that CMIN/DF was found 3.97, GFI = 0.927, AGFI = 0.86, RMSEA = 0.07, and RMR = 0.25. Chi-square difference test between unconstrained ( $\chi^2 = 190.8$ , df = 48) and constrained ( $\chi^2 = 196.2$ , df = 57) structural models for two groups of data collection model and we found invariant with  $p = 0.79$ . Therefore, groups are not different at model level, however they may be different at the path level. MIMIC model of the latent factors of aMBI burnout scale (EE, DP, and PA) was performed for different methods of data collection (online or paper), we found that none of the latent variables yield statistically significant coefficients, which means that there was no difference between the two methods of data collection as follows: Emotional Exhaustion (Regression Weight Estimate =  $-0.148$ , Standardized Error (S.E.) = 0.156, C.R. =  $-0.949$ ,  $p = 0.343$ ), Depersonalization (Regression Weight Estimate =  $0.077$ , Standardized Error (S.E.) = 0.139, C.R. = 0.553,  $p = 0.580$ ), and Personal accomplishment

(Regression Weight Estimate =  $-0.071$ , Standardized Error (S.E.) = 0.076, C.R. =  $-0.939$ ,  $p = 0.348$ ). **Figure 1B** shows the MIMIC model using paper-online variable as a differential factor.

### Burnout Results Using the Abbreviated Maslach Burnout Inventory

Of the study participants, 357 (67.1%) reported experiencing high emotional exhaustion (EE Score  $\geq 10$ ), while 252 (47.4%) reported experiencing depersonalization (DP score  $\geq 10$ ), and only 121 (22.7%) reported a lower sense of personal accomplishment (PA score  $\leq 10$ ). The mean score of emotional exhaustion was 11.3 (SD = 4.8). For depersonalization, the mean score was 8.5 (SD = 5.1), while for personal accomplishment mean score was 12.7 (SD = 3.7).

**Table 3** presents the scores for the entire scale and its subscales. We found a statistically significant association between emotional exhaustion and gender, years of work experience, department, and living in a conflict area ( $p < 0.05$ ). When we compared depersonalization with study characteristics, we found a statistically significant association between gender, age, department, internal displacement, and verbal abuse ( $p < 0.05$ ). However, for personal accomplishment [Decreased personal accomplishment ( $\leq 10$ ) and Mod-High personal accomplishment ( $> 10$ )], we did not identify a statistically significant association with other study variables. A comprehensive comparison between participants characteristics and subscales of burnout can be found in **Supplementary Material**.

#### Emotional Exhaustion

Three hundred and fifty-seven (67.1%) participants scored 10 or higher for EE, indicating a higher risk of burnout syndrome (see **Figure 2**). A Spearman's rank-order correlation test identified a positive correlation between gender and EE score [ $r_s(530) = 0.099$ ;  $p = 0.022$ ]. There was a negative correlation between age and EE score [ $r_s(530) = -0.151$ ;  $p < 0.001$ ]. A significant negative correlation was found regarding years of experience [ $r_s(530) = -0.118$ ;  $p = 0.007$ ], while a significant positive correlation was identified between department type and EE score [ $r_s(530) = 0.113$ ;  $p = 0.009$ ], living in conflict area [ $r_s(530) = 0.13$ ;  $p = 0.003$ ], feeling stigmatized [ $r_s(530) = 0.174$ ;  $p \leq 0.001$ ], and working hours per week [ $r_s(530) = 0.125$ ;  $p = 0.004$ ]. There was no statistically significant correlation between EE score and marital status, living conditions, employment status, smoking, illicit drug use, internal displacement, verbal abuse, physical abuse, and number of shifts per month ( $p > 0.05$ ).

#### Depersonalization

Two hundred and fifty-two (47.4%) participants scored 10 or higher for DP, indicating a higher risk of burnout syndrome (**Figure 3**). A Spearman's rank-order test showed a positive correlation between gender and DP score [ $r_s(530) = 0.129$ ;  $p = 0.003$ ], department type [ $r_s(530) = 0.105$ ;  $p = 0.015$ ], internal displacement [ $r_s(530) = 0.119$ ;  $p = 0.006$ ], and living in conflict area [ $r_s(530) = 0.09$ ;  $p = 0.038$ ].

However, there was no statistically significant correlation between DP score and age, marital status, living conditions, employment status, feeling stigmatized, smoking, illicit drug

**FIGURE 2 |** Number of physician responses for the emotional exhaustion subscale of the abbreviated Maslach Burnout Inventory.

**FIGURE 3 |** Number of physician responses for the depersonalization subscale of the abbreviated Maslach Burnout Inventory.

use, verbal abuse, physical abuse, working hours per week, and number of shifts per month ( $p > 0.05$ ). Two hundred and thirty-six (44.4%) scored ten or more on both EE and DP, representing a higher risk of burnout syndrome.

### Personal Accomplishment

One hundred and twenty-one (22.7%) participants scored  $\leq 10$  for PA, indicating a higher risk of burnout syndrome (Figure 4). A Spearman's rank-order correlation test indicated that none of the study subject characteristics were correlated with PA score such as gender, marital status, age, years of work experience, department, living conditions, employment, feeling stigmatized, smoking, illicit drug use, internal displacement, living in a conflict area, verbal abuse, physical abuse, working hours per week, and number of night shifts per month ( $p > 0.05$ ).

## DISCUSSION

This study aimed to assess burnout among healthcare workers in departments which are high-risk for COVID-19 in Libya, which is currently experiencing a civil war. To our knowledge, the present study is the first to examine burnout syndrome during COVID-19 in a civil war setting.

The present study demonstrated a high prevalence of anxiety and depression among physicians during the COVID-19 pandemic amidst the civil war. The study provided a justified sample size of 532 physicians working on the frontlines of the pandemic in March and April of 2020. The response rate

and data completion were in good range. Risk of burnout scores reported by participants were 67.1% for emotional exhaustion, 47.4% for depersonalization, and 22.7% for lower personal accomplishment. However, 44.4% have both emotional exhaustion and depersonalization.

In our study, gender (35) was associated with both high EE and high DP. However, it was not associated with a low PA. In terms of age, being 35 years or older was associated with high depersonalization. Marital status was not associated with high levels of burnout. High-risk departments for COVID-19 were significantly associated with high EE and DP; specifically, those in the surgical department, emergency department, and intensive care units were more likely to have high EE and DP. Personal accomplishment was not associated with the department or professional specialty. Employment sector, i.e., government or private, was not found to be associated with burnout. In addition, fear of COVID-19 infection was associated with higher EE and DP.

Years of work experience was statistically associated with personal accomplishment. Our findings indicated that those with higher personal accomplishment scores were those with less working experience, and those with more experience felt less accomplishment. Smoking and illicit drug use were not associated with EE or DP. Feelings of stigmatization due to COVID-19 was associated with high scores in DP. In addition, verbal abuse was associated with DP only. Internal displacement and verbal abuse were associated with higher risk of DP. Living in conflict area was associated with higher risk of EE.

We observed that burnout prevalence among Libyan physicians was higher than in other countries. A study on radiology residents in the USA found that high EE, high DP, and low PA scores were reported by 37, 48, and 50% of participants, respectively (42). A further study conducted among Iranian healthcare workers reported participant scores of 12.3, 5.3, and 43% for high EE, high DP, and low PA, respectively (43). In Nigeria, a study conducted among residency training physicians found that 45.6% of physicians had high EE, 57.8% had high DP, and 61.8% had low PA. These findings were similar to those of the present study. However, a systematic review and meta-analysis of 4,664 medical residents found that the overall prevalence of burnout was 35.7% for surgical staff, and critical care workers had a higher prevalence of 40.8% (44). Additionally, a study conducted in Malaysia showed a burnout prevalence of 26.5% among junior doctors (45), and another study in Saudi Arabia indicated that 25.2% of physicians can be classified as having burnout (35). This wide variation is explained by socioeconomic and cultural differences, as well as the differences in healthcare infrastructure among these countries. However, a study in the United States found that about 50% of physicians suffer from burnout, which is similar to our results (46).

Burnout is known to be highly prevalent among physicians due to the psychologically demanding nature of the profession. Physicians are also exposed to a high level of socioeconomic pressure that may lead to burnout. Burnout has been found to be a risk factor for training attrition, suicide, and low quality of life. It has further been linked with sleep deprivation, family issues, and feeling overwhelmed with tasks and paperwork (20). In addition, burnout was associated with a high level of medical errors and a decreased level of patient care (47). Therefore, interventions aimed at reducing the stress levels of physicians are needed to improve well-being and quality of life among this population (48). For example, coaching for female physicians who are undergoing strain and experiencing stress about starting a family, and need external support from general practitioners, have been suggested in previous research (49).

There are a number of contributing factors for the increased level of burnout among Libyan physicians found in this study. First, due to the country's economic crisis, these healthcare workers are irregularly compensated and suffer socioeconomic hardships. Second, physicians are subject to a high level of abuse by patients and militias (50). The present study found that the prevalence of verbal abuse and physical abuse is 57 and 17.5%, respectively. Additionally, the civil war has caused displacement among physicians; 32.5% of physicians have left their homes due to the conflict. This situation places more pressure on these healthcare professionals, who fear their homes being destroyed or taken over by militias (51). Finally, they have concerns regarding the COVID-19 pandemic. The physicians fear being infected and infecting their families. They also have concerns about the shortage of treatment supplies and personal protective equipment (52, 53).

The present study has several limitations. First, because of the observational study design, we were unable to determine causation or demonstrate strong relationships between variables.

Therefore, larger studies are needed to examine predictive factors and to focus on other contributing factors that were not included in the present study. Second, the present study was conducted in one country where physicians face multiple stressors, including COVID-19, civil war, financial crisis, and a scarcity of mental health centers, which can explain the high level of burnout we observed. In addition, we believe that the fear of stigmatization may have resulted in response bias. Another limitation is that there is no standard definition of burnout. Although the aMBI is a validated tool that can detect and screen those who are at high risk of burnout, some studies have discussed the overestimation of the tool's effectiveness (32, 54, 55).

This study highlights the importance of addressing burnout among healthcare workers. Issues of burnout should be prioritized by authorities. This study identified a high demand for physician support interventions such as social support programs, financial support, and increased security measures in hospitals to prevent and decrease abuse. Furthermore, there is a need to recognize external contributing factors and the impact they have on physician's lives, such as internal displacement and living in conflict areas. Thus, the government should provide support in these areas to prevent humanitarian crises.

In conclusion, the rising prevalence of mental disorders among physicians and inadequate availability of healthcare facilities during the COVID-19 pandemic and civil war has demonstrated the need for healthcare policies to address the well-being of healthcare workers to decrease the risk of medical negligence, deteriorating mental health, and suicide.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Bioethics Committee of the Biotechnology Research Center in Libya. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

MELh analyzed and interpreted the data, supervised the project, and wrote the first draft of the manuscript. All authors contributed to the study design and data collection. All authors have read and approved the final manuscript.

# Depressive Symptoms, Anxiety Disorder, and Suicide Risk During the COVID-19 Pandemic

Aurel Pera\*

Department of Teacher Training, University of Craiova, Craiova, Romania

This study reviews the existing literature on psychiatric interventions for individuals affected by the COVID-19 epidemic. My article cumulates previous research on how extreme stressors associated with COVID-19 may aggravate or cause psychiatric problems. The unpredictability of the COVID-19 epidemic progression may result in significant psychological pressure on vulnerable populations. Persons with psychiatric illnesses may experience worsening symptoms or may develop an altered mental state related to an increased suicide risk. The inspected findings prove that psychological intervention measures for patients affected by the epidemic should be designed and personalized adequately. Preventive measures seek to decrease infection rates and cut down the risk of the public healthcare system to eventually be overburdened. Throughout the COVID-19 crisis, people with psychiatric illnesses may confront a decrease in mental health services. As limitations in the current review, by focusing only on articles published in journals indexed in Web of Science, Scopus, and ProQuest, I inevitably disregarded other valuable sources. Subsequent research directions should clarify the effectiveness of online mental health services in providing remote psychiatric interventions to individuals affected by the COVID-19 epidemic.

## INTRODUCTION

COVID-19 has placed a significant strain on health systems on a large scale (Kelly, 2020b). There may be a prevalent deterioration of mental health in the affected people (Sønderskov et al., 2020). Being confined in self-isolation or quarantined may have short- to long-term adverse consequences on the mental health of affected individuals (Mukhtar, 2020). Emotional, physical, and mental fatigue may occur as a result of immoderate and persistent stress (Zhang et al., 2020a). In September 2020, I undertook a systematic review of Web of Science, Scopus, and ProQuest, employing Preferred Reporting Items for Systematic Reviews and Meta-analysis (PRISMA) guidelines. The inclusion criteria were (i) publication date: 2020 only, (ii) original empirical research, review articles, and editorial materials having non-theoretical content, (iii) written in English, and (iv) covering “COVID-19,” “depressive symptoms,” “anxiety disorder,” and “suicide risk” as search terms. I excluded from the review (i) books, (ii) proceedings papers, and (iii) theoretical comments. I have employed the Systematic Review Data Repository (SRDR), a powerful tool for the extraction, handling, and inspection of data for the systematic review. As I focused on research published exclusively this year, only 193 various types of articles met the eligibility criteria. By removing

those whose results were inconclusive, unconfirmed by replication/retracted, too general, or having similar titles, I selected 68, mainly empirical, sources (Table 1).

## HEALTH-RISK COVID-19 BEHAVIORS ASSOCIATED WITH DEPRESSIVE SYMPTOMS

Adequate conformity to spatial distancing in addition to home confinement, self-isolation, and quarantine may have the repercussion of social disconnection with adverse effects for psychological wellbeing (Mesa Vieira et al., 2020). The mandatory and beneficent quarantine has led to an unwitting outcome of escalated stress in old individuals dwelling in nursing homes who have a high risk of contracting COVID-19, in conjunction with increased morbidity and mortality (Padala et al., 2020). Low education level, job loss and unemployment stress, post-traumatic stress disorder symptoms, and adverse coping styles are the main determinants of mental health during the COVID-19 pandemic (Liang et al., 2020).

Fiorillo and Gorwood (2020) insist that persons who have been in direct or indirect contact with COVID-19 infected patients, who are easily affected by biological or psychosocial stressors (e.g., individuals having mental health issues), having a significant level of exposure (e.g., frontline healthcare providers), or following COVID-19 pandemic-related news (Popescu Ljungholm and Olah, 2020) provided by mainstream journalism organizations or social media platforms (Bratu, 2020a,b; Lăzăroiu et al., 2020; Rommer et al., 2020; Sheares et al., 2020) are at risk of mental health and psychosocial effects. Given that extreme stressors may aggravate or cause psychiatric problems, there will be an intensification of mental health issues, behavioral perturbations, and substance use disorders. Duan and Zhu (2020) assert that with disease evolution, clinical symptoms come to be critical and psychological issues in COVID-19 infected patients will aggravate, and thus psychological intervention measures for patients affected by the epidemic should be designed and personalized adequately.

Cao et al. (2020) show that the COVID-19 epidemic has generated excruciating psychological pressure related to the risk of passing away from infection. Having the loved ones infected with COVID-19 is an independent risk determinant for long-endured fear. Cheung et al. (2020) remark that the swiftly increasing volume of COVID-19 infected patients has been experiencing persistent fear and limitations of their current activities. Rigorous preventive measures (e.g., social distancing and extended quarantine) may adversely affect physical and psychological wellbeing, inter-familial connections and socioemotional support networks of the general population (Mircică, 2020), possibly exacerbating psychiatric morbidity, while seeking to decrease infection rates and cut down the risk of the public healthcare system to eventually be overburdened. Rajkumar (2020) writes that subsyndromal mental health issues constitute a typical reaction to the COVID-19 pandemic: symptoms of anxiety and depression in addition to self-reported stress are prevalent psychological responses and may be related to disturbed sleep.

Druss (2020) says that individuals having severe mental illnesses along with the public mental healthcare system pivotal in attending to them are at significant risk. Such patients need timely, precise information concerning approaches for diminishing risk, while discerning when to ask for COVID-19 medical treatment, and, if they are employed, they may not have a break from work and may fall short of adequate insurance coverage to secure COVID-19 testing or medical treatment. Undeveloped social networks may restrict chances to gain support from the loved ones should people having severe mental illnesses get infected with COVID-19. Apprehension may both intensify and be magnified by prevalent anxiety disorders and depressive symptoms. Shigemura et al. (2020) reveal that apprehension of the unknown during the COVID-19 crisis increases anxiety and depression levels in healthy persons and in individuals having preexisting mental health conditions, emotional responses comprising intense psychosocial distress and insecurity. Negative societal behaviors related to COVID-19 are mainly triggered by panic and misrepresented perceptions of risk.

DePierro et al. (2020) observe that the COVID-19 pandemic may give rise to high rates of post-traumatic stress disorder, depression, and substance misuse among affected people. Most individuals from underserved groups may confront chronic mental health effects by lacking the ability to access first-rate healthcare services. Mental health monitoring, timely detection of persons at risk, and medical treatment notwithstanding financial constraints are pivotal for reducing chronic distress. By harnessing cutting-edge technological devices (Nica et al., 2020; Pridmore et al., 2020; Taylor, 2020; Wright and Birtus, 2020), mental health support services can be adopted adequately by use of video telehealth platforms. Huang and Zhao (2020) hold that young persons, individuals spending excessive time mulling over the COVID-19 outbreak, and frontline healthcare providers are at significant risk of mental illness (Allen and Cug, 2020), possibly developing anxiety symptoms. The unpredictability of the COVID-19 epidemic progression may result in significant psychological pressure on vulnerable populations. Age and time

spent by obsessing over COVID-19 are possible risk determinants for the psychological issues of the affected people who may have depressive symptoms and sleep problems.

On Holmes et al. (2020)'s view, COVID-19 may affect the brain or generate immune reactions that have further detrimental consequences on infected patients' brain function and mental health, leading to harmful behaviors. The COVID-19 lockdown and social isolation may have mental health consequences for vulnerable groups, that is persons with underlying mental or physical health disorders or who show a tendency to be psychologically unwell. Psychological processes and social effects (e.g., brain function, cognition, emotion, and behavior) associated with COVID-19 (Clark, 2020a,b) may affect mental health of certain individuals who are on risk of anxiety, depression, stress, and self-inflicted violence. Remote work and job loss, together with social and physical distancing have unexpectedly discontinued numerous social prospects relevant to physical and mental health.

The COVID-19 epidemic has generated extreme stressors that may aggravate or cause psychiatric problems, affecting the brain or generating immune reactions. Emotional responses comprise intense psychosocial distress and insecurity. Such patients need timely, precise information concerning approaches for diminishing risk.

## COVID-19 RISK FACTORS RELATED TO EMOTIONAL AND ANXIETY DISORDERS

COVID-19 pandemic-related, compulsory self-isolation, home confinement, and quarantine are related to poor psychological and physical health (Balanzá-Martínez et al., 2020). Taking into account the COVID-19 infection and deficiencies in personal protective equipment, direct access to patients is restricted excepting for the frontline health care providers who are trained to supply adequate medical care (Mohindra et al., 2020). Psychological interventions and social support provided to vulnerable people to handle panic, anxiety, and confinement during the COVID-19 pandemic may be efficient by use of mobile health platforms (Sim et al., 2020).

Torales et al. (2020) stress that, during COVID-19 pandemic, individuals' emotional reactions tend to comprise extreme fear and confusion (Rommer, 2020; Thompson, 2020), while adverse social behaviors are typically activated by anxiety and misrepresented perceptions of risk. Psychosocial stressors are mainly associated with panic (Breillat and Birtus, 2020) generated by isolation or quarantine and mental instability among the affected individuals. Venkatesh and Edirappuli (2020) suggest that individuals with underlying mental illness may be affected by restricting their interpersonal relations that are pivotal to their mental healthcare, in addition to diminished access to possibly delayed psychiatric services. Personal care workers can provide specialized support (Moore and Kolencik, 2020; Sheares, 2020) by remotely monitoring individuals at risk of mental illness and vulnerable populations. Serafini et al. (2020) note that inequities and intolerance as regards to marginalized people (e.g., aged individuals having mental disorders) may be

typically increased in situations of social distress, panic, irritation, and apprehension.

Lima et al. (2020) put it that primary care providers working in critical and intensive care units and hospitals should receive specialized training for supplying mental healthcare. In hopes of better handling the pressing psychological issues of individuals affected by the COVID-19 crisis, psychological crisis interventions can be enhanced by harnessing Internet technology (Lyons and Lăzăroiu, 2020), as particularly older persons having psychiatric conditions may endure additional distress. Xiang et al. (2020b) emphasize that psychiatric patients constitute an extremely vulnerable population to get infected with COVID-19, but the shortage of adequate medical procedures, insufficient mental health resources, and unsatisfactory training may prevent mental health professionals from supplying mental health services in hospitals and isolation infectious units. Assimilating mental health crisis interventions coherently in the prevalent implementation of disease prevention and treatment may curb the risk of COVID-19-related detrimental psychological outcomes.

Roy et al. (2020) state that the stress and worries in society are disturbing each person to unequal extents. There are amplified anxieties and concerns among the general population about acquiring the COVID-19 infection. Individuals have significant perceived needs to handle their mental health issues, reporting fearfulness, discomfort, and obsession about contracting such a life-threatening infectious disease, in addition to sleep disturbances. Zhang et al. (2020c) maintain that, for COVID-19 infected patients with psychiatric disorders, antiviral drugs should be used together with psychotropic ones, as otherwise they can experience deterioration of their mental illness. Due to stressor events, symptoms such as anxiety, nervousness, and insomnia may occur in such patients. Kavour (2020) posits that deterioration of severe mental disorders associated with COVID-19 may bring about unsatisfactory hygiene, difficulties in practicing preventive strategies, dearth of prompt reporting or pursuing medical attention, and limitations in conforming to required treatment.

On Kelly (2020a)'s reading, infectious disease outbreaks such as COVID-19 bring about mental health conditions (e.g., psychiatric disorders), that is the illness brought about by the virus itself (typically self-limiting but lethal, particularly in the ill-protected people, the old individuals, and the persons having preexistent health conditions) and the fear, apprehension, and psychological issues (Dobson-Lohman and Potcovaru, 2020) related to the pandemic. Vulnerable populations (e.g., homeless persons, individuals having infirmities, chronically ill people, etc.) are at particular risk to have summative risk determinants (e.g., unsatisfactory physical and psychological health, reduced access to services, inadequate control over their ordinary activities, etc.). People with mental illness are less probable to access public health advice about COVID-19, more expected to contract the virus, and less plausible to receive expeditious adequate diagnostic and treatment services.

Moghanibashi-Mansourieh (2020) indicates that individuals' anxious responses may lead to socially disruptive behaviors such as mass panic buying. The rampancy of mental health disorders,

particularly anxiety, diminishes affected persons' resiliency against the COVID-19 infection. Xiang et al. (2020a) find that confirmed or suspected COVID-19 patients may experience uncertainty and apprehension as regards the repercussions of acquiring a potentially deadly infection (Dawson and Potcovaru, 2020; Mihăilă and Martin, 2020; Popescu Ljungholm, 2020), while individuals in home confinement and self-isolation may confront frustration, sadness, and annoyance. Compulsory contact tracing and extended quarantine, which constitute important public health reactions to the COVID-19 outbreak, may heighten patients' anxiety and remorse as regards the consequences of contagion and stigma on their loved ones.

Infectious disease outbreaks such as COVID-19 bring about mental health conditions as individuals' emotional reactions tend to comprise extreme fear and confusion, while their anxious responses may lead to socially disruptive behaviors. Symptoms such as anxiety, nervousness, and insomnia may occur in COVID-19 infected patients with psychiatric disorders.

## COVID-19-RELATED SUICIDAL IDEATION AND BEHAVIOR

The level of risk of COVID-19 spread among persons having a severe mental illness may be more significant than that in the general population, as a consequence of constant unhealthy behaviors and standards of living (Starace and Ferrara, 2020). Individuals who stopped working as a result of the COVID-19 pandemic may experience poor mental and physical health conditions in addition to psychological distress (Zhang et al., 2020b).

As Ahmed et al. (2020) put it, social isolation and economic downsides on a large scale has led to serious psychological troubles for a lot of individuals, configuring severe neurological symptoms of COVID-19 infection. Confirmed patients are afraid of being abandoned by society and in addition to the remorse of having infecting others the outcome may be mental disturbance. The incidence of psychological issues is considerably higher among persons whose colleagues, friends or family members got infected or passed away from COVID-19. Yao et al. (2020) show that epidemics do not exert influence on all populations uniformly and imbalances can facilitate the transmission of infections. Unawareness of the distinctive effect of the epidemic on people with mental health disorders may impede any purposes to slow down increased escalation of COVID-19, while amplifying current health inequalities. Such patients may be more considerably affected by the emotional reactions generated by the COVID-19 epidemic, giving rise to deterioration of a mental health condition due to significant vulnerability to psychological distress in contrast to the general population.

Hao et al. (2020) demonstrate that comprehending the psychological consequences on patients with mental disorders throughout the COVID-19 pandemic may clarify how to set up an efficient immunopsychiatry service. Determinants to deteriorating mental health are possible postponement in supplying psychotropic medications, deficiency in access to primary care and outpatient emergency rooms, significant

financial hurdles, anxiety of getting infected with COVID-19 (Hughes, 2020), prolonged interval of confinement and penurious living conditions caused by paucity of supplies. Such abrupt, unexpected changes may result in feelings of anguish and heightened suicidal ideation among people with psychiatric illnesses. Nearly all the stabilized psychiatric patients need to receive out-hospital treatment to diminish the risk of infection. Immunopsychiatry services should provide point-of-care test for COVID-19 detection, while negative results may offer moral support to persons with mental disability.

Gunnell et al. (2020) observe that the spread of COVID-19 pandemic may trigger distress, leaving affected individuals exposed to mental health disorders (Scott et al., 2020) and suicidal ideation and behavior. Severe mental health issues may be experienced by the healthy population and by persons having significant levels of vulnerability to COVID-19 illness (e.g., primary care providers and individuals who have contracted the virus). Suicide risk may be amplified due to stigma toward infected patients and their family members. Persons with psychiatric illnesses may experience worsening symptoms or may develop an altered mental state related to an increased suicide risk (e.g., anxiety, depression, and post-traumatic stress).

Reger et al. (2020) state that exceptional public health undertakings to regulate the transmission of COVID-19 will decrease the rate of further infections, but the likelihood of detrimental consequences on suicide risk is considerable. Social relationships are pivotal in suicide prevention as self-isolation and lack of companions may exacerbate suicide risk. Diminished access to mental healthcare may adversely impact patients having suicidal ideation. Aggravated physical health issues may escalate risk behavior for old patients, in whom health issues are related to deliberately killing themselves. Wang et al. (2020) point out that prolonged lockdown may have severe detrimental consequences on mental health. The persistent link between physical symptoms and the psychological effect of COVID-19 indicates the necessity of developing a swift diagnostic test having extended availability to attenuate the psychological repercussions and psychiatric symptoms endured by affected people.

On Pfefferbaum and North (2020)'s account, ambiguous prognoses, imminent drastic scarcities of resources for COVID-19 testing and treatment and for ensuring the safety of frontline healthcare providers from infection, enforcement of unusual public health actions that interfere with personal human rights, significant and increasing financial losses, and contradictory directives from governing bodies and medical experts (Lăzăroiu and Adams, 2020) constitute main stressors resulting in pervasive emotional distress and heightened risk for psychiatric disorders. Individuals who get infected with COVID-19, people at increased risk to contract the disease, and persons having preexisting psychiatric or substance use issues may develop adverse psychosocial reactions.

People with mental health disorders may be more considerably affected by the emotional reactions generated by the COVID-19 epidemic. Affected individuals are exposed to mental health disorders and suicidal ideation and behavior, resulting in pervasive emotional distress and heightened risk for psychiatric disorders. Social relationships are pivotal in suicide prevention.

## CONCLUSION

The swift spread of COVID-19 and important death rate may aggravate the risk of mental health issues and intensify current psychiatric symptoms, damaging their proper functioning and cognition to a greater extent (Yang et al., 2020). The conclusions drawn from the above analyses indicate the differential psychiatric distress of COVID-19 affected populations. Psychological processes and social effects associated with COVID-19 may affect mental health of certain individuals who are on risk of anxiety, depression, stress, and self-inflicted violence. Most individuals from underserved groups may confront chronic mental health effects by lacking the ability to access first-rate healthcare services. As limitations in the current review, by focusing only on articles published in journals indexed in Web of Science, Scopus, and ProQuest, I inevitably disregarded other valuable

sources. Subsequent research directions should clarify the effectiveness of online mental health services in providing remote psychiatric interventions to individuals affected by the COVID-19 epidemic.

Perinatal Depression of Exposed  
Maternal Women in the COVID-19  
Pandemic in Wuhan, China.  
Front. Psychiatry 11:551812.  
doi: 10.3389/fpsy.2020.551812

**Objective:** This study aims to investigate perinatal depression in women who gave birth during the COVID-19 pandemic in Wuhan, and to evaluate the effect of the pandemic on perinatal depression prevalence.

**Methods:** A cross-sectional investigation was conducted into women hospitalized for delivery in Hubei Maternity and Child Healthcare Hospital from December 31, 2019 to March 22, 2020, a period which encompasses the entire time frame of the COVID-19 pandemic in Wuhan. The Edinburgh Postnatal Depression Scale (EPDS) was adopted to evaluate perinatal depression status. A Chi-square test and logistic regression model were utilized for data analysis.

**Results:** A total of 2,883 participants were included, 33.71% of whom were found to suffer from depressive symptoms. In detail, 27.02%, 5.24%, and 1.46% were designated as having mild, moderate, and severe depressive symptoms, respectively. The perinatal depression prevalence increased as the COVID-19 pandemic worsened. Compared to the period from December 31, 2019 to January 12, 2020, perinatal depression risk significantly decreased within the 3 weeks of March 2–22, 2020 (1st week: OR = 0.39, 95% CI: 0.20, 0.78; 2nd week: OR = 0.35, 95% CI: 0.17, 0.73; and 3rd week: OR = 0.48, 95% CI: 0.25, 0.94); and the postnatal depression risk significantly rose within the four weeks of January 27–February 23, 2020 (1st week: OR = 1.78, 95% CI: 1.18, 2.68; 2nd week: OR = 2.03, 95% CI: 1.35, 3.04; 3rd week: OR = 1.48, 95% CI: 1.02, 2.14; and 4th week: OR = 1.73, 95% CI: 1.20, 2.48).

**Conclusion:** The dynamic change of perinatal depression was associated with the progression of the COVID-19 pandemic among new mothers who were exposed to the pandemic. An elevated risk of postnatal depression was also observed during the COVID-19 pandemic.

**Keywords:** COVID-19, EPDS, prenatal, postnatal, depression

## INTRODUCTION

In December 2019, a novel virus, officially named SARS-CoV-2, caused an outbreak of pneumonia in Wuhan. The disease was named coronavirus disease 2019 (COVID-19) by the WHO. The newly identified SARS-CoV-2 virus was one of high transmissibility (1). The COVID-19 pandemic has since spread across China and around the world. On January 30, 2020, the WHO declared the virus a public health emergency of international concern, and then a worldwide pandemic on March 12, 2020 (2). The ongoing pandemic has posed a great threat to the physical and mental health of affected individuals.

Chinese governments have taken extensive and efficient actions to control the pandemic. Many provinces and regions in China implemented highest-level public health measures in response to the emergency. The *Guidance Manual on the Prevention and Control of Novel Coronavirus-Infection Pneumonia in the Community* issued by the national government on January 28, 2020, suggested traffic restrictions, home quarantine, and other social distancing measures (3). Besides, to avoid cross-infection opportunities in hospitals, designated hospitals and medical centers were established to exclusively treat the SARS-CoV-2 infection.

Global public health emergencies may promote psychological disorders in affected individuals. The severe acute respiratory syndrome (SARS), which caused a worldwide epidemic in 2003, equipped China with valuable lessons on how to control and prevent COVID-19, and has evidenced the importance of public psychological crisis management in the control of major public health events (4). The SARS epidemic was demonstrated to have negative psychological effects on infected patients (5), health professionals (6), students (7), and the general public (8). Scholars have called for attention to be drawn to the psychological disorders related to COVID-19 pandemic exposure (9). To tackle the potential psychological problems of affected individuals, the Chinese Center for Disease Control and Prevention issued the *Guiding Principles for Intervention in Emergency Psychological Crises during the Novel Coronavirus-Infection Pneumonia Epidemic*, and announced that an intervention of psychological crises should be involved in the whole deployment of COVID-19 pandemic prevention and control (10). Moreover, some hospitals and psychologists provided free online courses on psychological crisis treatment for COVID-19 affected individuals (11).

However, there are limited mental health services available for maternal women, as well as evidence for efficient management against the psychological effect of the pandemic. As a vulnerable group affected by high levels of estrogen and progesterone, the upper respiratory tract mucosa of pregnant women thickens causing edema and mild congestion, which are prone to respiratory infection. And SARS-CoV-2 infected pregnant patients were presented to have poor prognoses. Therefore, perinatal mothers deserve priority in psychological health guarantees (12). Maternal depression is one of the most common complications among perinatal women, which may result in devastating life events to mothers, infants, and families (13). Perinatal depression may have negative effects on offspring

well-being throughout their whole life (14–16). The mortality rate attributed to perinatal depression resulted suicide even exceeds that caused by postpartum hemorrhage and pregnancy induced hypertension (17). New mothers need delivery-related medical services in hospitals where they may be confronted with nosocomial SARS-CoV-2 infection, which possibly increases their psychological crisis during the perinatal period. With all this in mind, the perinatal depression status of maternal women is worthy of assessment during the entire COVID-19 pandemic period.

This study aims to investigate the prevalence of perinatal depression in hospitalized maternal women and to evaluate the depression risk in relation to COVID-19 pandemic exposure. The findings of our study will provide helpful experiences for the handling of subsequent large-scale psychological crises among perinatal women.

## METHODS

### Data Sources and Study Population

The participants were general healthy pregnant women receiving delivery services at Hubei Maternity and Child Healthcare Hospital in Wuhan, one of the largest cities in central China. The hospital is the largest Class III Grade A maternity center in Hubei Province. In 2018, one out of five newborns in Wuhan were expected to be delivered in this hospital. Their delivery help services mainly provided for women not infected with COVID-19 during the pandemic.

The study conducted included hospitalized individuals with a gestation of 28 weeks and above or  $\leq 7$  days after delivery (as of the perinatal period). Our study was approved by the Ethics Committee of the hospital. The cross-sectional study was implemented from December 31, 2019 to March 22, 2020, a period that spanned the whole COVID-19 pandemic in Wuhan. All participants provided oral informed consent before the investigation, in line with the Declaration of Helsinki regarding human participation. The questionnaire survey was mainly completed online using the WeChat-based survey program Questionnaire Star (questionnaire link: <https://www.wjx.cn/jq/55187836.aspx>), which was widely used during the COVID-19 pandemic. A total of 5% of the participants completed a paper questionnaire with the exact same items due to the temporary unavailability of their mobile phone in hospital.

### Variable Definitions

#### Exposure Variable

The COVID-19 pandemic was regarded as an exposure variable. The daily reported number of confirmed COVID-19 patients was key to the psychological responses of the exposed new mothers, manifesting perinatal depression during the entire epidemic period. Sequential events occurred with the updated measures against the pandemic, including: 1) the first reported patients with unknown pneumonia on December 31, 2019; 2) newly reported patients with an onset of January 16, 2020 on January 18, 2020; 3) the official announcement of the human-to-human transmission on January 20, 2020; 4) the beginning of inner-city traffic restrictions and home quarantine on January

23, 2020; 5) centralized treatment and quarantine strategies to the confirmed patients, suspected patients, patients with a fever symptom, and close contacts; and 6) the first reported zero number of new COVID-19 patients up to March 18, 2020 on March 19, 2020 (18, 19). In response to the concurrent COVID-19 pandemic, maternal women may suffer a different degree of perinatal depression throughout several time intervals.

### Covariates

Covariates included sociodemographic variables such as age (< 25, 25–29, 30–34, and > 34), ethnicity (Han and other), education (junior high or below, senior high, and college or above), Hukou (urban and rural), annual family income (<50,000 ¥, 50,000–100,000 ¥, more than 100,000 ¥, and unknown), delivery status (prenatal and postnatal), gravidity (1, 2–3, and  $\geq 4$ ), parity (0–1 and  $\geq 2$ ), gestational age (<37 and  $\geq 37$ ), health-related behaviors like prior history of traumatic delivery experiences (yes and no), sleep quality (good, fair, and poor), smoking (no, yes, and passive smoking), alcohol drinking (no and yes), and exercise (no and yes) during pregnancy.

Otherwise, most mothers lived with their family and family members played an important role in their social interaction. An Adaptation, Partnership, Growth, Affection, and Resolution Scale (APGAR) was used to evaluate the family function of each respondent. The scale was developed by Smilkstein and has been widely used (20, 21). It consists of five dimensions (adaptation, partnership, growth, affection, and resolution) (22). Each item

was rated on a scale from 0 (*hardly ever*) to 2 (*almost always*). The APGAR scale was translated into Chinese in this study and was confirmed to be of good internal consistency (Cronbach's  $\alpha = 0.80$ ). A final summarized score of 0–3, 4–6, and 7–10 indicated poor, fair, and good family functions (23).

### Dependent Variables

The Edinburgh Postnatal Depression Scale (EPDS) was used for perinatal depression assessment. The EPDS was compiled by Cox et al. (24) and has been proven to have good reliability and validity, and be suitable for depression assessment during pregnancy and postpartum periods. The scale comprises 10 items, each of which is scored on a four-point scale ranging from 0 to 3 by severity. Finally, the summarized score is classified into four grades, with 0–9, 10–16, 17–21, and 22–30 points indicating none, mild, moderate, and severe depression levels, respectively (25). The internal consistency of this scale was good in our study (Cronbach's  $\alpha = 0.92$ ).

### Statistical Analysis

The statistical analyses were performed using SAS 9.4 for Windows. A Chi-square test was used to analyze differences in categorical variables, including sociodemographic variables, health behavior factors, and the exposure variable. Multiple logistic regression models adjusted for the mentioned covariates were used to evaluate the dependency of perinatal depression risks on the exposures. Results of the multiple logistic regression

model were reported as adjusted odds ratios (OR) and corresponding 95% confidence intervals (CI). All analyses were two-sided and a  $p$ -value of  $<0.05$  was considered statistically significant.

## RESULTS

A total of 4,895 inpatients in the hospital were eligible during the study period, and 2,937 of them agreed to participate in the survey. After removing those with incomplete data ( $n = 18$ ) and with prior depression ( $n = 36$ ), 2,883 participants were included in the statistical analysis. **Figure 1** shows the number of daily confirmed COVID-19 cases and the perinatal depression prevalence per week during the study period. From the end of 2019 when the first COVID-19 cases emerged in Wuhan,

the perinatal depression prevalence continued to increase along with the increasing number of daily reported COVID-19 cases. During the time intervals of January 13–19 and February 3–9, the daily reported number of new cases increased rapidly in Wuhan. Meanwhile, the depression prevalence rose from 30.99% within the week of January 13–19 to 42.98% within the week of February 3–9. The highest prenatal depression value was 46.97% within the week of January 6–12. And the highest postnatal value was 44.15% within the week of February 3–9. As the emergence of SARS-CoV-2 infections slowed down, the perinatal depression prevalence showed a downward trend from 42.98% during February 3–9 to 23.85% during March 9–15.

**Table 1** and **Supplementary Table 1** show the sociodemographic characteristics of participants stratified by depression levels. In total, 33.71% of all participants were

found to have depressive symptoms, 27.02, 5.24, and 1.46% of which were indicative of mild, moderate, and severe depression, respectively (**Supplementary Table 1**). The majority of participants were aged 25–29 (41.42%), of Han race (97.29%), highly educated (79.01%), urban (64.61%), and had a family income of  $\geq 100,000$  ¥ (52.03%). The depression prevalence was higher (of marginal significance) in the participants over 34 years of age than those of  $\leq 34$  years (16.36 vs. 12.82%,  $p = 0.0462$ ).

**Table 2** and **Supplementary Table 2** show the health behavior factors stratified by depression levels. Most of the participants (92.47%) reported no previous traumatic delivery experience;

and those who experienced a traumatic delivery had a higher depression prevalence (10.36 vs. 6.08%,  $p < 0.0001$ ). Only 52.37% of participants reported a good sleep quality during pregnancy. Participants with a poor or fair sleep quality had significantly higher depression prevalence than those with a good sleep quality. Moreover, most participants did not smoke or drink alcohol during gestation. Compared to those without smoking habits, the participants who smoked either actively or passively had higher depression prevalence (5.37 vs. 2.95%,  $p = 0.0013$ ). Participants who did not exercise during pregnancy had more prevalent depression than those who exercised regularly (44.81

vs. 37.26%,  $p < 0.0001$ ). The majority of participants (90.67%) reported good family functions, and those reporting poor or fair family functions had significantly higher depression prevalence.

**Table 3** and **Supplementary Table 3** show the dynamic changes of exposures and depression levels of participants. The depression prevalence in the participants was significantly different during several time intervals throughout the COVID-19 pandemic.

**Table 4** shows the results of the logistic regression model for the effects of the COVID-19 pandemic on perinatal depression. Compared to the 1st week (December 31, 2019–January 12, 2020) of the pandemic, the prenatal depression risk was significantly decreased during the 3 week period starting from March 2, 2020 (1st week: OR = 0.39, 95% CI: 0.20, 0.78; 2nd week: OR = 0.35, 95% CI: 0.17, 0.73; and 3rd week: OR = 0.48, 95% CI: 0.25, 0.94), whereas the postnatal depression risk significantly rose during the 4 weeks between January 27 and February 23, 2020 (1st week: OR = 1.78, 95% CI: 1.18, 2.68; 2nd week: OR = 2.03, 95% CI: 1.35, 3.04; 3rd week: OR = 1.48, 95% CI: 1.02, 2.14; and 4th week: OR = 1.73, 95% CI: 1.20, 2.48).

## DISCUSSION

In this study, the prevalence rate of perinatal depression was reported among the hospitalized pregnant women exposed to the COVID-19 pandemic in Wuhan. The prevalence of perinatal depression per week ranged from 23.85 to 42.98%. The overall prevalence of perinatal depression was higher in low- and middle-income countries (19–25%), than that in developed countries (7–15%) (26, 27). It should be noticed that a population-based participant enrolment method was adopted in other studies, whereas a hospital-based method was used in our study. Participants enrolled using the different methods possibly

differ in general characteristics, and hence differ in perinatal depression risk. Moreover, the participants had just experienced or were about to experience a delivery, which might cause an increased risk of perinatal depression for them.

The prevalence of prenatal depression was at a high level during the COVID-19 pandemic in Wuhan. Okagbue et al. performed a review study of 26 articles, observing that the prevalence of EPDS-evaluated prenatal depression was 23.8% in pregnant women in their third trimester (28). Huang et al. conducted a cross-sectional survey of 320 pregnant women in their second and third trimesters in Wuhan, reporting a depression prevalence of 29.06% (29). Another study reported that prenatal depression prevalence ranged from 22.10 to 31.94% in Shiyan City, Hubei Province (30, 31). The prenatal depression prevalence in this study was higher than Western China (14.2%) and lower than Eastern China (34.9–36.8%) (32–35).

These results are a warning that the COVID-19 pandemic may possibly bring negative mental impacts to pregnant women all over the world. Controlling for sociodemographic and health behavior variables, the risk of prenatal depression decreased during the period of March 2–22, 2020 compared with the counterpart value at the beginning of the pandemic (December 31, 2019–12 January 12, 2020). The obscure and confusing public information about the pandemic during January 6–12, 2020 may have contributed to the high prenatal depression prevalence in this period. The first report of COVID-19 was published on December 31, 2019; however, the official announcement of the human-to-human transmission of COVID-19 did not occur until January 20, 2020. With implementations of public health measures against the pandemic, including isolation, quarantine, social distancing, and community containment, etc., the daily reported number of new onsets continued to decline, which was smaller than 200 per day after March 1, 2020 (18). This achievement in the prevention and control of the pandemic may

be a reason for the decreased prenatal depression prevalence during that period. Flowers et al. studied the biopsychosocial effect of influenza pandemics, showing that pregnant women were vulnerable to a sense of pressure concerning influenza pandemics and death from influenza (36). As a negative and stressful life event, the COVID-19 pandemic probably increased mental depression. It was found that negative life events during pregnancy were associated with increased depression in the third trimester (37–39). The previous SARS outbreak which caused an international public health crisis, has been proven to have had adverse effects on people's mental health, especially in the severely affected areas (40, 41). Otherwise, the Wuhan city quarantine measure started on January 23, 2020 may also have increased postnatal psychological pressure.

This study is the first to reveal the prevalence of perinatal depression in individuals exposed to the COVID-19 pandemic. Some limitations of the study should be noted. First, as a cross-sectional study, it was not able to confirm a causal relationship between the COVID-19 pandemic and depression risks. Second, we enrolled generally healthy prenatal and postnatal women without SARS-CoV-2 infection in this study. And all participants were from a single maternity institution located in the seriously affected area (with respect to the number of COVID-19 cases). Prudence is needed to extend the research conclusions to those SARS-CoV-2 infected individuals and other areas. Third, the study was hospital-based, which possibly resulted in the limited representability of participants and hence limited the extensionality of our conclusions. Fourth, this study included only the inpatient participants recruited in perinatal periods. The mental health effects of exposures in the first and second trimesters still need to be studied in the COVID-19 pandemic.

During the COVID-19 pandemic, intervention measures against perinatal depression are crucial for the well-being of new mothers and babies. The dynamic change of perinatal depression was associated with COVID-19 pandemic progression among the maternal women studied. An elevated risk of postnatal depression was also observed during the COVID-19 pandemic.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethics Committee of Hubei Maternal and Child Health Care Hospital. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

## AUTHOR CONTRIBUTIONS

GS: design, data collection, and manuscript editing. QW: data collection, data interpretation, and literature search. YC: manuscript draft, design, data collection, and data analysis. YL, RL, LY, and XL: data collection, data interpretation, and manuscript review. MP, HW, and XY: data collection, manuscript review, and visualization. WR and HY: data collection, data validation, and manuscript revision. All of the authors gave final approval of the version to be submitted, and agree to be accountable for all aspects of the work.

## ACKNOWLEDGMENTS

We would like to express our gratitude to all the medical staff of the Department of Obstetrics for their responsible work during the COVID-19 pandemic to ensure the safety of maternal inpatients. We are also grateful to all the inpatients who participated in this study.

Case. *Front. Psychol.* 11:577763.  
doi: 10.3389/fpsyg.2020.577763

The COVID-19 pandemic has changed the lives of millions of people around the globe and some of the unprecedented emerged disruptions, are likely to have been particularly challenging for young children (e.g., school closures, social distancing measures, movement restrictions). Studying the impact of such extraordinary circumstances on their well-being is crucial to identify processes leading to risk and resilience. To better understand how Spanish children have adapted to the stressful disruptions resulting from the pandemic outbreak, we examined the effects of child coping and its interactions with contextual stressors (pandemic and family related) on child adjustment, incorporating in our analysis a developmental perspective. Data was collected in April 2020, through parent-reports, during the acute phase of the pandemic and, temporarily coinciding with the mandatory national quarantine period imposed by the Spanish Government. A sample of 1,123 Spanish children (50% girls) aged 3 to 12 (Mage = 7.26; SD = 2.39) participated in the study. Results showed differences in the use of specific strategies by children in different age groups (i.e., 3–6, 7–9 and 10–12-year-olds). Despite the uncontrollable nature of the pandemic-related stressors, child disengagement coping was distinctively associated to negative outcomes (i.e., higher levels of behavioral and emotional difficulties), whereas engagement coping predicted psychosocial adjustment across all age groups. Moreover, interactively with child coping, parent fear of the future and parent dispositional resilience appear as relevant contextual factors to predict both negative and positive outcomes, but their effects seem to be age dependent, suggesting a higher contextual vulnerability for younger children. These findings might have implications for identifying individual and contextual risk and informing potential preventive interventions aimed to reduce the impact of future pandemic outbreaks on children of different ages.

**Keywords:** children coping, pandemic, COVID-19-related stressors, adjustment, parent resilience

## INTRODUCTION

The global crisis originated by the recent COVID-19 pandemic is not comparable, neither in magnitude nor in kind, to any other similar experienced before (e.g., SARS- outbreak, Prime et al., 2020). It is unprecedented as, for the first time, we are exposed to a considerable number of unfamiliar stressors (e.g., social distancing, restriction of movement; Yan, 2020), acutely emerged,

but timely sustained by public preventive health measures imposed world-wide (i.e., mandatory home confinement). The psychological long-term effects of these measures remain, currently, largely unknown (Brooks et al., 2020; Green, 2020).

Children, too, have been exposed to these and other aged-related specific stressors (e.g., school closures and online homeschooling, *The Lancet Child Adolescent Health*, 2020). Only recently, some empirical evidence relative to the negative effects on children adjustment is beginning to be gathered from studies conducted, mainly, in affected developed countries. Altogether, these preliminary findings point out to an increased risk of experiencing negative consequences such as depressive and anxiety symptoms (Xie et al., 2020) and changes in emotional states and behaviors (e.g., difficulty concentrating, boredom, irritability, Orgilés et al., 2020). However, at this point, the literature on the impact of COVID-19 pandemic on children psychosocial well-being is still very scarce and the insights from previous pandemic experiences quite limited (Koller et al., 2010; Murray, 2010; Sprang and Silman, 2015).

At the same time, there is enough evidence from developmental, preventive and clinical literature suggesting that children's adjustment to these extraordinary social disruptions is likely to be multi-determined by individual and environmental factors, whose effects might contribute to short and long-term adaptation (Compas, 2006; Grant et al., 2006; Luthar, 2006; Cicchetti, 2010; Blair and Raver, 2012).

First, the ability to effectively cope with the stressful situation, that is to "mobilize, modulate, manage, and coordinate the own behavior, emotions and attention under stress" (p. 6, Skinner and Zimmer-Gembeck, 2009), has been consistently associated to child adjustment in diverse difficult circumstances and at different ages (Smith et al., 2006; Cicchetti and Rogosch, 2009; Zimmer-Gembeck and Skinner, 2011a; Terranova et al., 2015). In children coping research, at a broader level, engagement and disengagement coping (i.e., oriented toward or away the source of stress and/or one's emotions and thoughts) are distinctively associated to different outcomes (Compas et al., 2001). However, these associations seem to be dependent on the controllable or uncontrollable nature of the stressful events (Altschuler and Ruble, 1989; Compas et al., 1991; Clarke, 2006; Wadsworth, 2015). For instance, under controllable stressful conditions, engagement coping is predictive of lower levels of internalizing and externalizing symptoms, whereas disengagement coping, on the contrary, contributes to higher levels of these difficulties (Connor-Smith et al., 2000). However, an avoidant-distractive coping was linked to less negative emotions and short-term maladjustment when children must deal, respectively, with uncontrollable medical stressors (Band and Weisz, 1988) and family marital conflict (O'Brien et al., 1995). Interestingly, there is also evidence suggesting that emotional disengagement (i.e., attempting to eliminate subjective feelings and outward signs of emotion) is a useful short-term strategy for regulating negative emotion (Rice et al., 2007). Applying an engaged-oriented coping to uncontrollable conditions, could increase psychological distress due to the inefficacy of these strategies to modify the objective stressful conditions or maximize one goodness of fit with them as they are (Yeo et al., 2014). Hence, these findings are,

because of the very nature of the current widespread pandemic, of much relevance.

In addition, distal and proximal contextual influences can independently affect child adjustment but also moderate the coping-outcomes relationship (Compas, 2009; Main et al., 2011). Globally, despite individual differences at micro-level contexts, children and their families were exposed, world-wide, to mild-moderate levels of stress resulting from potentially experiencing multiple and unique COVID-19-related stressors. Beyond the domain of individual physical health and psychological well-being (e.g., COVID-19 contagion, Guo et al., 2020), the economic capacity and financial security (e.g., job loss, Baker et al., 2020) and family dynamics (e.g., parent-child relation, Cluver et al., 2020; Prime et al., 2020) were also unexpectedly and profoundly altered. Thus, the way in which parents respond to these disruptive experiences is also essential to define the impact of COVID-19 crisis on children, as for it directly influences not only the youngsters' response to normative stressors (Kliewer et al., 1996) but also to extremely challenging conditions (e.g., natural disasters, war; Bradley, 2007). Modeling processes are one of the core mechanisms through which parents contribute to children's response to stress (Power, 2004). In fact, a positive model of coping, along with the exposure to mild-moderate stress levels and an age-appropriate scaffolding are necessary conditions for the children to develop a healthy repertoire of coping skills (Wadsworth, 2015). Thus, it is likely to be the case that a relatively stable and consistent parental disposition to resist adverse circumstances (i.e., trait resilience, Almedom and Glandon, 2007; Connor and Davidson, 2003) would affect the children capacity to cope under adverse conditions. Moreover, besides these vicarious influences, the use of ineffective coping strategies could also directly undermine parent individual well-being and consequently affect child well-being, by damaging the parent-child relation during the COVID-19 pandemic (Prime et al., 2020). For these reasons, the current scenario offers a unique opportunity to study these interactive coping-context relations and the moderator effect of distal and immediate contextual factors on coping-outcomes relation.

Finally, along with these environmental transactions, children's ability to successfully cope with adverse and stressful conditions is primarily shaped and constrained by their cognitive and emotional development (Skinner and Zimmer-Gembeck, 2009). Child developmentally determined skills and capacities account not only for the differences in the type of coping strategies displayed by children in different age groups but also for the age-dependent normative shifts occurring at certain points (Skinner and Zimmer-Gembeck, 2016a). In fact, their progressive acquisition explains the quantitative and qualitative normative changes in the development of coping occurring during critical transitions (e.g., in infancy to toddlerhood, between ages 5–7 or in late childhood to early adolescence, Skinner and Zimmer-Gembeck, 2007). However, despite the wide recognition of this need to adopt a developmental perspective in the study of children coping, and the evidence supporting the feasibility of its empirical examination even at very early ages (i.e., preschool years, Yeo et al., 2014), these developmental considerations have been rarely incorporated

**TABLE 1 |** Descriptive statistics of the CONFIA-20 study sample: COVID-19-related stressors, demographics variables of participating parents, children and family relevant domains.

	Total (N = 1123)	Range
Person filling the questionnaire: Mother, N (%)	1004 (89.5%)	
<b>COVID-19 crisis related stressors</b>		
Number of days of confinement, M (SD)	30.57 (6.47)	0–60
Number of people during confinement, M (SD)	3.89 (1.01)	1–10
House dimensions in square meters, M (SD)	126.68 (93.98)	35–1600
House with garden: Yes, N (%)	567 (50.7)	0–1
COVID-19 contagion in close circle (family, friends), N (%)	187 (16.7)	0–1
COVID-19 related death in close circle (family, friends), N (%)	59 (5.3)	0–1
Perceived economic impact on the family, M (SD)	1.36 (1.00)	0–3
Negative influence of confinement on family relations, M (SD)	0.80 (0.78)	0–3
<b>Families</b>		
Geographic area of residency: Galicia, N (%)	899 (94.2)	–

Depression, M (SD)*	2.39 (0.73)	0–4

Items from the PHQ (Kroenke et al., 2009) were rated on a 5 point comparative scale from 0 ("much less") to 4 ("much more") aiming to represent the change self-perceived in the emotional state as a result of the COVID-19 crisis.

into the empirical research (Compas et al., 2001; Skinner and Zimmer-Gembeck, 2007, 2009).

The main goal of this study is to examine how child coping, unique contextual conditions and parent dispositional resilience, might contribute to the children psychosocial adjustment during the extraordinary context of COVID-19 pandemic, incorporating in our analysis a developmental perspective. Specifically, we aimed (1) to explore the use of specific strategies and broad dimensions of coping by children of different age-groups (2) to determine the positive and negative outcomes of child engagement and disengagement coping under uncontrollable circumstances, (3) to examine to which extent the relation between coping and outcomes is moderated by situational stressors specifically related to the current crisis, (4) to analyze if contextual factors within the family system (i.e., parental resilience) also moderate the coping-outcomes relation and finally (5) to test if these effects are age-dependent. We hypothesized, based on the literature reviewed, that the main coping strategies and dimensions used by children would differ between age groups. Also, the associations of engagement and disengagement coping with child adjustment might be different to the often observed under controllable stressful situations, but distal and proximal contextual factors would moderate the coping-outcomes relation anyhow. Finally, these moderation effects could be age dependent.

## MATERIALS AND METHODS

### Participants

Data for the current research is from the CONFIA-20 Study (*Confinement Effects on Families and Children*), which was aimed to examine the psychological, emotional and behavioral effects of home-confinement in children and families from the region of Galicia, NW Spain. It was conducted in April 2020, during the acute phase of COVID-19 pandemic, temporarily coinciding with the mandatory national quarantine period imposed to the whole population by the Spanish Government from March 13th to April 26th of 2020. Children and families considered to participate in this study had to live in Spain. Despite Galicia being the primary geographical area of interest, families from other Spanish regions were allowed to participate. Families from other countries and/or continents were excluded. Also, parents had to fill the questionnaire strictly within the temporal limits of the national quarantine period, that is, never after April 27th of 2020. Finally, the “target-child” to whom the questionnaire was referred to, could not be younger than three or older than twelve years old. The sample of 1,123 children (50% girls) aged 3–12 ( $M_{age} = 7.26$ ;  $SD = 2.39$ ) was composed by 481 preschoolers (aged 3–6;  $M_{age} = 4.95$ ;  $SD = 0.93$ ; 50.6% girls), 393 middle-aged children (aged 7–9;  $M_{age} = 7.98$ ;  $SD = 0.83$ ; 51.3% girls) and 248 early adolescents (aged 10–12;  $M_{age} = 10.62$ ;  $SD = 0.67$ ; 48.8% girls), when divided by meaningful age subgroups. Data collected was parent-reported (89.5% mothers) and most of the participating families were from Galicia (94.2%) with the remaining 5.8% from other Spanish regions (e.g., Madrid, Ciudad Real, Barcelona, Cantabria, Zamora). Most of the parents were working before

the crisis (86.9%) and, at the time of data collection, almost a half of them (46.9%) declared no difficulties making ends meet. Among those previously employed, they globally maintained their jobs (17.9% kept attending, 33.9% kept working from home, 19.1% were on temporary stoppages, 8.6% were on a medical leave), whereas 2.4% of them lost their employment due to the COVID-19 crisis. At the time of data collection, families had been 30.87 ( $SD = 6.37$ ) days confined, at homes of around 126.68 square meters (ranging from 35 to 1,600; 50.7% of them with garden), with about four people per home ( $M = 3.90$ ,  $SD = 1.01$ ). Finally, 16.7% of the participating parents reported the existence of COVID-19 contagion cases in their close social circle (i.e., family and friends) and 5.3% of them informed of close COVID-19 related deaths (for a detailed characterization of the sample see **Table 1**).

### Procedure

This study was conducted within the context of a large ongoing research, focused on studying child behavioral, emotional and social early development, and was approved by the Bioethics Committee of the University of Santiago de Compostela. We first developed a parent-reported questionnaire to be filled on an online secure platform. Then, we initiated a dissemination strategy by providing information of the study objectives and access to the survey link through (1) the official research group web page, (2) social media (3) telematic contacts with schools and parents associations and (4) informal diffusion actions. Data collection began at April 8th and ended at April 27th of 2020. Participation was anonymous and voluntary. Before filling the survey, parents gave their consent by explicitly agreeing to participate in the study. They were asked to refer their answers strictly to the COVID-19 situation crisis. The duration of the survey was around 15 min and participating families did not receive any reward or compensation.

### Measures and Instruments

**Child Coping.** We assessed context-specific coping on a parent-reported 22-item scale specifically developed for the CONFIA-20 study. After reviewing the available literature (Blount et al., 2008; Pfefferbaum et al., 2012), we selected, translated and adapted items from well-known children coping measures to be appropriate and relevant in content for the COVID-19 pandemic situation. We included items from the KidCOPE (13 items, Spirito et al., 1988) and The Children’s Coping Strategies Checklist (6 items, Ayers et al., 1996), plus 3 more *ad hoc* created items. Then, we grouped them into two broad categories (engagement and disengagement coping) on a conceptual basis, following the model of Connor-Smith et al. (2000). The resulting final scale was composed by two 11-item subscales assessing strategies such as “tries to calm him/herself” or “spontaneously proposes possible solutions to current crisis” (engagement coping) and “avoids thinking of the current situation” or “remains without doing anything because thinks that the current crisis cannot be solved” (disengagement coping). Parents rated the items on a 4-point Likert scale ranging from 0 (“never”) to 3 (“always or almost always”). The internal consistency of the engagement and disengagement scales was acceptable ( $\alpha = 0.77$

and  $\alpha = 0.66$ , respectively). For further information about the specific items selected, see **Supplementary Table 1**.

**Child Maladjustment during the COVID-19 Pandemic.** We selected three subscales of the Strengths and Difficulties Questionnaire (SDQ, Goodman, 1997) to assess the negative consequences of COVID-19 crisis in child behavioral and emotional functioning. Specifically, conduct problems, hyperactive behaviors and emotional problems subscales. Examples of items selected are, respectively, “often has temper tantrums or hot tempers,” “is constantly fidgeting or squirming” or “is often unhappy, down-hearted or tearful.” The original 4-point scale response was adapted to a 5-point comparative format (0: much less, 1: some less, 2: no change, 3 some more, 4: much more), aiming to reflect the possible observed changes on child behavior compared to the pre-COVID-19 pandemic functioning. The internal consistency of the scales was acceptable ( $\alpha = 0.81$ ,  $\alpha = 0.61$  and  $\alpha = 0.77$ , respectively).

**Child Adjustment during the COVID-19 Pandemic.** We assessed the potential positive outcomes resulting from the pandemic crisis on a parent-reported 14-item scale specifically developed *ad hoc* for the CONFIA-20 study (see Romero et al., 2020 for further information about the scale). The four scales are routine maintenance (4 items; e.g., “he/she has adapted him/herself to a scheduled daily activity routine;  $\alpha = 0.55$ ), prosocial involvement (5 items; e.g., “shows interest to spare time with family”;  $\alpha = 0.70$ ), social-oriented reflection (3 items; e.g., “he/she assumes that we all should collaborate to slow down the pandemic”;  $\alpha = 0.84$ ), and social bonding (2 items; e.g., “keeps contact with his/her beloved ones who are not close, by phone, internet...”;  $\alpha = 0.48$ ). Parents rated each item on the same 5-point comparative scale used to assess negative outcomes.

**COVID-19 related Stressors.** *Ad hoc* items were created to assess CONFIA-20 participant parents’ experiences with COVID-19 related stressors. For the purposes of the current research, we have exclusively focused on health, financial and future-threatening acute stressors. They were assessed through single parent-reported items such as “I think that the COVID-19 crisis has damaged the economic situation of my family” or “the current crisis makes me fear the future” rated on a 4-point scale from 0 (“not at all”) to 3 (“very much”). Also, Yes/No independent questions asking for the existence of any COVID-19 related contagion and/or death on the social close circle were included. In case of an affirmative answer, parents were asked to detail the number of close contagions and/or deaths.

**Parent Resilience.** We used the 10-item version of the Connor-Davidson Resilience Scale (CD-RISC-10, Connor and Davidson, 2003; Campbell-Sills and Stein, 2007) to measure parental dispositional resilience. Items such as “I am able to adapt when changes occur,” “having to cope with stress can make me stronger” or “I try to see their humorous side when I am faced with problems” were rated by parents on a 4-point Likert scale ranging from 0 (“not at all”) to 4 (“true nearly all the time”). The CD-RISC-10 has been used in various samples (Wang et al., 2010; Notario-Pacheco et al., 2011) and in different cultures (Lauridsen et al., 2017) showing high reliability across studies. The internal consistency of the scale in our sample was excellent ( $\alpha = 0.90$ ).

**Covariates.** We included an assessment of family socioeconomic status (SES), which was derived from questions about (1) parent education, (2) family income, and (3) family financial solvency to face daily overheads. Education level was computed as the mean of mother and father ratings on a six-point scale ranging from 1 (“without basic studies”) to 6 (“postgraduate”). Family income was based on parents’ reports of family income rated on a four-point scale from 1 (“serious problems making ends meet”) to 4 (“well off”). A composite SES was computed by first transforming the aforementioned variables into z-scores. Finally, we included child gender (0 = male, 1 = female) and age in years as covariates.

## Analytic Strategy

We first computed the descriptive statistics of the CONFIA-20 study sample, including the means, standard deviations and frequencies of COVID-19-related stressors, demographic variables of parents and children, and family relevant domains. We then ran an analysis of variance to compare the mean differences in broad dimensions of coping (engagement and disengagement) and fine-grained coping strategies by age groups (i.e., preschoolers, aged 3–6, children aged 7–9 and early adolescents, aged 10–12). Before the regression analyses, we explored the bivariate correlations between the study variables. All the above-mentioned analyses were conducted on SPSS Statistics version 26 (IBM Corp, 2019). Finally, on Mplus vs. 8.0 (Muthén and Muthén, 2019) we conducted multiple linear regression analysis to model the main effects of child coping on adjustment, controlling for other relevant variables such as sociodemographic covariates (i.e., sex, age, SES), COVID-19 related stressors (i.e., close contagion, close death, economic impact, fear of the future) and parental resilience. In the subsequent regression models, we included the interaction terms of the context-specific coping, with the contextual factors, to examine their potential moderating effects on the coping-outcomes relation. As it was hypothesized that these main and interactive associations could be age-dependent, complementary regression analysis, were conducted separately by age group subsamples.

## RESULTS

### Age Differences in Coping

Overall, the context-specific coping of the CONFIA-20 children during the COVID-19 crisis was more engagement than disengagement-oriented (**Table 2**). In fact, a significant increase in the use of engagement strategies was found at the end of the preschool period. When analyzing the specific strategies used by the different age group subsamples (i.e., 3–6-year-olds, 7–9-year-olds and 10–12-year-olds) significant differences were found. Compared to older children, preschoolers tended to use more predominantly strategies such as “yelling or getting angry” (negative emotion regulation). Seven to nine year olds, however, seemed to start to display more engaged-oriented strategies such as “trying to do specific actions to solve the current crisis” (problem solving), “trying to understand how things like this

**TABLE 2 |** Total sample means and mean differences in broad dimensions of coping and specific coping strategies between children of different age groups.

ENG, Engagement coping subscale; DIS, Disengagement coping subscale. Age group 1 (3–6-year-olds), *N* = 481; Age group 2 (7–9-year-olds), *N* = 393; Age group 2 (10–12-year-olds), *N* = 248. Post-hoc comparisons (Bonferroni's): only the groups between which the differences are significant are indicated.

happens”(seeking understanding) or “seeking help to try to improve the situation” (instrumental social support). Finally, early adolescents repertoire of behavioral and cognitive coping skills becomes not only more diverse [e.g., “ making jokes or trying to laugh about the current situation” (humor) and “wishing it never had happened” (wishful thinking)] but also sustained in more complex regulatory capacities (e.g., “trying to calm him/herself,” positive emotion regulation).

### Correlations Between the Study Variables

In the full sample, child’s age was positively related to favorable outcomes (e.g., reflection and social bonding) and negatively related to conduct problems and hyperactive behaviors (Table 3). An older age was also positively related to engagement coping.

Engagement and disengagement coping were positively and modestly correlated and, as expected, indicators of adjustment and maladjustment were negatively correlated to each other.

High significant positive correlations among indicators of maladjustment (i.e., conduct problems, hyperactive behaviors and emotional problems) were found, along with moderate positive correlations with child disengagement coping. Similarly, significant positive correlations between indicators of adjustment (i.e., routine maintenance, prosocial involvement, social-oriented reflection, social bonding), with slightly lower magnitudes, were found, along with moderate positive correlations with child engagement coping.

Some of the COVID-19-related stressors (i.e., close death, economic impact, and particularly fear of the future) were positively correlated with disengagement coping. On the

contrary, dispositional resilience, was negatively correlated with child disengagement and positively correlated with child engagement coping.

Finally, a higher family socioeconomic status was negatively correlated with COVID-19 perceived economic impact, self-reported parent fear of the future and child disengagement coping. Perceived high economic impact was positively and moderately correlated to self-reported parent fear of the future.

### Which Are the Associations Between Broad Dimensions of Child Coping and Behavioral, Emotional and Social Outcomes During the COVID-19 Pandemic?

Child disengagement coping was distinctively and similarly associated to negative outcomes, including both externalizing - conduct problems and hyperactive behaviors - and internalizing problems- emotional difficulties (Table 4). However, the effects of engagement and disengagement coping, yet opposites in direction, were similar in magnitude for conduct problems. Child engagement coping was distinctively and extensively associated to indicators of adjustment, and, particularly to social-oriented reflection. These associations were significant even when controlling for other covariates whose contribution is assumed to be relevant in the prediction of the variables of interest (i.e., sex, age, family SES, contextual stressors related to COVID-19 crisis and parental resilience).

Additionally, as regards of the main effects of the contextual factors, the existence of a close contagion and a higher parent-perceived economic impact of the COVID-19 crisis on

\* $p < 0.05$ , \*\* $p < 0.01$ , \*\*\* $p < 0.001$ . These results are derived from the total sample. They were replicated by age group subsamples in complementary analysis (3–6-year-olds, 7–9-year-olds and 10–12-year-olds). We modeled pathways from all covariates (age, sex, and SES) to all other predictors in the regression models. Main predictors were mean centered before entered into the equation.

family, were positively and significantly associated to higher levels of externalizing behaviors such as conduct problems and hyperactive behaviors. On the contrary, higher levels of parent self-reported fear of the future were positively and significantly associated to adaptative outcomes such as higher levels of social-oriented reflection and prosocial involvement. Similarly, parental resilience was positively related to positive outcomes across all the models exploring adjustment, particularly to children's routine maintenance and prosocial involvement with others during the COVID-19 crisis.

### Which Are the Contextual Characteristics Interacting With Child Coping to Predict Outcomes During the COVID-19 Pandemic?

On the basis of the results previously obtained, after having modeled the main effects of child coping on different indicators of adjustment, we created interaction terms between child disengagement coping and contextual factors to specifically predict negative outcomes, and engagement coping and contextual factors to specifically predict positive outcomes (see **Supplementary Table 2**).

When interaction terms were introduced in the regression models, most of the situational stressors analyzed did not interact with children coping to predict either maladjustment or adjustment. Only parent perceived fear of the future interacted with child disengagement and engagement coping tendencies to predict negative and positive consequences, respectively. For instance, higher levels of parent perceived fear of the future predicted higher levels of child behavioral ( $\beta = 0.13, p < 0.04$ , **Figure 1**) and emotional problems ( $\beta = 0.14, p < 0.03$ ) when children displayed disengagement coping. On the contrary, higher levels of parent perceived fear of the future predicted higher levels of child social-oriented reflection ( $\beta = 0.17, p < 0.03$ ) when the children coping style was engaged-oriented (**Figure 2**).

**FIGURE 1 |** Interactive effect of parent self-reported fear of the future with child disengagement coping to predict child maladjustment concurrent to the COVID-19 pandemic: conduct problems.

## Does Parental Dispositional Resilience Interact With Child Broad Dimensions of Coping to Predict Outcomes During the COVID-19 Pandemic?

Similar to what was done for other contextual factors and based on the results previously obtained, we created interaction terms between child disengagement and engagement coping with parental resilience to specifically, and respectively, predict negative and positive outcomes (see **Supplementary Table 3**).

There was an interactive effect of parental dispositional resilience with child situational coping for the prediction of both negative and positive outcomes resulting from the COVID-19 crisis. Specifically, lower levels of parent resilience interact with high levels of child disengagement coping to produce higher levels of emotional problems ( $\beta = -0.07, p < 0.02$ , **Figure 3**). Conversely, higher levels of parent resilience enhance the child prosocial attitude toward others during the COVID-19

crisis when they tend to use approach-oriented coping strategies ( $\beta = 0.10, p < 0.001$ , **Figure 4**).

## Are the Main and Interactive Effects Found Age-Dependent?

To test if the main and interactive effects of interest varied in function of age, we run the same previous models by age group subsamples in complementary analysis, addressing the preschool period, middle childhood and early adolescence (see **Supplementary Tables 4, 5**). Overall, the findings pertaining the main effects of coping remained unaltered, but some age-determined differences emerged when analyzing the contextual interactions by age-group.

First, for all three age groups, disengagement coping strategies predicted higher levels of conduct problems, hyperactive behaviors and emotional problems (**Supplementary Table 4**). On the contrary, for all the three age groups, engagement coping was associated to a better behavioral and psychosocial adjustment (routine maintenance, prosocial involvement, social-oriented reflection and social bonding (**Supplementary Table 5**).

However, the moderator effects of contextual stressors on the child coping-outcomes relation were slightly different in function of the age group considered to predict both negative and positive outcomes. Only preschoolers, but not older children (i.e., above 7 years of age) were particularly vulnerable to experience behavioral ( $\beta = 0.21, p < 0.02$ ) and emotional difficulties ( $\beta = 0.22, p < 0.01$ ) when displaying a disengagement coping style in the context of a higher parent self-reported fear of the future. At the same time higher parent self-reported fear of the future also positively influenced the routine maintenance ( $\beta = 0.23, p < 0.02$ ) of young engaged-oriented children but not their older counterparts (i.e., above 9-year-olds). For 7–9-year-old children, however, the existence of a COVID-19 contagion in the close social circle was the stressor whose interaction with a disengagement coping was significantly associated to a poorer emotional functioning ( $\beta = 0.11, p < 0.05$ ). Finally, for early adolescents (i.e., 10–12-year-olds) none of the situational

stressors analyzed interacted with disengagement or engagement tendencies to produce particular outcomes.

Similarly, the moderator effects of the parental dispositional resilience on the child coping-outcomes relation were slightly different by age group subsamples, fundamentally when predicting negative outcomes. Only preschoolers seemed particularly vulnerable to the effect of low levels of parent resilience. Specifically, lower levels of parent self-reported resilience interacted with high levels of disengagement coping to produce higher levels of conduct problems ( $\beta = -0.08$ ,  $p < 0.02$ ), hyperactive behaviors ( $\beta = -0.09$ ,  $p < 0.007$ ) and emotional problems ( $\beta = -0.12$ ,  $p < 0.001$ ) in children aged 3–6. Interestingly, for 7–9-year-old children, lower levels of parent-self reported resilience interact with high levels of child engagement coping to predict higher levels of child social-oriented reflection ( $\beta = -0.13$ ,  $p < 0.006$ ).

## DISCUSSION

Our main goal was to examine how child coping, unique contextual conditions and parent resilience, might contribute to children's psychosocial adjustment during the COVID-19 pandemic, incorporating in our analysis a developmental perspective. Consistent with our hypothesis, the psychological impact of the pandemic on children well-being, might be variable, depending on individual and situational characteristics, which would serve, independently and through person by context interactions, as risk or protective factors for children adjustment to these circumstances.

We first studied the main effects of child context-specific coping on psychosocial well-being. Interestingly, our findings show that, disengagement coping is associated to negative outcomes, whereas engagement coping would be predictive of concurrent child psychosocial adjustment during the pandemic. Contrary to what would be expected due to the uncontrollable nature of the stressful situation, child disengagement coping distinctively accounted for negative outcomes, both externalizing and internalizing, and this pattern of findings was replicated in all of three age levels in complementary age-group analysis, suggesting that this association might emerge early in preschool years and remain significant across early development. Thus, our results are in line with other findings from preschool samples examining normative uncontrollable developmental stressors (e.g., night fears, Chalmers et al., 2011), but clearly diverge from the main line of findings pertaining youth populations, testing the effects of other normative uncontrollable stressors (e.g., medical procedures, parental conflict, Band and Weisz, 1988; Altshuler and Ruble, 1989; O'Brien et al., 1995). In adult literature, however, there is evidence suggesting that avoidant coping in the context of a pandemic (e.g., SARS) is predictive of higher levels of psychological symptoms (Main et al., 2011). Unsurprisingly, certain tendency of younger children to rely more prominently on disengagement coping strategies during the current pandemic would be expected. Similarly, the use of these type of strategies by children whose emerging metacognitive capacities allow them to distinguish between controllable and uncontrollable situations

(i.e., children about 7 years old, Altshuler and Ruble, 1989). However, to explain their negative effect on child well-being it might be essential to recall some of their specific functions. Just as some of the disengagement tactics could mitigate the short-term impact of the uncontrollable COVID-19-related stressors (e.g., cognitive and behavioral distraction allowing the redirection of attention from the stressor to an alternative target) others (e.g., partial or complete avoidance), might prevent children from detecting, appraising and dealing with the current crisis in more potential adaptive ways (e.g., reminding him/herself that his/her situation is not that bad), exacerbating the behavioral and emotional negative consequences of the stressors (Compas et al., 2001; Skinner and Zimmer-Gembeck, 2016c).

As expected, we found a moderator effect of contextual factors on the relation between child coping and adjustment. However, remarkably, this effect was only significant for parent self-reported fear of the future and not any of the other contextual factors examined (i.e., close COVID-19 contagion and/or death, and perceived economic impact of the health crisis). This finding is subjected to different, yet complementary, interpretations. First, rather than solely by the experiencing of "objective stressors" in their close social circle, children's coping and adjustment processes seem to be more dependent on "subjective-like factors" exerting their influence from the proximity of their *immediate* socialization circle, in a developmental period in which, contrarily to others (e.g., adolescence) parental influences on child coping responses are more prominent (Kliewer et al., 1996; Skinner and Zimmer-Gembeck, 2016b). Second, the moderator effect of these stressors could be only properly examined if the potential confounding effect of children's knowledge about the circumstances (e.g., does she/he know about the close contagion?) was controlled in our study. It might be the case that these pandemic-related stressors do not have a significant effect on child engagement and disengagement coping strategies to produce specific outcomes, simply due to the absence of children's explicit knowledge about them. In any case, our findings suggest that high levels of parental fear of the future do have a moderator effect on child coping-outcomes relation. In fact, this effect might be described as paradoxical, as higher levels of parental fear of the future could serve as both a risk or protective factor for child psychosocial well-being, depending on which type of child coping they interact with (disengagement and engagement, respectively). This might be partially explained by the sense of threat and the uncertainty that COVID-19 pandemic has caused (Peters et al., 2017). Despite we have adaptive mechanisms that allow us to successfully navigate the inherent uncertainties of life (e.g., the reliance on past experiences when trying to anticipate future events, Grupe and Nitschke, 2013), they are very likely to be insufficient and their beneficial effects limited, when we must function under highly stressful situations such as the current COVID-19 pandemic (Wang et al., 2020). In these conditions, we are forcedly and abruptly confronted with high levels of uncertainty about a seemingly uncontrollable and unpredictable imminent future (Pfefferbaum and North, 2020). Because of this uncertainty, even as diffuse or tangible as the threat might be (Baker et al., 2020), our anxiety levels could increase because our perceived

capacity of anticipation is diminished (Grupe and Nitschke, 2013). Thus, in this scenario, parent fear of the future would act as an amplifier of the child disengagement coping negative effect on child emotional and behavioral adjustment. Yet, at the same time, and interactively with child engagement coping, it could exert a protective effect, by functioning as a trigger to initiate compensatory processes aimed to restore a certain sense of predictability and controllability, through simple actions directed to maintain daily routines during the pandemic home-confinement. Essentially, these findings are explicitly confirming not only the importance of contextual risk (Main et al., 2011), but also the important role of the individual differences in coping. Ultimately, the consequences of high levels of the same contextual stressor (i.e., fear of the future) depend on the type of coping on which they operate.

Similarly, and supporting our hypothesis, parental resilience also exerts a moderator effect on child coping-outcomes relation. In fact, our findings suggest that both risk and resilience to maladjustment can result from these interactive processes. The parental personality trait of resistance to adversity (i.e., resilience, Bensimon, 2012) interacts with child engagement and disengagement coping to produce positive or negative outcomes. First, low levels of parent resilience could serve as a risk factor for emotional difficulties at high, but not low levels of child disengagement coping. Therefore, consistent with classical hypothesis, our results suggest that this differential effect of parental resilience seems uniquely determinant in the presence of high, but not low levels of risk (Stattin et al., 1997). Second, a similar, yet less strong effect, is found when parental resilience operates along with child engagement tendencies, as its positive effect is clearly strong for higher levels of child engagement coping compared to lower levels. Interestingly, high levels of engagement and resilience coming together or, conversely, high levels of disengagement and low of resilience combined, might be the reflection of the underneath similarities between child and parent coping resulting from socialization processes (Kliwer et al., 1996) which remain on course during the pandemic. Thus, a parental dispositional adaptive coping would be essential to explain not only the concurrent level of child adjustment to the COVID-19 crisis, but also to understand how children cope the way they do under these conditions (Abaied et al., 2010; Cappa et al., 2011; Skinner and Zimmer-Gembeck, 2016b). In fact, despite being an atypical and non-normative scenario, the pandemic is still an opportunity for parents and children to advance in the coping socialization tasks.

Altogether, these findings reinforce, on the basis of a systemic theory, the interdependence principle, as the functioning of one family member impacts the others and vice versa (Carr, 2015). Moreover, systems theory could serve as a useful framework to integrate these findings, by signaling concrete channels (e.g., parent resilience) through which broader contextual risk (e.g., economic pressure on especially vulnerable families) negatively affect individual family members (e.g., child adjustment, Prime et al., 2020).

Finally, as hypothesized, interesting age-group differences emerged in our complementary analysis. As coping is both

a reflection and a contribution to development (Zimmer-Gembeck and Skinner, 2011b), children age influences not only the distinctive strategies they use, but also the vulnerabilities that might lead them to short-term negative outcomes within the context of the pandemic. Undoubtedly, COVID-19 crisis has immersed children into an environment of unprecedented challenging demands, likely to be particularly overwhelming for younger ones (Fegert et al., 2020; Green, 2020). Hence, as our findings show, the higher vulnerability of preschoolers to distal and proximal contextual risk is not surprising. For instance, consistent with the idea that the parent-child interpersonal coping systems are initially coregulated, it is reasonable that young children depend on external sources (e.g., parent trait resilience) for regulation (Skinner and Zimmer-Gembeck, 2007). Conversely, as our findings suggest, older children' permeability to the influence of COVID-19 related stressors could be lower in favor of a prominent role of their individual resources (i.e., coping skills), as a consequence of their behavioral and cognitive coping skills becoming more diverse and complex in nature as they grow.

Considering the current predictions about likely recurrent future COVID-19 breakouts and the lack of any previous similar experiences in our recent history, our findings might provide some insights to guide, at a practical level, the identification of individual and contextual risk, informing tailored preventive interventions aimed to reduce the psychosocial impact of future pandemic recurrences on children of different ages. Certainly, coping-based interventions are inherently a difficult endeavor (Coyne and Racioppo, 2000) and children coping-based interventions might be subjected to additional challenges (Frydenberg et al., 2017). However, there is room for hope. Universal stress management programs have shown positive outcomes for children (e.g., reduced levels of stress and anxiety, Kraag et al., 2009) and schools seem to be feasible settings for their application (Pincus and Friedman, 2004). Moreover, besides children, the beneficial effects of these programs are extensible to their parents (Frydenberg et al., 2014). Consequently, any intent to meaningfully adapt and transfer some of these effective preventive intervention's components to the highly specific context of the COVID-19 pandemic, would be an interesting contribution to the field of children coping research and more importantly, a mighty useful service to children and families during the COVID-19 times.

## Strengths and Limitations

To our knowledge, this is one of the first studies to date, to analyze the coping-outcomes relation within the context of the COVID-19 pandemic. Despite examining the changes derived from the crisis on a large community sample of Spanish home-confined children during the acute phase of the pandemic, using a wide range of adjustment measures, and incorporating a developmentally friendly approach, this research has important methodological limitations.

First, the measures for the coping construct may be limited. As a result of prioritizing a shorten length for the coping measure due to time-cost reasons, the number of items selected might fail to capture the wide variety of strategies used by children of these ages. Also, despite following a theory driven strategy in the

*ad hoc* development of the questionnaire and considering the adequacy of the items to the current crisis for their selection, this procedure has clear limitations. For instance, the content of some items is likely to be age un-appropriated or too abstract to be applicable to young children. For this reasons, empirical difficulties to reach acceptable fit indices in factor/confirmatory analysis and, also, scale-reliability analysis would be expected. Second, some of the subscales used to operationalize child adjustment during the pandemic showed unacceptable levels of internal consistency (e.g., routine maintenance,  $\alpha = 0.55$ ; social bonding,  $\alpha = 0.48$ ). This could be partially explained, in the latter case, by the small number of items composing the scale (i.e., 2 items). Third, data collection relied exclusively on parent reports of observable and non-observable child behavior. Besides the threat of single informant biases, without a multi-informant approach, we lack valuable self-report information, particularly interesting in the case of older children (e.g., early adolescents). Fourth, cross-sectional analyses are only informative of short-term effects, offering a limited view on the true scope and magnitude of the pandemic impact on children. To test if these effects are sustained over time, longitudinal analysis to compare them during versus after quarantine would be needed. Additionally, without a prospective design it is not possible to make causal inferences on coping-outcomes relation or explore possible reciprocal effects. Fifth, relevant pre-COVID-19 child and family predictors accounting for child functioning during the current crisis were not included in our analysis (e.g., serious family economic hardships). Sixth, the cumulative effects of concurrent additional stressors to the COVID-19 crisis were not modeled (e.g., chronic child health condition or domestic violence). Finally, we did not control the presumably important effect of the moment, that is, the specific date, when the data was collected (i.e., at the beginning or the end of the home confinement period).

With more sophisticated and rigorous designs, combining multi-informant and multi-method assessments with a longitudinal approach, future research should necessary address the specific emotional, behavioral and cognitive mechanisms through which children coping during extreme circumstances such the COVID-19 pandemic, exerts its influence to produce specific outcomes. Specifically, a longitudinal follow-up of our study sample, would provide a better picture of how children cope with the long-standing pandemic-related stressors beyond the acute phase examined for this work, providing valuable insights on the mechanisms involved in potential maladaptive courses observed in children with particularly higher levels of vulnerability due to cumulative risk.

## Conclusions

Our findings contribute to better understand how children adapt (or fail to) during the COVID-19 pandemic by highlighting the explanatory value of child context-specific coping, pandemic and family contextual factors and child development level over observed adjustment. Overall, they suggest the need of

combining both child and family components in tailored-preventive interventions aimed to reduce the psychological impact of future pandemic outbreaks, as how children and their parents cope plays a crucial role for their adjustment. Also, they confirm the need to adopt a developmentally sensitive perspective in which aged-graded specifications are considered.

## DATA AVAILABILITY STATEMENT

The datasets presented in this article are not readily available in a public repository. However, they are expected to be publicly available soon. Until then, they will be available upon request to the corresponding author. Requests to access the datasets should be directed to BD-Á, [beatrizdominguez.alvarez@usc.es](mailto:beatrizdominguez.alvarez@usc.es).

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Bioethics Committee of the Universidade de Santiago de Compostela. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## AUTHOR CONTRIBUTIONS

All authors were involved in the process of data collection. LL-R, JG-F, AI-T, and ER organized and prepared the database for the statistical analysis. BD-Á and JG-F contributed to the conception and design of the study. BD-Á performed the statistical analysis and wrote the manuscript. All authors contributed to the revision of the manuscript and read and approved the submitted version.

## FUNDING

FEDER/Ministerio de Ciencia, Innovación y Universidades – Agencia Estatal de Investigación/Grant (PSI2015-65766-R) and Axudas para a Consolidación e Estruturación de Unidades de Investigación Competitivas e outras Accions de Fomento nas Univeridades; GRC, 2018 (Consellería de Cultura, Educación e Ordenación Universitaria, Xunta de Galicia) provided financial support for this research. In addition, this study was supported by Programa de Formación de Profesorado Universitario/Ministerio de Educación, Cultura y Deporte (Reference: FPU 16/06777).

The exceptional pandemic due to the 2019 coronavirus disease (COVID-19) has obliged all Italians to stay at home. In the literature, there are evidences that traumatic global events, such as natural catastrophes and pandemic, have negative effects on the physical and psychological health of the population. We carried out a survey to analyze the physical and psychological conditions of Italians during the pandemic. Due to the severe limitations in moving during the phase one lockdown, the survey was administered by internet. Results show that Italians followed the provisions established by the Italian government to avoid contamination, but 43% of them declared to have suffered from physical symptoms, in particular migraine, sleep disorders, persistent exhaustion, and difficulty of concentration. They have great fear to be contaminated or that relatives or friends can be contaminated, and they actively take actions to avoid contamination. Participants declared that they had suffered a lot of inconveniences due to restrictions in their movements, and that their life habits were strongly changed. They spent their time at home in different activities, but their psychological well-being was strongly impaired by the lockdown. The level of anxiety tripled, in relation to the pre-pandemic period, and 30% of males and 41% of females declared to have severe levels of depression. Participants with high levels of optimism and hopefulness show a stronger resilience against anxiety and depression. In addition, there is a negative correlation between anxiety and depression and the five factors of personality. These results show that psychological diseases must not be neglected, and that people in lockdown do need support for their psychological health, also with the help of internet and communication technologies.

**Keywords:** COVID-19, anxiety, depression, resilience, lockdown

## INTRODUCTION

The 2019 coronavirus disease (COVID-19) pandemic is a global event that is causing enormous changes in lifestyles and daily activities of people of every part of the world. In Italy, particularly, the pandemic has caused a high level of deaths among Italian citizens (14.1% of the contaminated population), especially among persons who are over 65 years old. In all the world, there are more than 4.5 million cases of contaminated people with more than 312,000 deaths

[data obtained from the Center for Systems Science and Engineering (CSSE) at Johns Hopkins University on 5 May 2020<sup>1</sup>). On the basis of this high risk for citizens health, the Italian government from 10 March declared the lockdown for all working and social activities (phase one lockdown); the closure of schools, universities, public offices, and private businesses; and the mandatory quarantine for all Italians who were contaminated by the virus. Italians have to stay at home, with the possibility to move outside only in cases of strong necessity, and they have to follow procedures for securing themselves against contamination. In addition, the Italian government reinforced the public medical system to deal with the pandemic. We decided to analyze, with a survey, the impact of the pandemic and of the first phase of the lockdown on the behavior and psychological well-being of people.

There are evidences from the literature that global negative events, such as natural catastrophes, cause physical damages and psychological distress (Janney et al., 1977; Kanno et al., 2013). Also, the pandemic has negative effects on psychological well-being, not only in physicians and medical workers who have to deal with the effects of the pandemic on human beings (Greenberg et al., 2020; Tan et al., 2020) but also in normal people who have to abruptly change their life habits (Wheaton et al., 2012; Sood, 2020). COVID-19 immediately emerged as a dangerous virus for human beings health because of its high level of contamination, and researchers recommended an immediate intervention to

reduce its dangerousness (Wang et al., 2020). By reviewing studies of the psychological impact of previous pandemics [e.g., severe acute respiratory syndrome (SARS), H1N1, or Ebola], Brooks et al. (2020) evidenced that during the pandemic period, people suffer from stress, depression, and anxiety and can develop fears and worries about their economic status. The authors also claim that further research is necessary to analyze the impact of public health measures activated for preventing contamination and the real efficiency of these measures (Brooks et al., 2020). The pandemic can have negative impacts on physical health (Li et al., 2020), but other authors highlighted the strong necessity to study the effects of the pandemic and government restrictions of individual activities on people's psychological health, especially on their level of anxiety and depression (Holmes et al., 2020). Psychological stress, anxiety, and depression have negative impacts not only on human beings but also on the entire society, from both an economic and a political standpoint (Gyani et al., 2013; Layard, 2013).

Italy was the first European country to face the risk of a pandemic on a large scale (Saglietto et al., 2020). The rapid increase of positive cases in the last days of February induced the Italian government to take severe measures that blocked nearly all working and social activities, and these measures could have had a strong impact on Italians' mental health. In particular, the duration of the restrictive measures against free movement, the reduction of social contacts, the fear of possible infections, the shortage of economic resources or supplies, and the lack of clarity in information could have

negatively affected citizens and their psychological well-being (Orrù et al., 2020); thus, methods of prevention for stress and mental health diseases (Marazziti et al., 2020) should be taken into consideration, also by the public authority, to reduce pandemic distress. Therefore, the pandemic can be considered a strong cause of stress for Italian people without any doubts, and it is necessary to estimate the level of psychological disease generated by the pandemic in order to develop the best methods of interventions to contrast its harmful impact on the life of each individual and on the functioning of the entire society. However, empirical data are necessary to evaluate the real physical and psychological conditions of the population.

## MATERIALS AND METHODS

### Sample

The sample was composed of 418 participants (72.97% females). Mean age was 32.23 years ( $SD = 12.46$ ). **Table 1** shows the demographic characteristics of the sample. Even if there were participants of nearly all Italian regions (only Valle d'Aosta was not present), a higher percentage of participants were from the central and southern parts of Italy.

### Materials

The online survey included different questions and psychological questionnaires to collect data about the physical and psychological conditions and the diseases produced by quarantine on participants. In addition, we provided questions about the level of knowledge of COVID-19 and its mechanisms of propagations. Personality traits, anxiety, depression, and resilience of participants were measured with standardized psychological tests.

### Assessment of Participants' Health Status

In the survey, questions were provided to collect information about the health status of participants. We asked if participants were contaminated or believed to have been contaminated by COVID-19, if they were eventually recovered in hospitals, if they suffered from other chronic pathologies (and in case of positive response, which was their pathology), what kind of physical symptoms they suffered in the last 2 weeks, how long was the duration of these symptoms, and if they had relatives or friends recovered from COVID-19.

### Assessment of Participants' Knowledge and Fear About COVID-19

To assess participants' knowledge of COVID-19, a series of questions was used asking participants if they had correct or incorrect notions about COVID-19. For example, a correct notion is that COVID-19 causes respiratory diseases, and an incorrect notion is that it can infect only old people. Participants responded using a Likert scale from 1 (not true) to 4 (totally true). Another series of questions assessed participants'

knowledge of the various means of transmission of COVID-19 (e.g., *via* physical contact or fluid contamination). Participants had to evaluate the most probable means of contamination using a Likert scale from 1 (not true) to 4 (totally true). Other questions assessed different kinds of fear about COVID-19 (e.g., to be contaminated or that relatives or friends can be contaminated) using a Likert scale from 1 (no fear) to 4 (highest fear).

### Assessment of Participants' Problems and Behavior During the Lockdown

Participants were asked which were the most important problems they suffered after the movement restrictions due to lockdown or quarantine (e.g., obligation to stay at home or possible economic difficulties) using a Likert scale from 1 (not true) to 4 (totally true). We asked participants to rate the global disease caused by the lockdown (no disease,

**TABLE 3** | Mean ratings and standard deviation (SD) of participants' scores to assess knowledge and fear about COVID-19 and its means of contamination.

Covid knowledge		Covid fear		Covid means of contamination	
Items	Means (SD)	Items	Means (SD)	Items	Means (SD)
It causes respiratory diseases	3.56 (0.56)	To get seriously ill	2.92 (0.91)	By contact with fluids(e.g., blood)	2.84 (1.03)
It was generated in a laboratory	1.82 (0.89)	My beloved persons got harmed by the virus	3.62 (0.54)	By cough or sneeze	3.67 (0.49)
It was created by a secret agency	1.34 (0.65)	Damages in my profession or work	2.37 (0.98)	By contact with objects or clothings	2.66 (0.86)
It is a banal flu	1.37 (0.61)	Generation of wars or social conflicts	2.59 (0.93)	By air conditioning installations	2.07 (0.94)
It affects only old people	1.57 (0.76)	Impossibility to find a vaccine	2.48 (1.01)	By food	1.55 (0.78)
It can damage everyone	3.63 (0.54)	Impossibility to find valid therapies against the virus	2.58 (0.97)	By domestic animals	1.17 (0.43)
It can kill only people with other illnesses	2.12 (0.83)	The high probability to be contaminated	3.33 (0.71)	By wild animals	1.42 (0.70)
Animals transmitted it to human beings	2.44 (1.12)	High level of virus mutation	3.12 (0.84)		
It can be defeated only with medicines	2.20 (0.98)				

low disease, medium disease, high disease) and how strong was the impact of the lockdown on their life habits (no impact, low impact, medium impact, high impact, total impact). To assess the actions or behaviors participants took on to contrast contamination, we asked if they remained at home and what they did to avoid infection (e.g., if they washed their hands or wore masks when going out). In addition, we asked what kind of activity they were doing during their permanence at home when they were not working (e.g., watching TV or reading books). Other questions were provided to assess if they received social support from family, local institutions, or voluntary associations during the lockdown

("Are you receiving any help from someone or from services and institutions?").

### Assessment of Psychological Conditions

We assessed the personality traits of the five factor model of personality (extraversion, agreeableness, conscientiousness, emotional stability, and openness) using the Big Five Observer (BFO) questionnaire (Caprara et al., 1994). The BFO is composed of 40 items that are a couple of adjectives that define the characteristic of the five traits of personality. Scores were based on a Likert scale from 1 to 7. The higher the score, the higher the presence of the trait. Emotional

stability of the BFO is the inverted measure of neuroticism (Caprara et al., 1994).

We assessed anxiety and depression of participants to have indications of their psychological well-being during the lockdown period. Anxiety was measured using the State Trait Anxiety Inventory (STAI) of Spielberger with 20 items (Spielberger, 1983). Scores were based on a Likert scale from 1 (not at all) to 4 (very much). We used the standardized scores of the Italian population collected for the CBA 2.0 to estimate if participants suffered from a severe level of anxiety (Sanavio, 1997). The global STAI scores corresponding to the 95th percentile were 55 and 61 for males and females, respectively. Depression was assessed using the short form of the Beck Depression Inventory (BDI) with 13 items (Beck and Beck, 1972). The Italian version of the BDI was validated by Sica and Ghisi (2007). Scores ranged from 0 to 3 for each item. Different levels of depression severity were established in relation to range scores (Beck and Beck, 1972; Reynolds and Gould, 1981; Knight, 1984; Stukenberg et al., 1990). Scores from 0 to 4 indicate the absence of depression, from 5 to 7 mild depression, from 8 to 15 moderate depression, and scores higher than 15 indicate severe depression. Participants' resilience was estimated using the Revised Life Orientation Test (LOT-R) scale by Scheier et al. (1994), which measures optimism, and the Hope Herth Index (HHI) scale (Herth, 1992), which measures hopefulness. Resilience is composed of many characteristics or qualities

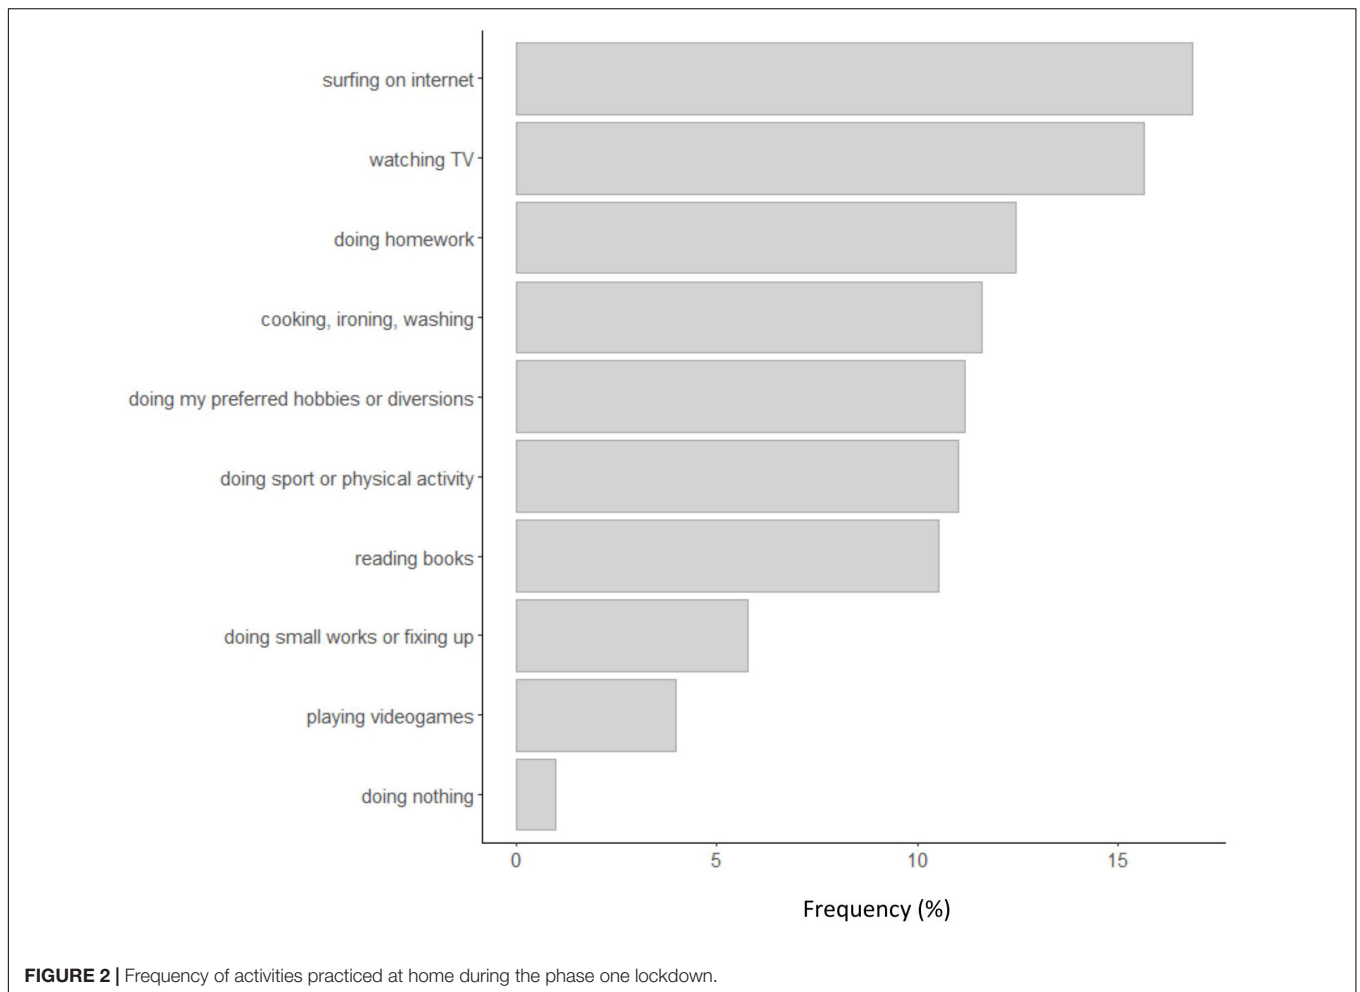

(Richardson, 2002), and among the optimal characteristics indicated in a special issue of the American Psychologist and of the Journal of Social and Clinical Psychology, there are optimism (Peterson, 2000) and hope (Snyder, 2000). We selected optimism and hopefulness because other studies defined them as protective factors against traumas and negative life events (Madsen and Abell, 2010). The LOT-R scale has 10 items, with scores on a Likert scale from 1 (strongly disagree) to 5 (strongly agree), and it measures the level of optimism and faith on positive outcomes in the future. The higher the score, the higher the level of optimism. The Italian standardization of the LOT-R was made by Chiesi et al. (2013). The Italian standardization of the HHI was made by Ripamonti et al. (2012). The scale consists of 12 items with a Likert scale from 1 (strongly disagree) to 4 (strongly agree), and it assesses three dimensions of hopefulness: inner sense of temporality and future, that is the ability to preserve a positive vision of the future (HHI temp); interconnectedness with self and others or subjective beliefs to have a strong interior force and to be not isolated from others (HHI conn); and inner positive readiness and expectancy, that is the ability to react to negative situations and the confidence that our personal actions can improve negative situations (HHI exp). This scale was used particularly for estimating resilience in patients suffering from cancer disease (Ripamonti et al., 2012). In addition, we used the Italian standardized version of the Marlowe–Crowne (MC) scale for social desirability (Manganelli Rattazzi et al., 2000), to check the validity of subjective responses in psychological scales. We used the short form with nine items with a Likert scale from 1 (low social desirability) to 5 (high social desirability). Positive or negative correlations with MC indicate a tendency to over- or underestimate psychological characteristics or traits, respectively.

**TABLE 4 |** Lockdown disease causes, global level of disease, impact of phase one lockdown on normal life, and permanence at home of the sample.

Quarantine disease causes	Means (SD)
Obligation to stay at home	2.84 (0.93)
Impossibility to see relatives and friends	3.36 (0.71)
Impossibility to work	2.48 (1.04)
Reduced physical or sporting activity	2.29 (1.02)
Impossibility to receive adequate health care	2.08 (1.04)
Economic difficulties	2.22 (1.07)
Impossibility to attend schools for children	1.69 (0.95)

Permanence at home	%
I stay always at home	27.03
I get out only for necessity	72.01
I get out as before	0.96

## Procedure

Participants responded by compiling an online survey made with Google modules. The link of the survey was distributed *via* social networks (Facebook and WhatsApp). Participants were contacted through the social networks of the authors of this work and were asked to propagate the link to other relatives or friends. Participants before doing the survey were informed about the aims of the research, and they were given information about the privacy of their data. We followed the Helsinki Declaration of ethical principles for medical research involving human participants, and the study procedure received the approbation of the Department of Medicine and Aging Sciences for its execution. Before compiling the survey, participants had to declare their effective will to participate in the survey. Without this declaration, they could not start the compilation. Participation was voluntary. Because of the possibility to repeat the test, at the end of the survey, we asked participants if they wanted to compile the survey on a successive moment. Data were collected from 8 April to 5 May. Anonymity and privacy of the participants were guaranteed according the Italian and the European laws about privacy (Italian law n. 196/2003 and EU GDPR 679/2016, respectively).

## RESULTS

### Missing Data

The online survey was projected to reduce the risk of missing data. For completing the survey, it was necessary to respond to all items. In addition, some items were activated only when participants declared to possess specific characteristics (e.g., items asking the kind of chronic pathology, if the participant declared it). In this way, we reduced the number of missing data to zero.

### Assessment of Participants' Health Status

**Table 2** shows the participant's health status. Nearly all participants declared not to be contaminated by COVID-19 (>95%). Of the participants, 4% declared that they believed to be contaminated, even if they did not make any medical test, and less than 1% declared to have been effectively contaminated.

Only 1% of participants reported to have been hospitalized for COVID-19. Furthermore, 8.13% of participants suffered from chronic diseases, not related to COVID-19. The most frequent diseases were asthma, diabetes, inflammatory diseases, migraine, hypertension, and thyroid disease. In addition, 43% of

participants declared to have suffered from physical symptoms in the last 2 weeks. The majority of symptoms lasted less than 10 days. Moreover, 20.1% of participants declared that they had some relatives or friends infected by COVID-19. **Figure 1** shows the frequency of the different symptoms declared by participants. The most prevalent physical symptoms were insomnia or sleep disorder, followed by migraine, persistent exhaustion, and general malaise.

### Assessment of Participants' Knowledge and Fear About COVID-19

**Table 3** shows the mean ratings and standard deviation of participants' scores when they were asked to respond to some items to assess their knowledge and fear about COVID-19 and the risk to be contaminated.

Participants know that COVID-19 creates respiratory disease, that it can contaminate everyone, and that, initially, it was transmitted by animals to humans. Participants do not generally believe that COVID-19 is an artificial virus created in the laboratory, that it is only a banal flu, and that it affects specifically old people. Participants show a high level of fear about COVID-19. The greatest fears are the possibility that beloved persons can

be contaminated by the virus, the possibility to be contaminated, the genetic mutation of the virus, the difficulty to find valid therapies or vaccines, and the risk of social conflicts or wars. In relation to the means of contamination, participants say that the principal means are through air (cough or sneeze) and through contact with organic fluids (e.g., blood) or with contaminated objects.

### Assessment of Participants' Problems and Behavior During the Lockdown

**Table 4** shows what are the principal problems that caused disease in participants. The principal causes are the impossibility to see relatives or friends, the duration of the lockdown, and the obligation to stay at home.

Of the participants, 59.81% reported a medium or high level of general disease, and 50% declared that the quarantine strongly changed their life and habits. Furthermore, 27% of participants stayed always at home, whereas 72% got out home only for necessity. Less than 1% declared to get out as they did before the lockdown. **Figure 2** shows the activities practiced at home during the lockdown (when not working) by participants.

Many of them watched TV or used the internet and did homework or hobbies. Very few people were completely inactive (less than 1%). **Figure 3** shows what were the most frequent precautions taken by participants to avoid contamination.

The most frequent precautions were the use of masks and gloves, washing hands frequently, sanitization of objects and rooms, observance of a safety distance from others, and avoidance of crowded places. Therefore, participants followed the principal instructions of the Italian Ministry of Public Health to reduce contamination risks. Less than 0.2% of participants declared that they did not take any precaution against contamination. **Figure 4** shows the principal agents of social support received by participants during the lockdown. Participants received social support principally from family (parents, sons, relatives), family doctors, friends, civil protection, police, and volunteers.

### Assessment of Psychological Conditions

**Table 5** shows the descriptive, reliabilities and correlations of the psychological scales used to assess psychological well-being, psychological resilience, and personality. Values of skewness and kurtosis are included in the range of  $-2$  and  $2$ ,

confirming that score distributions are prevalently normal (Gravetter and Wallnau, 2014).

Cronbach's  $\alpha$  values indicate acceptable or good reliability for each psychological scale (Kline, 2000). There are significant correlations between the MC scale for social desirability and the psychological measures, but correlations have small effect sizes because they are lower than 0.5 (Cohen, 1992). Anxiety, assessed by STAI, and depression, assessed by BDI, are strongly correlated with each other ( $r = 0.65$ ,  $p < 0.001$ ) and are all significantly and negatively correlated with the five traits of personality (extraversion, agreeableness, conscientiousness, emotional stability, and openness). Correlations vary from  $-0.68$  to  $-0.19$  for STAI and from  $-0.59$  to  $-0.25$  for BDI. We also reported the partial correlations after removing the variance due to age and gender. The  $p$ -values of correlations were adjusted according to the false discovery rate procedure (Benjamini and Hochberg, 2000). Anxiety and depression have the highest correlations with emotional stability and the lowest correlations with openness. Therefore, personality traits have some relations on psychological well-being. Anxiety and depression are negatively correlated with optimism, assessed with LOT-R, and with the three dimensions of the HHI scale. Therefore, people with a high level of optimism and hopefulness are less affected by anxiety and depression. The variation of life habits (life change) has some relations on anxiety ( $r = 0.19$ ,  $p < 0.001$ ), but not on depression, whereas the disease caused by the lockdown

is related to both o anxiety and depression ( $r = 0.42$  and  $0.36$ , respectively).

**Figure 5** shows the scatterplots of the correlations reported in **Table 5**, in relation to anxiety, assessed with the STAI, and depression, assessed with the BDI. Raw scores were transformed into standardized scores ( $z$  points) for allowing comparisons between scales. Scatterplots do not evidence particular anomalies in data distributions.

Of the participants, 15.04% of males obtained scores at the STAI equivalent to or higher than 55 (95th percentile for the male population), whereas 16.06% of females obtained scores at the STAI equivalent to or higher than 61 (95th percentile for the female population). Thus, the level of anxiety in the Italian sample during the phase one lockdown is practically tripled in relation to the cutoffs estimated in the normal population in the pre-pandemic period (Sanavio, 1997). The values of STAI corresponding to the mean of the Italian population are 37 for males and 40 for females (Sanavio, 1997). During the lockdown, the mean values of STAI increased to 41.45 and 47.38 for males and females, respectively. Therefore, the presence of a higher level of anxiety during the lockdown is confirmed by empirical data. **Figure 6** shows the frequencies of the level of depression (none, mild, moderate, and severe) in participants. More than 50% of participants show moderate or severe symptoms of depression. In particular, 41.31% of females and 30.97% of males show severe symptoms of depression, respectively. Therefore, the presence of a high level of depression during the lockdown is also confirmed.

## DISCUSSION

During the lockdown period, people are obliged to stay at home, even if they have permission to go out (to buy food, medicines, or for strong necessities). The data collected from our sample show

that people, during their mandatory permanence at home, are not totally inactive, and that they follow the provisions established by the Ministry of Public Health to avoid contamination (use of masks and glove, washing hands, safety distance observance from others, permanence at home). Only very few people declared

to have been contaminated by COVID-19, and many of them still claimed to be in a good health conditions, even when they were people suffering from other chronic diseases. About 20% of individuals reported having at least one relative or friend infected by COVID-19, and this could have affected their psychological status. The physical symptoms reported by participants were, above all, symptoms connected with a stressful condition of life. Migraine, sleep disorders, difficulty of concentration, and persistent exhaustion are typical signs of stress (American Psychological Association, 2010). Participants were clearly aware that COVID-19 was not a banal flu, that it could contaminate everyone, and that contamination could happen through air dispersion of the virus or through contact with contaminated objects. They were worried about a possible contamination toward themselves or toward their relatives or friends, about a possible virus mutation, or about the difficulty to find a valid therapy against the virus.

The principal result of our study is that the level of anxiety and the level of depression are very high in Italians during the lockdown period. The percentage of extreme anxiety is tripled, in relation to the pre-pandemic measured levels (Sanavio, 1997), and about 50% of participants show a moderate or severe level of depression. About 30% of males and 41% of females suffer from severe depression. Therefore, there are evidences that the lockdown have had negative effects on psychological well-being. However, some participants showed low levels of anxiety and depression, in particular, those who had high level of optimism and hopefulness. These people have a positive vision of the future and a strong confidence that their actions and behaviors can improve the negative situation and these characteristics, reasonably, can attenuate their psychological sufferance. Also, personality traits have some relations with anxiety and depression. People with high level of extraversion, agreeableness, conscientiousness, emotional stability, and openness have lower tendency to suffer from anxiety and depression.

Generally, the negative effects of the lockdown on psychological conditions are evident, confirming the importance of mental health prevention (Marazziti et al., 2020) and the necessity of psychological interventions against the negative impact of the pandemic on individuals (Holmes et al., 2020). Participants need psychological support, even if they do not suffer from mental or physical diseases (Brooks et al., 2020; Marazziti et al., 2020). Because of the impossibility to freely move outside the home during the lockdown, it could be useful to develop digital technologies for providing psychological support *via* internet, social networks, or apps for smartphones (McCord et al., 2015; Silva et al., 2015; Orrù et al., 2020). Through internet, it could be possible not only to provide direct assistance to people at home with the help of clinical psychologists and psychiatrists but also to teach and explain techniques for reducing psychological diseases and improving well-being, as, for example, mindfulness (Bullis et al., 2014; Saggino et al., 2017; Sood, 2020).

Both governments and private institutions should invest on mental health care of citizens, when big catastrophes happen. When negative events with a radical impact on population

activities happen, remedies for the population should be taken to overcome the consequential diseases (Holmes et al., 2020; Saglietto et al., 2020). Psychological diseases should not be neglected, because they have negative consequences on individuals, institutions, societies, and governments (Gyani et al., 2013; Layard, 2013; Brooks et al., 2020).

In 4 May, the Italian government declared the passage to the phase two of the pandemic for 18 May. Limits and restrictions of movement for the population were reduced, and some economic activities could restart. To test the evolution of anxiety and depression in this new phase, we asked participants if they wanted to repeat the survey. About 60% accepted positively to repeat the test.

One possible limit of this research is that the online survey cannot guarantee a perfect randomized selection of participants, but this was the only possibility because of the limits imposed by the lockdown. However, the different channels used to propagate the survey and the high number of participants allowed a collection of data from a sample composed of heterogeneous individuals of different parts of Italy. Another possible limit is the use of psychological tests, especially for the estimation of depression, that are not the typical test used by professional psychiatrists or clinical psychologists. However, we have to say that the BDI was used in more than 2000 studies (Richter et al., 1998), and that it is widely used by Italian clinical psychologists (Sica and Ghisi, 2007).

**Background and aims:** The COVID-19 pandemic has caused social and economic turmoil, which has led to enormous strain for many families. Past work with pandemic outbreaks suggests that media attention can increase anxiety and compensatory behaviors. Social isolation can lead to increase in online communication and parents who use social media may be affected by other people's emotions online through what is known as digital emotion contagion (DEC). The current study aimed to examine the role of DEC in the relationship between stress, concern about COVID-19, parental burnout and emotion regulation (ER).

**Methods:** In April 2020, an online survey was advertised in Social Media Parenting Groups and published on FIU Psychology online research system SONA. Data were analyzed using correlational analysis, linear and multiple linear regression, and moderation analysis.

**Results:** Concern about COVID-19 predicted stress, depression, and parental burnout. Susceptibility to DEC significantly increased the impact of stress on parental burnout. Having relatives infected with COVID-19 increased the effect of DEC on parental burnout. A higher level of ER buffered the relationship between emotion contagion and concern about COVID-19.

**Conclusion:** These findings suggest that susceptibility to digital emotion contagion may have a negative effect on parents. Digital emotion contagion may increase parental burnout and is tied to stress.

**Keywords:** COVID-19, parental burnout, concern about COVID-19, digital emotion contagion, emotion regulation

## INTRODUCTION

The COVID-19 pandemic has caused social and economic turmoil, which has led to enormous strain for many families (1, 2). Parents who are currently living with children may have been particularly impacted by COVID-19 due to social and physical isolation, the risk of unemployment, the financial strain, and the challenges of balancing work and family life while schools are on

lockdown. Increasing numbers of US mothers have symptoms of clinical depression and anxiety during the pandemic (3, 4). Anxiety may lead to burnout (5), which can have detrimental consequences for parents' and children's well-being (6). It is important to study the ways that American families have been affected by the COVID-19 outbreak to determine how concerns about or fears of the virus may have led to excessive anxiety, stress, and parental burnout and to understand whether parental emotion regulation (ER) strategies may have buffered these effects.

In addition, being on lockdown during quarantine, many parents and children have used telecommunication to stay connected with their family, friends, teachers, and colleagues. The majority of contact occurs via the internet, which was actively used by mothers before the Pandemic: during the year 2018, 59% of U.S. mothers accessed social media several times per day, and spent 214 min browsing the internet on a daily basis (7). Thus, it is worth considering the ways in which digital connections may have affected mental health. As it spreads, COVID-19 has been frequently reported in mass media and social media (e.g., Facebook and Twitter). Importantly, past work with pandemic outbreaks suggests that media attention can increase anxiety and compensatory behaviors (8). Online communication takes a multitude of forms, including navigating social media either actively (e.g., posting on Facebook parenting groups and asking for advice) or passively (e.g., reading what other users post and not engaging in communication). Emotional experiences are often "contagious" in that they can be transmitted from one person to another, which is so-called emotion contagion effects. Parents who use social media may be susceptible to digital emotion contagion (DEC), which involves being affected by other people's emotional expressions online. In social isolation, parents may become prone to either positive or negative DEC, which can affect their anxiety, stress, and burnout. However, very little is known about the ways that DEC affected parents during the COVID-19 pandemic.

In light of its easy transmission and severity of its symptoms, many individuals have experienced anxiety about contracting COVID-19. This can be interpreted as a specific manifestation of illness anxiety, which refers to a set of emotional experiences that are tied to imaginary threats of becoming ill. It is normal and adaptive to have some level of anxiety and concern about one's health (9) because this can motivate protective actions like handwashing and following social distance guidelines. However, individuals who are fearful of a pandemic illness can become excessive and maladaptive, leading to significant distress and impairment in functioning (10). According to Schimmenti (11), the COVID-19 pandemic is characterized by the following fear experiences: (a) fear of the body/fear for the body, (b) fear of significant others/fear for significant others, (c) fear of not knowing/fear of knowing, and (d) fear of taking action/fear of inaction. This set of fears manifests in anxieties that people may have about the virus. One of the core features of these fears and anxieties is personal relevance of the pandemic that increases fear reactions along with the presence of the chronic illness and death in the family due to COVID-19 (4). In the present study, we asked participants if any of their relatives had been infected with

COVID-19, aiming to examine the relationship between one of the anxieties mentioned above (i.e., fear for significant others), excessive concern about COVID-19, and parental burnout.

Risk factors for excessive illness anxiety about COVID-19 include heightened trait health anxiety and cyberchondria, while receiving realistic information about the pandemic and using adaptive ER strategies appear to help individuals to cope with anxiety (4). According to Jungmann and Witthöft (4), excessive use of the internet during the pandemic may be considered a safety-seeking behavior that people use to cope with illness anxiety toward COVID-19. However, this intensive internet browsing may paradoxically affect people's emotions as they may read threatening information that increases anxiety.

COVID-19 is highly publicized in the mass and social media. Past research on other pandemic illness outbreaks showed that media reports about the spread of virulent illnesses such as H1N1 "Swine Flu," Ebola, and Zika led to excessive anxiety and stress (8). Therefore, the extent to which COVID-19 has been covered in the media and online is likely to lead to high levels of anxiety. However, the association between using social media and anxiety is complex and multifaceted. There is evidence of increased life satisfaction as a result of social media usage (12). Simultaneously, Dhir et al. (13) showed that compulsive social media usage evoked social media fatigue, which resulted in elevated anxiety, fear of missing out valuable information, and depression. Research indicated that mothers use social networking sites to seek information about the expectations of motherhood, improve confidence as a mother (14), compare themselves to other mothers, and express emotions (15). Online communication may involve social support and foster a sense of connection and increase well-being when people use Facebook actively (16). Meanwhile, passive usage of social media decreases emotional well-being and increases envy, which, along with social comparison, moderates the relationship between Facebook use and depression (17). Amaro (18) found that greater downward comparison led to greater parenting satisfaction. Thus, if a mother compares herself to other mothers and concludes that she is more successful, she feels satisfied as a parent.

Currently, there is a limited amount of data on the relationship between social media usage by parents, anxiety, and burnout during a Pandemic. These relationships may be moderated by susceptibility to digital emotion contagion (DEC), which is the tendency to mimic and synchronize nonverbal behaviors with those of another person (19). According to Hess and Fisher (20), emotional mimicry evolves in a specific social context when people seek affiliation, thus, most often people aren't mimicking emotions of strangers or antagonistic emotions. However, this relates mostly to positive emotions (e.g., excitement and happiness), while negative emotions (e.g., anger and sadness) are more likely to be contagious among strangers, which forms an emotional ripple effect (21, 22) and amplifies shared stressful experiences (23). Moreover, when people observe others dealing with a stressful situation, their cortisol levels elevate, eliciting affective stress contagion (24). Thus, if a person is surrounded by strangers, they will be more likely to "catch" negative emotions than positive ones. This is especially relevant for the online communication where

people are susceptible to DEC (25). DEC is further mediated by social media and other online communication platforms. It can increase both positive (e.g., joy, love, compassion) and negative (e.g., fear, anxiety, sadness) emotions (26). Additionally, social media (e.g., Facebook) may lead to envy and decline in positive mood over time (27). Given that the relationship between DEC and social media is still an evolving topic in the field and that COVID-19 is an emerging situation, little is known about how DEC affects parents who use social media platforms during COVID-19 pandemic. Furthermore, very few studies have examined personal characteristics related to emotion contagion. Goldenberg and Gross (25) argue that the degree of contagion may be affected by social media behaviors, age, gender, culture, and time spent online along with the activity vs. passivity. One of the personal characteristics that leads to emotion contagion may be proneness to engage emotionally with other people online. Doherty (28) developed a measure for emotion contagion to assess individual differences in “susceptibility to emotion contagion (i.e., the likelihood of “catching” the emotions of others)” (p. 132). Scores on this measure indicated that emotion contagion was positively associated with sensitivity to others, self-esteem, and empathy. Susceptibility to catch other people’s emotions was negatively associated with self-assertiveness, emotional stability, and alienation (p. 149). Ferrara and Yang (29) identified two types of individuals based on the level of susceptibility to emotion contagions: highly and scarcely susceptible users. Although people of both types are equally prone to take on positive emotions, there are different in the inclination to adopt negative emotions, with scarcely susceptible users having higher negative emotions.

Research on the relationship between burnout and emotion contagion is scarce. Petita and Jiang (30) found a positive relationship between burnout and contagion of fear and a negative relationship between joy contagion and burnout. The authors explored the relationship between job uncertainty and emotion contagion and argued that the contagion of fear increases the feeling of uncertainty, which leads to exhaustion. Uncertainty accompanies parents who are trying to balance work and family during the pandemic, leading to parental burnout.

Parental burnout is a combination of a shattering exhaustion and a feeling that you are not good enough as a parent (6), which often stems from social comparison (31). Precursors to parents becoming burned out may include experiencing high levels of parenting stress, social pressure to be an ideal parent, trying to avoid parenting mistakes, assuming primary responsibilities for caring for the children in comparison to the partner’s parenting responsibilities. Mikolajczak and Roskam (6) established a theoretical framework for understanding parental burnout through the perspective of keeping a balance between risks and resources. Risks are defined as factors that increase parental stress, such as low emotional intelligence, lack of support, and excessive parental duties. Resources, on the other hand, decrease stress and enhance well-being. Parental stress may be alleviated by regular self-compassion practices, self-care, social support, and positive co-parenting. During the COVID-19 pandemic outbreak, parental stress levels have increased as

the perceived risks increase. Many parents are fearful about becoming ill, not only for themselves but also for their loved ones. Additionally, the burden on many parents has increased as they juggle both working and homeschooling their children. Others have suffered lost jobs or have had to keep going to work in places where they could become infected with the COVID-19. These risks strain typical resources that parents use to maintain the risks/resources equilibrium. Thus, to cope and maintain well-being, a parent needs to add more resources, which is often challenging in the midst of the crisis, leading to the development of the burnout.

According to Roskam et al. (32), parental burnout consists of four components: (a) contrast, (b) saturation, (c) distancing, and (d) exhaustion. Contrast represents the change between what a person used to be as a parent and being ashamed for what they have become as caregivers. Saturation is metaphorically described as being “fed up” with parenting. Distancing is an inability to do anything outside of usual routines. Finally, exhaustion represents overtiredness associated with the parenting role. These four components are of particular interest to the current study. The contrast scale resembles the burnout coming from comparing oneself in the current situation with a parent you were before. Parents may compare themselves with how they used to parent before the COVID-19 pandemic and may feel ashamed for not being good enough parents. Distancing could show itself through inability to change the routine easily, which would be understandable given increased parenting demands. Exhaustion would show that parents do not have enough resources to handle their responsibilities during the pandemic. Saturation would explain how being a parent is not something mothers and fathers enjoy during quarantine.

Burnout is tied to stress, which increases in emergency situations such as COVID-19 pandemic. Various factors can moderate the relationship between stress and burnout, such as social support (33), optimism, pessimism, and coping (34). Etzion (33) found that social support mitigates the effect of stress on burnout. Riolli and Savicki (34) discovered that the lower optimism and higher pessimism were related to depersonalization and emotional exhaustion under high chronic stress, and higher escape coping led to depersonalization. Although these studies were not conducted on parents, they provide insight on the potential relationship between stress and burnout that researchers may find among parents during the COVID-19 pandemic. For instance, Koeske and Koeske (35) found that parental stress was associated with lower role satisfaction and self-esteem among mothers who did not get enough social support, which aligns with the research done by Etzion. Seeking social support may be one of the ER strategies that mothers may use when they try to change their negative emotions such as illness anxiety or depression. Social support can help mothers to get ideas on how to reinterpret the meaning of the situation with ER strategy of cognitive reappraisal. However, little is known about the role of ER in the relationship between stress and parental burnout. This represents an important gap in the literature, given that ER is a powerful resource that could aid in mitigating the stress brought up by COVID-19.

Experiences of stress, burnout and negative emotions during the COVID-19 pandemic take a toll on parents who may try to regulate how they feel using a variety of strategies and techniques to modify emotional experiences and expressions. Emotion regulation (ER) represents time-limited, goal-directed, situationally relevant efforts to change positive and/or negative emotional states. People use ER to uplift and/or down-regulate both positive and negative emotions [(36), p. 1]. ER benefits the self, partners, and family members, alleviating the burden of stress (37). Two most frequently researched ER strategies are cognitive reappraisal and expressive suppression (38). Cognitive reappraisal represents an attempt to change the meaning of the situation that evoked an emotion to change its emotional relevance (38). Expressive suppression defines efforts to hide emotional expression and pretend that the emotion is not taking place. Although, there is evidence showing positive effects of suppression [e.g., (39)], this strategy is found to be less effective than reappraisal because it decreases behavioral expression of an emotion and is less likely to change an emotion experience while increasing physiological reactions for people who suppress emotions (40). Cognitive reappraisal is effective in changing both internal emotional experience and external behavioral manifestation of this experience (41). One of the explanations why cognitive reappraisal may be more effective is that it is usually used when the emotion starts to unfold and is not as strong as it becomes when suppression is used, thus, requiring fewer resources to change the emotion (42). An example of cognitive reappraisal used by a parent during the COVID-19 pandemic could be trying to think about a situation with homeschooling as an opportunity to spend more time with children. An example of emotion suppression would be feeling frustrated with a child who is not doing their homework and trying to hide frustration, pretending that it doesn't affect the parent. Both reappraisal and suppression were found to be related to specific coping strategies. People who often use reappraisal are more satisfied with life, more optimistic, and have greater self-esteem (38). However, it is possible that parents under conditions of high stress may have limited abilities to use cognitive reappraisal (43). In the current study, ER was measured to assess its potential moderating role between concern about COVID-19 and parental burnout.

## RESEARCH HYPOTHESES

The current study provides insight about the mechanisms that moderate the effect of stress on parental burnout, including the potential mitigating function of ER on the development of parental burnout among parents during a Pandemic.

Our hypotheses were:

*H1: Degree of concern about COVID-19 predicts parental burnout.*

*H2: Digital emotion contagion moderates the relationship between concern about COVID-19 and parental burnout.*

*H3: ER moderates the relationship between digital emotion contagion and concern about COVID-19.*

**TABLE 1 |** Demographic background of participants.

Variables	Categories	Frequency	Percent
Gender	Mother	142	91.6
	Father	10	6.5
# of Children	1	62	40.0
	2	64	41.3
	3	19	12.3
	4	1	0.6
Education	less than high school	3	1.9
	High school or equivalent	1	0.6
	Some college	3	1.9
	Associate degree	47	30.3
	Bachelor's degree	14	9.0
	Master's degree	21	13.5
	Professional/Specialty degree	2	1.3
	Doctoral degree	61	39.4
Race	Others	1	0.6
	Black/African American	20	12.9
	White/Caucasian	114	73.5
	Asian	4	2.6
Ethnicity	Others	16	10.3
	Hispanic/Latino	50	32.3
	Non-Hispanic/Latino	100	64.5

## MATERIALS AND METHODS

### Procedure

Following institutional review board (IRB) approval, the first author recruited participants on social media (Facebook, Twitter, and Instagram) via poster flyer campaigns, online research system at the Florida International University (SONA), and word of mouth. The researchers also used a snowball sampling approach by asking participants to forward the information about the study to other parents. The researchers used Qualtrics, an online survey portal, to distribute the survey and collect data in April 2020.

### Participants

The targeted population was adults who had children living with them. There were 155 parents who participated in the study, 142 mothers (92%) and 10 fathers (7%). The average age of participants was 37.25 years old ( $SD = 8.20$ ), with an age range of 21–59. Forty percent of participants had one child, 41.3% had two children, and 12.3% had three children, and 0.6% had four children. The average age of a child was 12.6 years old. The majority of the parents were married (78.1%). Over a third of the participants had a doctoral degree (39.4%), 30.3% had associate and 13.5% had a master's degree. The participants were mostly White (73.5%), 12.9% of them identified themselves as Black, and 32.3% were Hispanic/Latino (see **Table 1**).

### Measures

#### Concern About COVID-19

Concern about COVID-19 was measured by COVID-19 Threat Scale [CTS; (44)]. The CTS is a self-report inventory that

was developed by adapting a questionnaire assessing anxiety in response to the H1N1 “Swine Flu” Influenza (8). Items on the CTS quantify threat-related perceptions of the Coronavirus utilizing a 5-point Likert Scale (from 1- “Not at all” to 5- “Very Much”). Items asked participants to rate their fears that COVID-19 will spread widely in the United States, their fears about becoming ill or family members becoming ill, as well as behavioral changes in response to COVID-19 (e.g., decisions to be around other people, handwashing). Higher scores reflect a greater level of anxiety and more threat-related behaviors due to COVID-19. The Cronbach’s Alpha of the scale was 0.84 in the current study.

## Digital Emotion Contagion

Susceptibility for digital emotion contagion was measured via a modified emotion contagion scale developed by Doherty (28). The scale has 15 items and five subscales: happiness, love, fear, anger, and sadness. The items were modified to reflect online communication. An example of an item for the love subscale was, “When I look at the social media pictures of the one I love, my mind is filled with thoughts of romance.” An example of an item for the happiness subscale was, “Being with a happy person on social media picks me up when I’m feeling down.” The sadness scale had items such as, “I cry at sad videos on social media.” An example of an item for the fear subscale was, “Watching the fearful faces of victims on the news makes me try to imagine how they might be feeling. The Anger subscale was represented by items such as, “I clench my jaws and my shoulders get tight when I see the angry faces on the news on social media.” Participants rated their responses on a five-item Likert-type scale (from 5— “Always” to 1— “Never”). Cronbach’s Alpha for the susceptibility for the digital contagion scale was 0.86 in the current study.

## Parental Burnout Assessment

Parental burnout was measured using the 23-item Parental Burnout Assessment (PBA; 24). The PBA is used to assess the levels of exhaustion, saturation, contrast, and distancing of parental burnout. Sample items include “I find it exhausting just thinking of everything I have to do for my child(ren),” (exhaustion subscale), “I feel like I can’t take any more as a parent” (saturation subscale), “I’m ashamed of the parent that I’ve become” (contrast subscale), and “I’m no longer able to show my child(ren) how much I love them” (distancing subscale). Participants rated items on a 7-point Likert scale with response options ranging from “Never” to “Every day.” High scores reflect a high level of parental burnout. Cronbach’s alpha of the total scale was 0.97 in the current study. Alphas of items measuring exhaustion, contrast, saturation, and distancing were 0.95, 0.92, 0.95, and 0.86, respectively.

## Depression, Anxiety and Stress Scale (DASS-21)

Distress was measured using Depression, Anxiety and Stress Scale (DASS-21; 35), which included three 7-item subscales (depression, anxiety and stress). Examples of items were, “I couldn’t seem to experience any positive feeling at all”

(depression subscale), “I found it difficult to relax” (stress subscale) and, “I was worried about situations in which I might panic and make a fool of myself” (anxiety subscale). Participants rated their responses on a 4-item scale, where 0 was “Did not apply to me at all,” 1— “Applied to me to some degree, or some of the time,” 2— “Applied to me to a considerable degree or a good part of time,” and 3—Applied to me very much or most of the time.” In the current study, Cronbach’s alpha of the total scale was 0.94. Alphas of items measuring stress, anxiety, and depression were 0.90, 0.82, and 0.87, respectively.

## Emotion Regulation

Emotion Regulation Questionnaire [ERQ; (38)] was used to assess participants’ tendency of using cognitive reappraisal and/or expression suppression to regulate their emotions. The items were rated on a 7-point Likert-type scale (1 = “Strongly disagree” to 7 = “Strongly agree”). An item example of the cognitive reappraisal subscale was, “When I want to feel more positive emotion (such as joy or amusement), I *change what I’m thinking about*.” An item example for the expressive suppression subscale was, “When I am feeling positive emotions, I am careful not to express them.” Cronbach’s Alpha of the ERQ was 0.82.

## DATA ANALYSIS

Before main data analyses were performed, we checked the effects of participants’ gender and age on the main variables we examined. Concern about COVID-19 was not significantly different across gender ( $t^1_{(9,31)} = 0.11, p = 0.91$ ). Though significant differences were found among different age groups [ $F_{(3,68.9=08)} = 4.72, p = 0.005$ ], *post-hoc* analysis showed that there was only a marginally significant difference between 21–30 and 41–50 age groups ( $t = 0.52, p = 0.05$ ). Digital emotional contagion among parents was not significantly different across gender ( $t_{(9,33)} = 0.80, p = 0.40$ ) and age groups [ $F_{(3,149=08)} = 0.85, p = 0.47$ ]. These were the same with total score of parental burnout (gender,  $t_{(9,61)} = 0.18, p = 0.86$ ; age groups,  $F_{(3,149)} = 2.27, p = 0.08$ ) and emotional regulation questionnaire scores (gender,  $t_{(9,28)} = 0.50, p = 0.63$ ; age groups,  $F_{(3,45.03)} = 1.39, p = 0.26$ ). DASS score was not significant across gender ( $t_{(9,54)} = 0.45, p = 0.66$ ). However, it was significantly different across age groups [ $F_{(3,49.76)} = 9.28, p < 0.001$ ] and parents of 31–40 years old had significantly higher score than those over 50 years old ( $p = 0.001$ ). Further analyses found that stress [ $F_{(3,149)} = 4.56, p = 0.004$ ] and depression scores were significantly different across age groups [ $F_{(3,149)} = 2.93, p = 0.04$ ], but anxiety was not significant [ $F_{(3,149)} = 1.84, p = 0.14$ ]. These indicated that gender was not a confounding variable in the main analyses but age was one when stress and depression were the dependent variables.

Correlational analysis was first used to examine the relationships between concern about COVID-19, stress,

<sup>1</sup>When statistical assumption of homogeneity of variance was not supported in the independent sample t-test, the degree of freedom was a decimal to correct for the non-homogeneity of variance. When the same assumption was not supported in ANOVA, Welch test was used and a degree of freedom with a decimal was reported for the same purpose.

DEC, general anxiety and depression, parental burnout, and ER. Linear and multiple linear regression analysis was conducted to assess the relationships between illness anxiety, parental burnout, DEC, and ER. Moderation analyses were performed to address hypotheses two and three. Moderation focuses on “when” questions and a moderation effect is usually present when a third variable affects the relationship between predictor and outcome variables (45). All the analyses were conducted in IBM SPSS (Version 26), and moderation analysis was conducted via PROCESS SPSS—a versatile modeling tool developed to integrate many features that exist separately in a few popular statistical software programs, such as, mean centering predictors to reduce multicollinearity (46), providing information about how much variance in the outcome variable can be explained by the model and specifically by the interaction (47). Additionally, participants were asked questions regarding their personal experiences during COVID-19 Pandemic, such as: “Do you personally know anyone who got infected with Coronavirus?” and “Do you personally have a relative who is currently infected with Coronavirus? They were also asked to report their demographic background information, such as age, gender, race, ethnicity.

## RESULTS

Correlations among study measures are presented in **Table 2**. Linear regression analysis then examined whether concern about COVID-19 predicted stress and depression. Because age was had a significant effect on stress and depression, it was added to the regression models (see **Table 3**). The results showed that both stress and depression were predicted by concern about COVID-19 [ $F_{(2,150)} = 10.80, p < 0.001$  for stress;  $F_{(2,150)} = 6.00, p = 0.003$  for depression]. However, age was not significant in both models ( $p = 0.50$  for stress;  $p = 0.94$  for depression). In turn, Concern about COVID-19 moderately predicted parental burnout,  $F_{(1,154)} = 5.465, p < 0.05$ , which supports H1. Comparatively speaking, concern about COVID-19 explained more variance in stress (12.6%,  $\beta = 0.36, t = 4.64, p < 0.001$ ) than in depression (7.4%,  $\beta = 0.27, t = 3.37, p = 0.001$ ) and parental burnout (3.4%,  $\beta = 0.19, t = 2.34, p = 0.02$ ) (see **Table 2**).

The moderation effect of digital emotion contagion (DEC) on the relationship between concern about COVID-19 and total score of the parental burnout measure was not significant, thus, H2 was not supported. However, analysis of the subscales of

$R^2 = 0.034$					

parental burnout yielded significant results. More specifically, the moderation effect of DEC on the relationship between stress and parental contrast sub-scale showed that both stress ( $p < 0.001$ ) and DEC ( $p = 0.02$ ) and the interaction between stress and DEC ( $p = 0.04$ ) significantly predicted contrast and all were positive predictors (see **Table 4**). This suggests that stress has a significant effect on parental contrast when emotion contagion is high, or in other words, emotion contagion significantly increases the impact of stress on parental contrast. The whole model explains 28% of the variance in parental contrast, with about 2% contributing from the interaction. Comparatively speaking, stress had a higher coefficient, while DEC and the interaction had very similar coefficients (see **Table 4**).

The same analyses were conducted with the other three subscales of parental burnout. Stress significantly predicted parental exhaustion ( $p < 0.001$ ) and saturation ( $p < 0.001$ ), but DEC did not ( $p = 0.35$  for exhaustion,  $p = 0.24$  for saturation) and the interaction terms were also not significant ( $p = 0.93$  for interaction in exhaustion model,  $p = 0.06$  for saturation model). In addition, stress significantly predicted parental distancing ( $p < 0.001$ ), while emotion contagion did not ( $p = 0.15$ ). However, the interaction of stress and DEC was a significant predictor

**TABLE 4 |** Moderation analyses of DEC between stress and parental burnout sub-scales.

Predictor	B	b 95% CI [LL, UL]	SE	t	p
<b>Moderation Effect of DEC between stress and parental contrast</b>

Interaction	0.35	0.02–0.69	0.17	2.09	0.04
$R^2 = 0.28$					
<b>Moderation Effect of DEC between stress and parental exhaustion</b>					
(Constant)	3.17	2.94–3.40	0.12	27.24	<0.001
Stress	1.35	1.06–1.64	0.15	9.09	<0.001
Emotion contagion	0.17	–0.19–0.52	0.18	0.94	0.35
Interaction	–0.02	–0.40–0.36	0.19	–0.09	0.93
$R^2 = 0.38$					
<b>Moderation Effect of DEC between stress and parental saturation</b>					
(Constant)	1.95	1.74–2.17	0.11	17.82	<0.001
Stress	0.86	0.58–1.13	0.14	6.13	<0.001
Emotion contagion	0.20	–0.14–0.53	0.17	1.17	0.24
Interaction	0.34	–0.02–0.70	0.18	1.87	0.06
$R^2 = 0.26$					
<b>Moderation Effect of DEC between stress and parental distancing</b>					
(Constant)	1.74	1.54–1.93	0.10	17.72	<0.001
Stress	0.65	0.40–0.89	0.12	5.19	<0.001
Emotion contagion	0.22	–0.08–0.52	0.15	1.44	0.15
Interaction	0.41	0.09–0.73	0.16	2.52	0.01
$R^2 = 0.23$					

of parental distancing ( $p = 0.01$ ) (see **Table 4**). This indicates that, like with the parental contrast subscale, emotion contagion increases the impact of stress on parental distancing. The whole model explained 23% of the variance in parental contrast, with about 3% variance accounted for by the interaction.

The effect of stress on parental burnout was further moderated by knowing people who are infected with COVID-19 ( $p < 0.001$ ). Stress ( $p < 0.001$ ) and the interaction between stress and knowing people infected with COVID-19 ( $p < 0.01$ ) had significant positive effects on parental burnout, indicating that having relatives infected with COVID-19 increased the effect of stress on parental burnout. The whole model explained 37% of the variance in parental burnout. The effect of DEC on parental burnout was also moderated by having relatives infected with COVID-19. DEC ( $p < 0.01$ ) and the interaction ( $p < 0.001$ ) between DEC and having a relative infected with COVID-19 had significant positive effects on parental burnout, indicating that having relatives infected with COVID-19 increases the effect of DEC on parental burnout. The whole model explained 15% of the variance in parental burnout (see **Tables 5, 6**).

We also tested *H3* through moderation analysis. The results indicated that DEC significantly predicted concern about COVID-19 ( $p < 0.001$ ), whereas individual ER did not ( $p = 0.29$ ). The interaction between DEC and ER had a significant ( $p < 0.001$ ) yet negative effect on the relationship (see **Table 7**). This indicates that a higher level of ER significantly reduces

the effect of DEC on concern about COVID-19, suggesting a beneficial effect of ER. The full model explains 18% of the variance in parental contrast, with about 10% accounted for by the interaction term.

## DISCUSSION

This study showed that concern about COVID-19 predicted stress, depression, and parental burnout. These results align with findings of Koutsimani et al. (5), who found that people experiencing higher levels of anxiety are more prone to burnout. Likewise, we found parents who experienced higher levels of anxiety in response to COVID-19 and who believed they had higher possibility of being infected tended to experience higher levels of parental burnout in all four domains.

Anxiety is accompanied with intrusive thoughts and may lead to mental fatigue, becoming a risk factor that increases parental stress disturbing the balance between risks and resources described by the theoretical framework of parental burnout developed by Mikolajczak and Roskam (6). Thus, parents who experience higher levels of concern about the virus might benefit from using resources such as self-compassion practices and social

support to decrease anxiety and stress. This is especially true if they have relatives infected with COVID-19 because the virus becomes more personal to them, which may increase their illness anxiety (4).

Having relatives infected with COVID-19 increased the effect of stress on parental burnout along with the effect of DEC on parental burnout. It is possible that the personal experience of having the virus affect someone you know increases the anxiety about the COVID-19, which becomes an additional risk factor for parents exhausting their coping resources. The increased DEC effect on parental burnout when a parent has a relative infected with COVID-19 could be due to that a person may engage in excessive use of internet during pandemic. This is considering a safety-seeking behavior that people use to cope with illness anxiety (4). However, actively searching for virus-related information may become a risk factor for parents as it may trigger negative emotions due to DEC.

The current research showed that parental burnout is affected by susceptibility to emotion contagion. More specifically, DEC increased the impact of stress on two subscales of parental burnout: contrast and distancing. During quarantine in a Pandemic, ways to obtain social support are often limited to digital communication. This result means that the more parents are susceptible to take on other people's emotions on social media, the more they tend to feel that they are not as good parents as they used to be and that they are no longer able to make efforts for their children and can't do anything out of usual routines as parents. One of the explanations for the moderating role of DEC on the relationship between stress and contrast is that pandemic changed lives of parents. While completing the survey, they may, consciously or unconsciously, have compared pandemic parenting with pre-pandemic parenting and felt that they were not coping well enough during this crisis. De los Santos et al. (15) found that mothers on social media tend to express negative emotions more often than positive, thus, susceptibility to DEC of negative emotions makes a mother experience more anger, sadness, and fear herself. Regarding burnout related to perceived contrast, mothers may seek information about the expectations of motherhood and try to improve their confidence as mothers (14). However, when they compare themselves to other mothers and see that they are not doing as well as other parents, they may feel ashamed and think about their pre-pandemic parenting, which was different and up to their standards of a "good mother."

Distancing-related burnout involves difficulty doing anything out of standard routines, and it may be exacerbated by social media discussions between mothers when they express negative emotions about new responsibilities they need to fulfill in pandemic parenting. For instance, in Facebook mothers' groups, parents emotionally discuss how tired they are and how they are not planning to do extra work as parents because they have no energy to do so. DEC may then make other parents experience the same emotions. Paradoxically, these results may show that social media does foster a sense of connection among parents during the Pandemic, but this connection is not making them feel better, rather it leads to burnout through DEC. It may happen because negative emotions in general are more contagious among strangers (21, 22), amplifying shared stressful experiences (23).

Thus, when mothers on social media observe other mothers' struggles, they feel more stressed themselves through affective stress contagion (24). However, we do not know if participants used social media actively or passively. Passive use is more likely to be problematic, as Appel (17) showed passive usage decreases well-being and increases envy, leading to depression.

The results showed that a higher level of ER reduced the relationship between digital emotion contagion and concern about COVID-19, thus ER may have a positive effect on this relationship. This means that when parents use ER strategies after they become emotionally involved in DEC on social media, they tend to have lower anxiety about COVID-19. This result aligns with the research on cognitive reappraisal as an ER strategy. Parents could use cognitive reappraisal to change the meaning of the situation and improve their emotional experiences (38). For example, when a parent is navigating social media websites and starts feeling anxious about COVID-19 because other users are expressing fears, they could try to re-interpret the situation and/or change its meaning. An example of a cognitive reappraisal would be, instead of thinking, "this virus is going to kill me," they think, "I am using all the necessary precautions and the chance to get infected for me or my family is low." This relationship may reflect the awareness of DEC among study participants. They may have recognized that being on social media may make them prone to take on other people's emotions and, thus, they may have tried to regulate their feelings and decrease anxiety.

## LIMITATIONS AND FUTURE RESEARCH

An important limitation of the present study is the use of a cross-sectional design, in which participants completed the measures only once. Thus, we are unable to draw cause and effect relationships among the study variables. Future research should utilize longitudinal measures to study the relationships among anxiety, internet use, ER, and parental burnout. Another limitation is the limited size and diversity of the sample. We also did not include questions regarding parental communication in social media groups, and didn't ask how much time participants spend looking for information about COVID-19, these questions could have informed present research and would have made our discussion of findings more robust.

Future studies may focus on socio-demographic differences between parents of different races, ethnicities, and marital status. Additionally, researchers may want to investigate fathers' emotional experiences during the Pandemic and compare those with maternal feelings and behaviors. Another limitation is that only cognitive reappraisal and expressive suppression were assessed. Future projects may focus on the difficulties in ER, assessing broader range of ER strategies and techniques that parents use to cope with concern about COVID and burnout.

Qualitative interviews with parents exploring ways that they use social media could help to obtain an in-depth understanding of the function of social media in parental burnout, concern about COVID-19, and emotion regulation during pandemic. One of the factors that impacts DEC is activity vs. passivity of a social media user. Future studies could investigate the relationship

between activity and/or passivity on social media, the type of social media, DEC, ER, and burnout among parents.

## CONCLUSION

The present study explored the role of susceptibility to digital emotion contagion in the relationship between concern about COVID-19, stress, parental burnout, and emotion regulation. We found that parents who were more susceptible to digital emotion contagion were experiencing higher parental burnout when feeling stressed. Parents who used emotion regulation strategies when they experienced emotion contagion had lower anxiety about COVID-19. These data suggest that digital emotion contagion media affects experiences of stress and burnout in parents and that emotion regulation helps to mitigate these effects during a pandemic threat.

**Introduction:** Since February 2020, the outbreak of COVID-19 spread to several countries worldwide, including Italy. In this study, we aimed to assess the psychopathological impact of the pandemic across the general population of Lombardy, the most affected Italian region, and to compare the prevalence of psychiatric symptoms between the general public and healthcare workers.

**Methods:** Four hundred and thirty-two participants completed an online survey including: the Depression, Anxiety and Stress Scale—21 items (DASS-21), the Impact of Event Scale—Revised (IES-R) and the Pittsburgh Sleep Quality Index (PQSI). Healthcare workers were also asked to complete the Maslach Burnout Inventory (MBI).

**Results:** At the DASS-21, 33.3% of the responders presented pathological levels of stress, 25.5% of anxiety, and 35.9% of depression. At the IES-R, 13.9% appeared at risk of developing Post-Traumatic Stress Disorder (PTSD). At the PQSI, 57.6% presented sleep disturbances. Female gender and younger age predicted higher scores of distress. Healthcare workers presented higher levels of psychiatric symptoms than the general public. Moreover, working in contact with COVID-19 patients predicted higher scores at the IES-R subscale Intrusion.

**Conclusion:** Our results showed that about a third of our sample presented symptoms of stress, anxiety, and depression during the first month of the COVID-19 pandemic outbreak in Lombardy; more than half of the responders presented sleep disturbances, and 13% appeared at risk of PTSD. Italian authorities should develop specific strategies to guarantee psychological support to the population of Lombardy, with particular attention to women, young people, and healthcare workers exposed to COVID-19 patients.

**Keywords:** COVID-19, SARS-CoV-2, stress, anxiety, depression, PTSD, sleep, healthcare workers

## HIGHLIGHTS

- We assessed psychiatric symptoms in Lombardy (Italy) during COVID-19 pandemic.
- A third of our sample presented symptoms of stress, anxiety, and depression.
- 13.9% appeared at risk of developing PTSD and 57.6% presented sleep disturbances.
- Healthcare workers presented higher levels of psychiatric symptoms.
- Working with COVID-19 patients predicted more Intrusion-type symptoms.

## INTRODUCTION

In December 2019, the city of Wuhan in China experienced an outbreak of atypical pneumonia caused by a novel betacoronavirus, named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Since February 2020, the outbreak rapidly spread to several countries worldwide. The World Health Organization officially declared coronavirus disease 2019 (COVID-19) a pandemic on March 11th 2020. At the moment of writing, Italy is one of the most affected countries, with 201,505 total cases and 27,359 deaths. With 74,348 total cases and 13,575 deaths, Lombardy is arguably the most severely stricken Italian region. The rate of transmissibility suggested by the COVID-19 reproductive number has been estimated at around 4 (1), indicating that every infected person might transmit the infection up to 4 people. In order to limit the outbreak, Italian authorities ordered a strict quarantine at the beginning of March, along with a complete lockdown of the country. The COVID-19 outbreak and subsequent measures might represent two different, albeit interconnected, risk factors for the development of psychiatric symptoms in the general population and in the subpopulation of healthcare workers who are directly involved in the management and treatment of COVID-19 patients (2). Two recent Chinese studies reported psychological distress, insomnia, anxiety, and depressive symptoms in the general public and in healthcare workers during the outbreak (3, 4). At the time of writing, only one study assessed the emotional impact of COVID-19 in the Italian general public and reported psychological distress symptoms during the early phase of the COVID-19 outbreak in a vast proportion of patients (5). However, no available studies assessed the prevalence of specific psychiatric symptoms, such as depressive, and anxious symptoms, in the Italian population. Moreover, no studies have been specifically conducted on a sample of Italian healthcare workers.

The main aim of the present study was to evaluate the prevalence of specific psychiatric symptoms (stress, anxiety, depression, sleeping disturbances) across the general public of Lombardy during the first month of COVID-19 outbreak in Italy. We also assessed the same symptoms, along with burn-out level, in a specific cohort of healthcare workers. Finally, in both populations, we aimed to identify potential risk and protective factors contributing to the development of these symptoms. This might help Italian authorities to strategically plan the promotion of mental well-being.

## METHODS

This study is a cross-sectional survey, using an anonymous online questionnaire. A snowball sampling strategy was used to recruit a sample from the general public and one from healthcare workers. Data collection took place between 24th March and 31st March 2020. All participants signed an online written informed consent form before completing the questionnaire. The study was approved by the local Ethics Committee. Through the online questionnaire, demographic information was collected including age, gender, education level, and employment status; moreover, healthcare workers were requested to specify whether or not they were working in direct contact with COVID-19 patients and since how many days.

The survey included the following questionnaires.

The Depression, Anxiety, and Stress Scale—21 items (DASS-21), a strongly validated self-report questionnaire, assessing depressive, and anxiety symptoms (6). A Total Score was calculated as an index of general distress; moreover, the following three subscale scores were calculated: (i) Stress, averaging items 1, 6, 8, 11, 12, 14, 18; (ii) Anxiety, averaging items 2, 4, 7, 9, 15, 19, 20; (iii) Depression, averaging items 3, 5, 10, 13, 16, 17, 21. According to each subscale score, participants were labeled on a severity scale. Specifically, the subscale Stress score was divided into 0–7 (normal), 8–9 (mild), 10–12 (moderate), 13–16 (severe) and  $\geq 17$  (extremely severe); the subscale Anxiety score was divided into 0–3 (normal), 4–5 (mild), 6–7 (moderate), 8–9 (severe), and  $\geq 10$  (extremely severe); the subscale Depression score was divided into 0–4 (normal), 5–6 (mild), 7–10 (moderate), 11–13 (severe), and  $\geq 14$  (extremely severe). Pathological levels of either stress, anxiety, or depression were identified for participants who fell in the category of “mild” or above (7, 8).

The Impact of Event Scale-Revised (IES-R), a 22-item self-report scale that assesses subjective distress caused by traumatic events (9). The IES-R Total Score, obtained by summing the answers to each item, was divided into 0–23 (normal), 24–32 (mild psychological impact), 33–36 (moderate psychological impact), and  $>37$  (severe psychological impact). Although the IES-R is not used to diagnose Post Traumatic Stress Disorder (PTSD), a cut-off score of 33 has been previously considered to define patients at risk of PTSD (10); moreover, three subscales were calculated, providing an indication of the level of distress experienced: (i) Intrusion (averaging the responses of items 1, 2, 3, 6, 9, 14, 16, 20); (ii) Avoidance (averaging the responses of items 5, 7, 8, 11, 12, 13, 17, 22); (iii) Hyperarousal (averaging the responses of items 4, 10, 15, 18, 19, 21).

The Pittsburgh Sleep Quality Index (PSQI) (11), investigating the quality of sleep in the month before the assessment. Seven scales were calculated following the authors' instruction: (i) Subjective Sleep Quality; (ii) Sleep Latency; (iii) Sleep Duration; (iv) Habitual Sleep Efficiency; (v) Sleep Disturbances; (vi) Use of Sleeping Medications; (vii) Daytime Dysfunction; a Total Score was calculated summing the scores of the seven subscales. Participants scoring equal or above 5 at the Total Score were considered “bad sleepers.”

Finally, healthcare workers were also requested to complete the Maslach Burnout Inventory (MBI), a validated self-report measure of burnout. Burnout is defined by the ICD-11 as “a syndrome resulting from chronic workplace stress that has not been successfully managed” (12). The MBI provides an index for three aspects of burnout: Emotional Exhaustion (summing items 1, 2, 3, 6, 8, 14, 16, 20); Depersonalization (summing items 5, 10, 11, 15, 22); and Personal Accomplishment (summing items 4, 7, 9, 12, 17, 18, 19, 21). Even in this case, according to the score at each subscale, participants were labeled on a severity scale. Specifically, the subscale Emotional Exhaustion was divided into 0–18 (low), 19–26 (moderate),  $\geq 27$  (high); Depersonalization was divided into 0–5 (low), 6–9 (moderate),  $\geq 10$  (high); Personal Accomplishment was divided into 0–33 (high), 34–39 (moderate),  $\geq 40$  (low) (13).

Participants showing high levels of distress were contacted and encouraged to seek for psychological counseling.

## Statistical Analysis

Statistical analysis was performed using SPSS version 26 (Statistical Package for Social Science). The significance level was set at  $\alpha = 0.05$ , and all tests were 2-tailed.

A series of dichotomic variables was created according to the results of the psychometric questionnaires: participants who scored above the aforementioned cut-offs for each scale / subscale were labeled Clinical (1), and participants scoring below were labeled Not Clinical (0).

First, descriptive statistics were calculated for sociodemographic characteristics and for scales score.

Second, two categorical variables were created: (i) Group, dividing healthcare workers (HW) and general public (GP); (ii) COVID-19, dividing healthcare workers in contact (CHW) and not in contact (NCHW) with COVID-19 patients.

Mann-Whitney U test was run to assess differences amongst the groups (HW vs. GP, and CHW vs. NCHW) for the demographic variables and for the results at the questionnaires. Categorical variables were analyzed via Pearson Chi Square ( $\chi^2$ ) test. Finally, we used multiple linear regression analysis to calculate whether sociodemographic characteristics predicted the presence of psychiatric symptoms in three groups: (i) the whole sample; (ii) healthcare workers only; (iii) healthcare workers exposed to COVID-19 patients only.

Analytical code is available in **Supplementary Material 1**.

## RESULTS

### Demographic Features

A total of 432 valid questionnaires was retrieved. All responders were Italian and were living in Lombardy at the time of testing. Three-hundred and eleven responders (72%) were female and two (0.5%) preferred not to declare their gender. The mean age of the total sample was 35.9 ( $\pm 12.1$ ) years old, and mean education was 16.8 ( $\pm 2.8$ ) years. Sixty-six participants (15.3%) were students, 357 were employed (82.6%), one was unemployed (0.2%), and eight were retired (1.9%). In our sample, 123 (28.5%) were healthcare workers and 49 of them (39.9%) were working directly in contact with patients affected by COVID-19.

### Psychopathological Assessment

According to the DASS-21 subscales, 144 responders (33.3%) had pathological levels of stress, 110 (25.5%) of anxiety, and 155 (35.9%) of depression. At the IES-R Total Score, 60 participants (13.9%) appeared to be at risk of PTSD. Finally, 249 (57.6%) were found to be “bad sleepers” at the PSQI Total Score.

Within the HW group only, 59 responders (48%) presented pathological levels of stress, 47 (38.2%) of anxiety, and 51 (41.5%) of depression; 23 (18.7%) appeared to be at risk of PTSD according to the IES-R Total Score and 88 (71.5%) fell in the “bad sleepers” category at the PSQI Total Score. According to the MBI subscales, 47 (38.2%) healthcare workers presented high levels of emotional exhaustion, 49 (39.8%) of depersonalization, and 59 (48%) low levels of personal accomplishment.

Finally, within CHW only, 28 responders (57.1%) presented pathological levels of stress, 23 (46.9%) of anxiety, and 25 (51%) of depression; 11 (22.4%) appeared to be at risk of PTSD according to the IES-R Total Score and 35 (71.4%) fell in the “bad sleepers” category at the PSQI Total Score. According to the MBI subscales, 28 (57.1%) of healthcare workers presented high levels of emotional exhaustion, 24 (49%) high rates of depersonalization, and 21 (42.9%) low levels of personal accomplishment.

Further details are available in **Supplementary Material 2**.

### Healthcare Workers (HW) vs. General Public (GP)

Groups were balanced for gender [ $\chi^2(2) = 4.838, p = 0.089$ ] and age [U (432) = 21,249,  $p = 0.055$ ]; HW had a higher level of education than GP [U (432) = 24,952,  $p < 0.001$ ].

Significant differences emerged between the two groups at the DASS-21 Total Score [U (432) = 24,388,  $p < 0.001$ ] and at all the DASS-21 subscales: (i) Stress [U (432) = 24,483.5,  $p < 0.001$ ]; (ii) Anxiety [U (432) = 25,230.5,  $p < 0.001$ ]; (iii) Depression [U (432) = 21,619.5,  $p = 0.025$ ], all with HW scoring higher than GP.

Healthcare workers scored higher also at the IES-R Total Score [U (432) = 22,408.5,  $p = 0.004$ ] and at the IES subscales Intrusion [U (432) = 24,098,  $p < 0.001$ ], and Hyperarousal [U (432) = 21,519,  $p = 0.031$ ]. No difference was found at the IES subscale Avoidance ( $p > 0.05$ ).

Finally, significant differences were found at the PSQI Total Score [U (432) = 23,846.5,  $p < 0.001$ ] and at the following PSQI subscales: (i) Subjective Sleep Quality [U (432) = 22,546,  $p < 0.001$ ]; (ii) Sleep Duration [U (432) = 25,423.5,  $p < 0.001$ ]; (iii) Sleep Efficiency [U (431) = 21,308,  $p = 0.011$ ]; (iv) Daytime Dysfunction [U (432) = 21,644.5,  $p = 0.007$ ], all with HW scoring higher than GP (therefore having a worse sleep quality).

See **Table 1** for further details.

### COVID-19 Healthcare Workers (CHW) vs. Non-COVID-19 Healthcare Workers (NCHW)

Groups were balanced for gender [ $\chi^2(2) = 2.506, p = 0.286$ ], age [U (123) = 1,927,  $p = 0.555$ ], and years of education [U (123) = 1,807.5,  $p = 0.967$ ]

**TABLE 1 |** Sociodemographic and psychometric assessment.

	Whole sample			Healthcare workers		
	GP (N = 309)	HW (N = 123)	p	NCHW (N = 74)	CHW (N = 49)	p

CHW, healthcare workers directly in contact with COVID-19 patients; DASS-21, Depression, Anxiety, and Stress Scale—21 items; GP, General Public; HW, healthcare Workers; IES-R, Impact of Event Scale-Revised; MBI, Maslach Burnout Inventory; N/A, Not Applicable; NCHW, healthcare workers not directly in contact with COVID-19 patients; PSQI, Pittsburgh Sleep Quality Index. Bold values mean  $p < 0.05$ .

No group differences were found at the DASS-21 Total Score, nor at the DASS-21 subscales. Similarly, no differences emerged at the IES-R Total Score and subscales. A trend toward

significance appeared for the IES-R subscale Intrusion [U (123) = 2,180,  $p = 0.058$ ], with CHW scoring higher than NCHW. CHW scored higher than NCHW at the PSQI subscale Habitual

Sleep Efficiency [ $U(122) = 2,210.5, p = 0.012$ ] and at the MBI subscale Emotional Exhaustion [ $U(114) = 2,058.5, p = 0.008$ ]; finally, a trend toward significance emerged at the MBI subscale Personal Accomplishment [ $U(114) = 1,932.5, p = 0.051$ ], with CHW scoring higher than NCHW.

See **Table 1** for further details.

## Regression Analysis

### Regression Analysis in the Whole Sample

The female gender was a predictor of the presence of psychiatric symptoms in terms of stress, anxiety, PTSD-like symptoms and sleep disturbances. In particular, the variable Gender was a predictor of: (i) the DASS-21 Total Score ( $p = 0.023$ ) and the DASS-21 subscales Stress ( $p = 0.03$ ) and Anxiety ( $p = 0.003$ ); (ii) the IES-R Total Score ( $p < 0.001$ ) and all the IES-R subscales [Avoidance ( $p = 0.032$ ), Intrusion ( $p < 0.001$ ), and Hyperarousal ( $p = 0.001$ )]; (iii) the PSQI subscales Subjective Sleep Quality ( $p = 0.003$ ), Sleep Latency ( $p = 0.02$ ), and Sleep Disturbances ( $p = 0.001$ ).

Symptoms of stress, anxiety and PTSD-like symptoms increased as age lowered; on the contrary, sleep disturbances increased with age. In particular, the variable Age was a predictor of: (i) the DASS-21 Total Score ( $p = 0.002$ ) and the DASS-21 subscales Stress ( $p < 0.001$ ) and Anxiety ( $b = -0.029; t = -2.39; p = 0.017$ ); (ii) the IES-R subscales Avoidance ( $p = 0.010$ ) and Hyperarousal ( $p = 0.025$ ); (iii) the PSQI Total Score ( $p = 0.002$ ) and its subscales Subjective Sleep Quality ( $p = 0.003$ ), Sleep Duration ( $p < 0.001$ ), and Use of Sleeping Medication ( $p < 0.001$ ).

Being a healthcare worker was a predictor of the presence of psychiatric symptoms in terms of stress, anxiety, PTSD-like symptoms and sleep disturbances. In particular, being a healthcare worker was a predictor of: (i) the DASS-21 Total Score ( $p < 0.001$ ) and its subscales Stress ( $p < 0.001$ ) and Anxiety ( $p < 0.001$ ); (ii) the IES-R Total Score ( $p = 0.032$ ) and its subscale Intrusion ( $p < 0.001$ ); (iii) the PSQI Total Score ( $p < 0.001$ ) and its subscales Sleep Duration ( $p < 0.001$ ), Habitual Sleep Efficiency ( $p = 0.004$ ) and Daytime Dysfunction ( $p = 0.02$ ).

None of the psychometric variables was predicted by responders' educational level.

### Regression Analysis Within the Healthcare Workers Group

Again, the female gender was a predictor of the presence of psychiatric symptoms in terms of stress, anxiety, PTSD-like symptoms, sleep disturbances and burnout. In particular, the variable Gender was a predictor of: (i) the DASS-21 Total Score ( $p = 0.008$ ) and its subscales Stress ( $p = 0.008$ ) and Anxiety ( $p = 0.001$ ); (ii) IES-R Total Score ( $p = 0.024$ ) and its subscales Intrusion ( $p = 0.033$ ) and Hyperarousal ( $p = 0.01$ ); (iii) the PSQI subscales Subjective Sleep Quality ( $p = 0.014$ ) and Sleep Disturbances ( $p = 0.023$ ); (iv) the MBI subscale Emotional Exhaustion ( $p = 0.044$ ).

Sleep disturbances were higher at a higher age. In fact, the variable Age was a predictor of the PSQI Total Score ( $p = 0.004$ ) and its subscales Sleep Duration ( $p = 0.004$ ), Habitual

Sleep Efficiency ( $p = 0.021$ ), and Use of Sleeping Medication ( $p = 0.006$ ).

Working directly in contact with COVID-19 patients was a predictor of the IES-R subscale Intrusion ( $p = 0.021$ ) and the MBI subscale Emotional Exhaustion ( $b = 7.245, t = 3.337, p = 0.001$ ), both with CHW presenting more symptoms of intrusion and emotional exhaustion than NCHW.

### Regression Analysis Within the COVID-19 Healthcare Workers Group

Gender was a predictor of the DASS-21 subscale Anxiety ( $p = 0.01$ ): in particular, female gender predicted the presence of anxiety.

Age was a predictor of the PSQI subscale Use of Sleeping Medication ( $p < 0.001$ ), with use of medication increasing with age.

The time (measured in days) spent directly in contact with COVID-19 patients was a predictor of the PSQI subscale Sleep Disturbances ( $p = 0.005$ ): sleep disturbances increased with the time spent with COVID-19 patients.

Further details, including statistical indexes, are available in **Supplementary Material 3**.

## DISCUSSION

In this study, we aimed to evaluate the prevalence of specific psychiatric symptoms across the general population and within a specific subsample of healthcare workers in the region of Lombardy, during the first month of the COVID-19 outbreak in Italy. Although we acknowledge that our findings might have been biased by the relatively small sample size and the majority of women in the sample, we strongly believe that our preliminary data should be taken into account as a first evidence of the psychological distress experienced by the population of Lombardy during the COVID-19 outbreak and the consequent lockdown measures. In particular, our data revealed an estimated prevalence of 25.5, 35.9, and 33.3% for symptoms of anxiety, depression, and stress, respectively. Moreover, 13.9% of the whole sample appeared to be at risk of developing PTSD. Our results are in line with those obtained both in the Chinese population, at the epicenter of the pandemic (3, 4), and in the general Italian population (5). In the first few weeks of the outbreak, Moccia et al. (5) reported that 38% of the Italian general population presented mild to severe psychological distress, which was related to specific temperament characteristics (cyclothymic, depressive, anxious) and adult attachment style. Here we expanded these findings by assessing specific psychiatric symptoms (anxiety, depression, stress, PTSD-like symptoms, and sleep disturbances); furthermore, we selected the population of Lombardy, the most affected Italian region with the largest number of infected people and deaths, accounting for almost half of all cases in Italy. Although the Italian population endured several traumatic events in the last decades (e.g., the series of earthquakes and tremors hitting central Italy since 2009), the entity of the current pandemic and measures taken by Italian authorities to contain the outbreak are unprecedented in the country's modern history. Our study provides an early insight on the psychopathological

impact of this phenomenon in a large sample of individuals. Moreover, this is the first study to investigate participants' quality of sleep and over half the sample (57.6%) was found to be a "bad sleeper" during the first month of the outbreak. Insomnia has previously been reported in several studies on mental health during quarantine, albeit with lower prevalence: Lee et al. (14) reported insomnia in 34.2% of residents at Amoy Gardens, the first officially recognized site of the SARS, 2003 community outbreak in Hong Kong; similar results were found the same year for inpatients with SARS in Canada (15) and for contacts of patients with Ebola in Senegal in 2014 (16). However, this is the first study to specifically assess sleep disturbances during the COVID-19 pandemic, and the high prevalence of bad sleepers might depend on the wide range of sleep disturbances assessed by the scale employed. Indeed, the PSQI is not restricted to insomnia but includes nightmares, feeling too hot or too cold while sleeping and sleep-related daytime disturbances.

We also identified predictors of high stress and psychiatric symptoms to provide indications for early psychological or psychiatric interventions. Our findings suggest that female gender represents a risk factor for the development of stress, anxiety, and sleep disturbances, together with PTSD symptoms Intrusion-type, Avoidance-type, and Hyperarousal-type. This finding, which is in line with studies conducted both in the context of previous epidemics (17) and in the context of the COVID-19 pandemic in China (4), suggests early interventions should be tailored for women. On one hand, higher age was found to be a protective factor for the development of stress, anxiety, depression and PTSD-like symptoms in our sample. On the other, it was found to predict a globally worse quality of sleep and an increased tendency to use sleeping medications. Taken together, these findings suggest that earlier interventions should be focused on younger individuals to address emotional distress and older ones for sleep disturbances.

In this study, we also compared the prevalence of symptoms between the general public and a subsample of healthcare workers in Lombardy. Similar studies have been conducted in the Chinese population during the outbreak of the COVID-19 pandemic (3, 18, 19) and in the context of other epidemics in the past, such as SARS in Canada in 2003 (10). Previous studies consistently reported a higher risk of developing psychiatric distress and sleep disturbances in HW, when compared to the general public [a review, see Brooks et al. (20)]. To the best of our knowledge, this is the first study to investigate the psychopathological impact of the COVID-19 pandemic on healthcare workers in Italy. Our findings are in line with the aforementioned studies, showing higher levels of stress, anxiety and depression than the general population, together with more PTSD-like symptoms (in particular, intrusion-type and hyperarousal-type) and sleep disturbances. Female gender was confirmed to be a predictor of (i) higher levels of stress and anxiety, (ii) PTSD symptoms of Intrusion-type and Hyperarousal-type, and (iii) sleep disturbances in this sample. Although any attempt to frame these preliminary findings should be considered speculative, the

gender inequality issues that dominate Italian society might have a role. Recent research has shown women healthcare workers to be discriminated in terms of salary and career progression (21). Furthermore, Italian welfare and social policy regimes often fail to address the needs of working women, who might experience a higher burden of distress during an unprecedented emergency that generates existential and collective uncertainty.

Furthermore, working directly in contact with COVID-19 patients appeared to be a predictor of the levels of Intrusion-type PTSD symptoms, regardless of the sociodemographic characteristics of healthcare workers, such as age and gender. The IES-R subscale Intrusion assesses the presence of repeated thoughts about the traumatic event (e.g., "Other things kept making me think about it." "Pictures about it popped into my mind." and "I had dreams about it."). Reynolds et al. (10) used the same instrument to assess the prevalence of PTSD in a group of healthcare workers operating against SARS in Canada in 2003; they found that the average score of healthcare workers at the Intrusion subscale was 0.7 ( $\pm$  0.9), similar to the one found in our sample of healthcare workers ( $1 \pm 0.8$ ). In this study, we further showed that even after controlling for sociodemographic characteristics such as age and gender, healthcare workers directly in contact with COVID-19 patients are most at risk of developing Intrusion-type PTSD symptoms. Among CHW, female gender predicted higher levels of anxiety and higher age predicted an increased use of sleeping medications. Interestingly, the time spent directly in contact with patients with COVID-19 was a predictor of the PSQI subscale Sleep Disturbances. This scale evaluates the frequency of different causes of sleep perturbation, such as: "cannot breath comfortably," "feeling too hot/too cold," "having bad dreams." It seems, therefore, that sleep disturbances increased with time spent with COVID-19 patients.

Finally, burnout levels were assessed within healthcare workers and compared between CHW and NCHW. High levels of Emotional Exhaustion and Depersonalization were presented, respectively, in 38.2 and 39.8% of the healthcare workers; furthermore, 48% of HW presented low levels of Personal Accomplishment, suggesting a worse satisfaction on the workplace and a sense of inadequacy about one's ability to relate to patients. CHW presented higher levels of Emotional Exhaustion, a scale describing the feeling of having no more emotional resources to cope with the situation at work (e.g., "I felt emotionally drained from my work"). This is in line with the findings of Marjanovic et al. (22), conducted on a group of nurses coping with the epidemic of SARS in Canada: they showed that a minor contact with SARS patients, together with a greater trust in the available equipment and in the infection control initiatives, predicted lower levels of emotional exhaustion.

Besides the small sample size and the majority of women, already mentioned at the beginning of the discussion, we acknowledge the following limitations: first, the use of an online survey did not allow the researchers to time the participants while administering it, to explain the study objectives directly and to debrief the participants;

second, the recruitment via snowball sampling strategy and the lack of a longitudinal follow-up might limit the generalizability of our results; third, we did not distinguish between people affected and not-affected by COVID-19, and we did not assess specific personality and psychological characteristics of our sample; thus, predictors of psychiatric symptoms could only be explored within the known sociodemographic characteristics of our sample (age, gender, years of educations).

## CONCLUSION

In conclusion, our results showed that about a third of our sample, recruited amongst inhabitants of Lombardy, Italy, presented psychiatric symptoms of stress, anxiety and depression during the first month of the COVID-19 pandemic outbreak; more than half of the responders to our survey presented sleep disturbances, and 13% appeared at risk of developing PTSD. Furthermore, younger age and female gender appeared to be risk factors for the development of psychiatric symptoms. These results might prove useful to Italian authorities that will strategically coordinate the promotion of mental well-being in upcoming months. Specific interventions tailored to the needs of healthcare workers, especially those directly exposed to patients with COVID-19, are also warranted.

Since its emergence, the novel coronavirus disease of 2019 (COVID-19) has had enormous physical, social, and psychological impacts worldwide. The aim of this article was to identify elements of our knowledge on asbestos exposure and malignant mesothelioma (MM) that can provide insight into the psychological impact of the COVID-19 pandemic and be used to develop adequate interventions. Although the etiology of Covid-19 and MM differs, their psychological impacts have common characteristics: in both diseases, there is a feeling of being exposed through aerial contagion to an “invisible killer” without boundaries that can strike even the strongest individuals. In both cases, affected persons can experience personality dysfunction, anxiety, depression, and posttraumatic symptoms; helplessness, hopelessness, and projection of destructive thoughts onto external forces often emerge, while defense mechanisms such as denial, splitting, repression, and reduced emotional expression are used by individuals to contain their overwhelming anxieties. We believe that in both diseases, an integrated multidimensional intervention offered by hospitals and other public health services is the most effective approach to alleviating patients' and caregivers' psychological distress. In particular, we emphasize that in the context of both MM and COVID-19, Brief Psychoanalytic Group therapy can help patients and caregivers attribute meaning to the significant changes in their lives related to the experience of the disease and identify adaptive strategies and more realistic relational modalities to deal with what has happened to them. We also highlight the importance of developing a surveillance system that includes individual anamnestic evaluation of occupational risk factors for COVID-19 disease.

**Keywords:** COVID-19, mesothelioma, asbestos, psychological intervention, occupational risk

## INTRODUCTION

The novel coronavirus disease of 2019 (COVID-19) emerged at the end of 2019 in China and was classified as a pandemic by the World Health Organization [WHO] (2020a) on March 11, 2020. Since then, it has had an enormous impact on society, forcing health professionals to work long and exhausting shifts, researchers to close their laboratories, teachers to find new ways of delivering education, and workers to adapt to remote working if they have not lost their jobs (Castelnuovo et al., 2020). In many places, local authorities have had to take extreme actions to contain the spread of COVID-19, including lockdown of entire countries. The disease itself, fear of contagion, and measures to contain these have significantly affected people's occupational and social lives as well as their physical health and psychological well-being. The latter two specifically have been a major challenge for national health systems. In order to develop effective strategies to support patients and their families, it is critical to determine the impact of COVID-19 on their psychological well-being.

As professionals working in close contact with the health system and with specific expertise in contaminated areas across different scientific fields, we have been repeatedly asked whether our experience with exposure to various harmful substances and associated diseases—in particular, asbestos exposure, and malignant mesothelioma (MM)—can be useful for analyzing the psychological impact of COVID-19.

During our decade of work at Contaminated Sites, we have emphasized the need for an integrated approach to the care of patients with MM and their caregivers that involves clinical psychologists and psychotherapists with specific expertise in the field throughout the care process from diagnosis to therapeutic decision-making and up to the end of life (Granieri, 2015; Novello et al., 2016; Granieri et al., 2018). From this perspective, some of the authors have developed a psychological intervention termed Brief Psychoanalytic Group (BPG) therapy that consists of 12 1 h weekly therapeutic sessions for MM patients and their caregivers in the first months following diagnosis (Granieri et al., 2018). To date, this intervention has been implemented only in the National Priority Contaminated Site (NPCS)<sup>1</sup> of Casale Monferrato, a town in Northwestern Italy that is well-known for the high incidence of and mortality from MM among its residents. The high rates of mortality are associated with exposure to asbestos originating from the Eternit factory, one of the largest asbestos-processing companies in Europe (DeGiovanni et al., 2004; Ferrante et al., 2007; Bertolotti et al., 2008; di Orio and Zazzara, 2013). Our aim in developing BPG therapy was to establish a clinical model that can be adapted to different circumstances and diseases. Therefore, we have been asked whether this type of intervention can be successfully applied to COVID-19 patients as well as their caregivers.

The aim of this article was to identify elements from our findings on communities affected by asbestos exposure, and more specifically MM patients and their caregivers that can offer insight

into the psychological impact of the COVID-19 pandemic and guide the development of adequate psychological interventions.

## EPIDEMIOLOGIC DATA

The history of epidemiologic surveillance of COVID-19 and MM differs considerably. MM was identified as resulting from asbestos exposure in the 1970s, and its incidence has been monitored by means of a national registry established in the 1990s and implemented since 2002 that includes diagnosed cases since 1993. In contrast, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a novel virus whose health-related effects in humans were unknown until the emergence of the COVID-19 epidemic in China in late 2019. In Italy, nationwide epidemiologic surveillance of COVID-19 was established in January 2020.

Asbestos-related health effects are a major health concern in Italy, where about 3,748,550 tons of raw asbestos were used in a variety of industrial activities before it was banned in 1992. The Italian mesothelioma registry has documented more than 1,600 incident cases of MM per year and an annual standardized rate of the disease > 3 per 100,000 male inhabitants in recent years (Istituto nazionale per l'Assicurazione contro gli Infortuni sul Lavoro [INAIL], 2018). The median age at diagnosis in occupationally exposed males is 70.5 years, and the male-to-female (M/F) ratio is 2.6 (Marinaccio et al., 2018). The prognosis in MM remains poor. Occupational exposure to asbestos has been ascertained in most cases, and MM is the most prevalent occupational cancer, with an incidence and attributable fraction among cases ranging from 70 to 90% (Rushton et al., 2010).

Italy has one of the highest clinical burdens of COVID-19 in the world; as of November 12, 2020, there were 1,028,424 cases of infection and 42,953 associated deaths in the country (European Centre for Disease Prevention and Control [ECDC], 2020); 53,276 of these (18.39%) were healthcare workers (Istituto Superiore di Sanità [ISS], 2020a). Of all confirmed cases, the median age at diagnosis is 56 years and the M/F ratio is 1.2.

## MM AND COVID-19: DIFFERENCES AND SIMILARITIES IN ETIOLOGY

**Table 1** compares MM and COVID-19 symptoms. There are several differences but also some similarities between the two diseases in terms of etiology. One striking similarity is that both MM and COVID-19 are almost always associated with a specific causative agent—i.e., asbestos and SARS-CoV-2, respectively. We previously reported that many inhabitants of asbestos NPCSS besides patients and their families fear aerial contagion by an “invisible killer” (Guglielmucci et al., 2015; Granieri, 2016a). Indeed, occupational and environmental exposure to asbestos involves entire communities. As suggested in previous research, working at a Contaminated Site such as Casale Monferrato implies taking into account each inhabitant's unconscious representation(s) for choosing to continue residing in a place that is now recognized as potentially dangerous, their awareness of

<sup>1</sup>National Priority Contaminated Sites are areas identified based on analysis of contaminating agents as those that are a health and ecologic hazard, have an environmental impact, and cause damage to cultural and environmental assets (Legislative Decree 22/97; Ministerial Decree 471/99; Legislative Decree 152/2006).

being exposed to an environment contaminated as a result of a profit-driven logic, and the corruptive and collusive dynamics of the relationship with a factory that has for years contributed to the economic prosperity of the community (Borgogno et al., 2015; Granieri, 2016a, 2017). Inhabitants of NPCSSs can harbor intense feelings of guilt or shame, which increases the burden of an already traumatic situation. This is similar to the experience of the COVID-19 pandemic (Benziman, 2020; Nana et al., 2020) in which communities are fearful of contagion and worried about spreading the virus to their families, friends, or colleagues. The potential for each individual to be a vehicle of virus transmission can elicit blame, remorse, and regret. At the same time, people may engage in repulsive or isolationist behaviors toward those who are infected. Indeed, the way the community responds to a disease affects how people with the illness feel and behave: when an illness is viewed as something shameful, the affected person may experience more intense feelings of guilt and is at greater risk of social withdrawal.

Both MM and COVID-19 affect the respiratory system. The most common organ affected by MM is the pulmonary pleura, and its signs and symptoms include shortness of breath due to fluid around the lungs, abdominal swelling, chest wall pain, cough, and fatigue (Moore et al., 2010; American Cancer Society [ACS], 2016). Similarly, > 90% of COVID-19 cases hospitalized in Italy showed pneumonia and respiratory failure, with the most common symptoms being fever, dyspnea, cough, and fatigue (Brioni et al., 2020; Lomoro et al., 2020). However, the two diseases differ in their etiology. Asbestos fibers are released into the atmosphere and inhaled; although these may have a natural origin, anthropogenic activities are the predominant source of atmospheric asbestos fibers (International Agency for Research on Cancer [IARC], 2012). In contrast, SARS-CoV-2 is a virus that is transmitted through direct contact with respiratory droplets of an infected person that are expelled through speaking,

coughing, and sneezing. Less frequently, infection can occur through contact with a surface contaminated with the virus (Li Q. et al., 2020; Rothe et al., 2020).

This highlights one of the most significant differences between MM and COVID-19. The former is non-contagious and is associated with environmental or, more frequently, occupational exposure to asbestos and primarily affects workers in asbestos-cement plants and other industrial settings (Vimercati et al., 2019; Catelan et al., 2020). However, MM can also affect anyone living in an asbestos NPCSS or who comes into contact with asbestos fibers carried by another person (e.g., in a domestic context such shared living quarters). Indeed, MM has been diagnosed in wives/relatives of workers who were occupationally exposed to asbestos through inhalation of fibers attached to surfaces and contaminated clothes and handling of asbestos waste (Ferrante et al., 2007; Noonan, 2017). This can lead to a feeling of danger in relationships, particularly within a family (Granieri et al., 2018; Padilha Baran et al., 2019). Living in an environment where the risk of exposure to the toxic agent is omnipresent, together with the awareness of the large number of victims and outcome of MM, can cause individuals to enter a state of social and emotional detachment (Guglielmucci et al., 2014; Kozlowski et al., 2014), which is similar to the feelings aroused by COVID-19.

COVID-19 is a transmissible disease that is mostly linked to exposure in living environments, especially indoor and crowded places (Parvin et al., 2020; Zhao et al., 2020). In some cases, adult sons or daughters are responsible for infecting their parents, who are more likely to have fragile health (Mapelli, 2020). From a clinical standpoint, this can lead to the feeling of being a harbinger of death, especially in those who have infected elderly parents; this is similar to what we have encountered in many MM patients living in asbestos NPCSSs, who report being stigmatized as a “plague spreader” by the community and experiencing feelings of intense guilt for having contaminated their families by transporting a toxic agent from the workplace into their home (Guglielmucci et al., 2018; Wang et al., 2020).

COVID-19 is an ongoing challenge for occupational health (Burdorf et al., 2020), with several work environments associated with high risk of viral transmission. During the epidemic, the Italian National Workers Compensation Authority (INAIL) introduced the notion of work-related SARS-CoV-2 infection as an occupational injury and processed compensation claims from workers all over the country including healthcare and public administration workers, nursing home staff, and workers in other economic sectors. In the case of COVID-19 but not MM, the occupational source of the disease is primarily related to the provision of care to affected patients (Roggli et al., 2002; Koh, 2020; Lewandowski, 2020; Ng et al., 2020). Exposure to SARS-CoV-2 varies according to the work environment and the employee’s occupational role (Bai et al., 2004; Brooks et al., 2018). Healthcare workers have very high exposure to the virus as they are in constant contact with infected individuals, making theirs a high-risk occupation in terms of the impact on their mental health, especially during a pandemic (Bai et al., 2004; Maunder, 2004; Chen et al., 2005; Maunder et al., 2006; Wu et al., 2009; Hamouche, 2020; Ho et al., 2020; Huang and Zhao, 2020; Huang et al., 2020; Koh, 2020; Xiang et al., 2020; Zhu et al., 2020).

American Society of Clinical Oncology (2017) and World Health Organization [WHO] (2020b).

Despite their distinct etiologies, MM and COVID-19 may have a similar psychological impact on individuals: inhabitants of asbestos NPCSSs often report a feeling of being exposed without protection to a threat in their living environment while in a broader sense, a virus such as SARS-CoV-2 does not have any geographic boundaries (Granieri, 2016a; Consumer News and Business Channel [CNBC], 2020) as anyone can be infected, and there can be a new infection or death at any moment of any day (Lazzerini and Putoto, 2020; Montemurro, 2020). The idea of a “phantom of death” that can strike even the strongest person has been expressed by inhabitants of asbestos NPCSSs (Granieri, 2016a). This is still relevant to COVID-19, although it is less deadly than MM and is most lethal in vulnerable populations. Thus, some people who have not contracted COVID-19 consider their home as their only refuge, and it remains so only through avoidance of all contact with the outside world. This can lead to a self-confinement that persists even after the lockdown imposed by authorities is lifted (Banerjee and Rai, 2020).

Another important difference in the etiologies of MM and COVID-19 is that asbestos is linked to industrial production and human activities, whereas SARS-CoV-2 is an infectious agent with a natural origin. Humans are facing an increasing number of contaminants associated with manufacturing (Goldsteen and Schorr, 1982; Cline et al., 2008, 2014). Epidemics related to pathogens such as viruses or bacteria are an archaic threat but are unexpected and frightening, especially in Western countries. While asbestos exposure can be blamed on specific people or interests, the same is not true for COVID-19. A calamity without anyone to hold responsible is difficult to accept, and when it cannot be attributed to a known source, people tend to protect themselves from their fears and sense of helplessness by ascribing the problem to a more familiar and controllable cause out of a psychological need to identify a culprit. This can include scientific laboratories, China, 5G, governments, the healthcare system, God, or even other people who do not behave as they think appropriate for containing the spread of the virus. In this context, myths and misconceptions (“fake news”) about COVID-19 have emerged especially on the internet, which has fueled anxiety among people (Barreneche, 2020), forcing national and international public health agencies to counter the propagation of misinformation by refuting false claims and communicating correct information (Italian Ministry of Health [IMH], 2020; Istituto Superiore di Sanità [ISS], 2020b; World Health Organization [WHO], 2020a,b).

There are important similarities and differences between MM and COVID-19 in terms of the affected populations and disease onset time. The interval from exposure to asbestos to the development of symptoms in MM is on average  $\geq 40$  years; as such, this cancer mainly occurs in adults and older people (Marinaccio et al., 2007; Barone-Adesi et al., 2012; Reid et al., 2014). In contrast, people of any age can be infected with COVID-19, although older people are more vulnerable (Niu et al., 2020). Thus, older people have a higher risk of both diseases, but with a fundamental difference in timing: MM has a long latency period, whereas the latency of COVID-19 ranges from a few days to 2 weeks (Lauer et al., 2020). A diagnosis of either disease can be traumatic, but the trauma of COVID-19 is current while

that of MM is rooted in the past—i.e., people are paying the price for decisions that were made and events that unfolded many years prior.

Workers can limit their exposure to asbestos by using personal protective equipment (e.g., masks, gloves, and suits); additionally, the risk of exposure for workers and the general public can be minimized by providing information and promoting awareness of the health-related effects and through compliance with Italian law 257/1992 and related legislation that prohibits production involving asbestos and requires the implementation of asbestos remediation processes. The spread of COVID-19 can likewise be limited by providing information on the risks and health-related effects, thereby increasing public awareness of preventative measures and promoting the adoption of health-protective individual behaviors (e.g., hand-washing, wearing personal protective equipment, and social distancing and restrictions to outdoor gatherings) (Hellewell et al., 2020; Liu et al., 2020; Xu et al., 2020). However, these measures undermine a fundamental need of humans to socialize and engage in relationships, as well as norms of reciprocity, social trust, and support; they also require individuals and communities to utilize adaptive resources that rely on bonding, bridging, and linking aspects of social capital to respond to public health threats (Szreter and Woolcock, 2004) and pandemics (Chuang et al., 2015; Pitas and Ehmer, 2020). Although digital technology may enable the preservation of social connections during physical distancing, complete physical isolation (which can be quarantine or shielding in some contexts) can affect people’s emotional well-being and sense of self and life purpose (Brioni et al., 2020).

Various drugs have been tested for the treatment of MM, but to date there is no cure and the prognosis is poor. Vaccines for COVID-19 are under development but are not yet available. However, it should be noted that the mortality rate of COVID-19 is around 10%; that is, patients recover in most cases.

## PSYCHOLOGICAL IMPACT OF ASBESTOS EXPOSURE AND SARS-CoV-2 INFECTION

### Factors Negatively Affecting Mental Health

Asbestos exposure as well as SARS-CoV-2 infection has lasting and negative consequences for both physical and mental health (Taylor et al., 2008; Guglielmucci et al., 2015; Adhanom Ghebreyesus, 2020). Psychological effects of MM and COVID-19 are observed not just in patients and caregivers, but in the entire exposed population (Table 2).

### Asbestos Exposure

For the general population living in NPCSSs, the traumatic experience is linked to the workplace but affects the entire community because of the hazards associated with their living place. People who have experienced this type of collective trauma exhibit personality dysfunction, anxiety, and depression, as well as an increased frequency of dissociative experiences,

**TABLE 2 |** Psychological impact of COVID-19 and MM on exposed population, affected patients, and their caregivers.

(2012), <sup>p</sup>Xiang et al. (2020), <sup>q</sup>Zhang J. et al. (2020), <sup>r</sup>Zhong et al. (2020).  
*V* = Aspects cited, but without prevalence percentage.

somatization, and enactment entailing many somatopsychic features (Borgogno et al., 2015; Granieri, 2016a; Colizzi et al., 2020). People living in NPCSS have had to find a balance between immunitas (isolation and enclosure within one’s own identity boundaries to protect oneself from contamination by others) and communitas (opening up one’s life to others and facing the fear of contagion in the encounter with the other’s specificity) (Granieri, 2013, 2016b; Guglielmucci et al., 2015). One study of MM patients found that 32% had clinical or subclinical anxiety, 19% had depression, and 39.8% reported stress (Ugalde et al., 2012). In particular, psychological distress was linked to “Dealing with concerns about your family’s fears and worries” (62%). Social isolation resulting from depression, apathy, and stigma is an issue faced by patients and caregivers (Hughes and Arber, 2008; Guglielmucci et al., 2018). MM patients reported a high level of frustration and emotional distress in reaction to physical symptoms (Hughes and Arber, 2008). MM has a unique psychosocial impact because of the high symptom burden, incurability, rarity, and asbestos-related etiology (Bonafede et al., 2018). Awareness of the work-related origin of the disease leads to specific forms of emotional distress in MM patients such as anger, anguish, and worry, along with a sense of guilt for having risked their families’ health (Braun and Kisting, 2006; Guglielmucci et al., 2014). These negative emotions are difficult to express, and MM patients—as well as other people who are exposed to asbestos—may experience loss of their sense of belonging and control (Guglielmucci et al., 2018).

**SARS-CoV-2 Infection**

A pandemic can place a severe strain on society’s mental health resources, potentially leading to untreated mental health issues

(Douglas et al., 2009; Banerjee, 2020; Yang et al., 2020). Fear of infection is a common reaction to pandemics; the possibility of infection can cause pervasive worry over one’s health and potential to infect others, especially family members (Bai et al., 2004; Desclaux et al., 2017). People in high-transmission areas may exhibit personality dysfunction, anxiety, and depression, and somatic disorders may be exacerbated by the intense fear of infection (Mohammed et al., 2015; Ornell et al., 2020; Vigo et al., 2020; Xing et al., 2020). Symptoms of posttraumatic stress disorder or complicated grief disorder are also sequelae of global emergencies or disasters (Eisma et al., 2019, 2020; Colizzi et al., 2020; Fekih-Romdhane et al., 2020; Tang et al., 2020). Mental health issues during a pandemic are related to the adverse effects of prolonged social distancing, social isolation, and quarantine, and the illness and loss of loved ones (Garety et al., 2001; Wang et al., 2017; Bao et al., 2020; World Health Organization [WHO], 2020c). Stress, anxiety, depression, and insecurity have emerged over the many months of the COVID-19 pandemic, even in non-infected individuals (Duan and Zhu, 2020); the overall prevalence of depressive symptoms, anxiety, and stress symptoms among adults was found to be 44.1, 32.4, and 37%, respectively (Odriozola-González et al., 2020). Anxiety can be accompanied by feelings of anguish, social isolation, panic, and irritation; inability to concentrate; and sleep disturbance (Monterrosa-Castro et al., 2020). One study reported that 7.4% of the population showed various somatic symptoms related to chronic stress caused by the COVID-19 pandemic (Zhang J. et al., 2020). Unemployment, uncertainty, distress, the increasing death toll, and restrictions imposed by lockdown can cause a strain on mental health (Banerjee and Rai, 2020). Higher rates of psychological symptoms such as emotional disturbance,

depression, and posttraumatic stress were reported in people under quarantine than in those who had not been quarantined (Brooks et al., 2020). Moreover, in the case of mass quarantine, social isolation, worry, and an inability to tolerate distress can exacerbate anxiety and feelings of being trapped and losing control (Rubin and Wessely, 2020).

Although a pandemic affects the entire population, individuals who have experienced potentially traumatic events such as a threat to one's own health or loss of a loved one or their livelihood have a higher risk of developing mental health problems (Inchausti et al., 2020; Li Z. et al., 2020; Lima et al., 2020; Sritharan and Sritharan, 2020). Even families who have not been in direct contact with SARS-CoV-2 may experience indirect effects of the pandemic (Van Bavel et al., 2020). The drastic change in daily habits and restrictions on movement and activities in order to limit virus transmission may enhance worry and insecurity. Families are more likely to experience increasing social isolation, which may further exacerbate distress and increase susceptibility to stress, which can have harmful effects on both mental and physical health (Hawkey and Cacioppo, 2010). With the pervasive news coverage of the exponential spread of COVID-19, some people may wonder whether they or a loved one will inevitably contract or even die from the virus (Bertuccio and Runion, 2020; Wallace et al., 2020). An increased prevalence of depression (29.2%) and anxiety (20.8%) was observed in patients who had experienced COVID-19 infection (Zhang J. et al., 2020), and the incidence of fatigue 10 weeks after initial COVID-19 symptoms was 52.3% (Townsend et al., 2020). Patients may be fearful of the consequences of the infection, and those in quarantine may experience boredom, loneliness, and anger (Xiang et al., 2020). The rate of loneliness in a sample of people exposed to and affected by COVID-19 was reported to be 35.86%, and people who had COVID-19-related symptoms were more likely to develop psychiatric disorders and experience loneliness (Li and Wang, 2020).

For most individuals, the COVID-19 crisis has become a new normal. People are often confined in their homes in some cases unable to work and may feel cut off from close friends and family. The extreme social restrictions as well as the emergency situations that healthcare professionals face daily require that individuals make psychosocial adjustments to the long-lasting and substantial impact of the disease on their lives. Distress and loneliness can profoundly affect people's perception of events (Murthy, 2017; Berg-Weger and Morley, 2020; Cerami et al., 2020; Zandifar and Badrfam, 2020). A recent study showed that health professionals working to fight COVID-19 were more severely affected by mental health issues (Dai et al., 2020; Lai et al., 2020; Zhang W. et al., 2020; da Silva and Neto, 2021) and indirect traumatization (Li Z. et al., 2020) than other occupational groups.

## Caregiver Burden

A diagnosis of MM often requires the intervention of a family member, who assumes the role of caregiver and represents the support structure for the patient through the various stages of the disease (Hughes and Arber, 2008). This requires a radical reassessment of the primary needs within the family and can involve drastic changes in daily activities, work, and

relationships and reformulation of roles within the family. Such conditions can lead to significant distress (Maguire, 1985; Frank, 1991). Caregivers of MM patients are prone to experiencing depression, anxiety, hopelessness, somatic symptoms, social isolation, and financial stress (Adelman et al., 2014; Kleine et al., 2019). It was recently shown that caregivers of MM patients were more severely traumatized than the patients themselves, reporting higher frequencies of intrusive thoughts about death and exhibiting physiologic hyperactivation (Bonafede et al., 2020). The risk of depression is associated with use of avoidance strategies in caregivers, with a higher risk in females as compared to males (Bonafede et al., 2020).

The COVID-19 pandemic is already exacerbating caregiver responsibilities especially among women, with schools and childcare centers preventatively closed nationwide (Graves, 2020). Caregivers of COVID-19 patients face many challenges (Gulia et al., 2020). A recent study showed that long-term caregivers were more likely than short-term caregivers to have had a mental health condition prior to the COVID-19 pandemic, and both groups were more likely than non-caregivers (Park, 2020). Long-term caregivers also developed more somatic symptoms, and the rates of depression, anxiety, and stress symptoms in this group were 62.5, 20.5, and 36.4%, respectively (Dhiman et al., 2020). Psychological distress in caregivers is also exacerbated by social distancing and restrictions to individual mobility and social activities, as low social support is associated with higher levels of worry and depression (Zhong et al., 2020).

## Effects of Isolation

Isolation and social distancing have affected MM and COVID-19 patients in different ways. As noted above, MM patients often report feeling stigmatized as "plague spreaders" by the community (Granieri, 2013; Guglielmucci et al., 2014), and their caregivers also experience social isolation. The COVID-19 pandemic has added a new dimension to this isolation both at home and in hospitals. In order to prevent transmission, COVID-19 patients are usually admitted to a separate ward from other hospitalized patients and face a prolonged period of quarantine after discharge. Patients often die alone, and family members are alone in their mourning, without the possibility of experiencing the moments of death and the start of the mourning process. In some instances, people have been cremated because of a lack of space even if this was not their wish before their death, such that relatives were deprived of the last chance to see their loved one's body in repose. In other cases, people have been buried wearing only a white sheet, reminiscent of past ages when life was given a lesser value. The negative psychological repercussions of isolation are further complicated by the fact that people in need do not always seek help if they perceive that experiencing pain after a collective traumatic experience or after isolation is common (Meda and Slongo, 2020; Samson, 2020).

## Defense Mechanisms

Common responses to traumatization—which depend on the mind's degree of integration and quality of functioning—range

from a frozen affective internal state based on dissociation and denial, to resilient behaviors developed following exposure to the traumatizing event (Granieri et al., 2018; Bonafede et al., 2020). Defense mechanisms in inhabitants of asbestos NPCSS are mainly aimed at maintaining, protecting, modifying, or repairing the shared group identity. Denial, splitting, repression, and reduced emotional expression allow individuals to contain their overwhelming anxiety and profound feelings of shame and guilt associated with the fact that they have accepted something dangerous to themselves and their families (Granieri, 2016b). Indeed, although asbestos production had many benefits, in time it became evident that it endangered the population and would continue to harm those residing in the NPCSS (Guglielmucci et al., 2014). Inhabitants of asbestos NPCSS often direct their rage toward asbestos, institutions, delays in diagnosis, experimental protocols, or the complicated process of applying for financial compensation (Guglielmucci et al., 2015, 2018). This projection of destructive feelings onto external objects is a self-protective measure against internally directed anger (e.g., frustration at being incapacitated as a result of the disease, fear of impending mourning and death, or the feeling of not being understood) or attempts to conceal feelings of deep depression (e.g., discouragement, sadness, and helplessness) (Granieri and Borgogno, 2014; Granieri, 2015; Granieri et al., 2018). It is likely that that people exposed to asbestos and SARS-CoV-2 experience similar feelings of helplessness and hopelessness and have aggressive cogitations directed toward the source of the trauma. As in the case of inhabitants of asbestos NPCSS, during a pandemic people rely on defense mechanisms such as denial, splitting, repression, reduced emotional expression, and a frozen affective state. For example, at the time of writing this article, some people were still denying the risk of COVID-19 and refused to adhere to government-ordered protective measures. On the contrary, others are so fearful that they have adopted obsessive-compulsive defenses (i.e., cancelation) to avoid infection. The rapid evolution of the pandemic (Cucinotta and Vanelli, 2020), lockdown measures (Wilder-Smith and Freedman, 2020), and reports of fatal outcomes (Onder et al., 2020) may unintentionally encourage societal over-concern, which can degenerate into heightened anxiety and stress responses and the development of fictitious symptomatology, leading to misguided health-protective and help-seeking behaviors (Garfin et al., 2020).

## Experience of MM Patients During the COVID-19 Pandemic

The British Thoracic Society recently published recommendations on COVID-19 and lung cancer/mesothelioma (British Thoracic Society [BTS], 2020). As the latter patients are at risk of a fatal outcome if they contract COVID-19, particularly strict restrictions to their movements and social interactions are necessary. This can magnify the sense of isolation that they experience as MM patients, resulting in not just an additive but a synergistic interaction between the impact of their existing disease and that of the measures they have to follow to prevent another potentially fatal disease (Golden, 2020; Mannino, 2020).

## PSYCHOLOGICAL INTERVENTIONS IN RESPONSE TO COVID-19 BASED ON EXPERIENCES WITH MM PATIENTS AND THEIR CAREGIVERS

Specific preventive strategies at the community level must be provided to mitigate the psychological and psychosocial impact of the COVID-19 pandemic. Our experience with MM patients and their caregivers has highlighted the need for an integrated intervention that restores in patients a sense of control over and responsibility for their health and treatment and reduces psychological distress in both patients and caregivers, while providing them with strategies to actively face the disease (Granieri, 2015). This is also important for addressing the COVID-19 pandemic (Orrù et al., 2020; Salari et al., 2020).

Psychoanalysis has been increasingly focused on large-scale disasters (e.g., natural catastrophes, pandemics, accidents, war, and so on) and their devastating physical, psychological, and relational impacts (Rosenbaum and Varvin, 2007; Boulanger et al., 2013; Granieri, 2016a), with therapeutic techniques adapted to specific contexts without overshadowing the basic theoretical model (Ferenczi, 1928). The BPG intervention designed by some of the authors of this paper for MM patients and their caregivers in the asbestos NPCSS of Casale Monferrato (Granieri et al., 2018) can also be applied to COVID-19 patients.

We believe that BPGs can be particularly useful in those situations where very intense feelings compromise the possibility to give meaning to the experience of the disease. In both the context of MM and COVID-19, we propose that BPG interventions can help patients and their caregivers give meaning to the significant changes in their lives connected to the experience of the disease and the therapies, allowing them to identify more adaptive strategies and more realistic relational modalities to deal with what has happened to them.

BPG therapy consists of 12 1-h weekly group sessions led by two psychoanalytically oriented psychotherapists with specific expertise in this field. The time-limited intervention was designed for the first months following diagnosis, given that this period is characterized by intense traumatization, disintegration, splitting, and posttraumatic stress (Arber and Spencer, 2013; Guglielmucci et al., 2018), and considering the limited life expectancy and rapid deterioration of health of MM patients after the diagnosis. Similarly, the traumatic experiences of COVID-19 patients and caregivers related to the disease, quarantine, and care process must be addressed as soon as possible, even though video conferencing, given the physical condition of affected patients.

In both MM and COVID-19, the traumatic experiences of patients have an impact on caregivers. Thus, an intervention aimed at both groups may reveal unconscious processes connected to the overwhelming impact of the disease and the death anxieties aroused. Patients and caregivers are encouraged to project the traumatic emotions they are experiencing and can be helped in elaborating what is happening to them, in facing the fear of loss and death, and can receive help in translating their dissociated traumatic experience into thoughts and words (Granieri, 2016a, 2017; Granieri et al., 2018). Moreover, the

presence of other families with different psychological and relational characteristics allows participants to experience within the group that there are different strategies and processes—which may be more or less mature or dysfunctional—for managing the disease, as well as their physical and psychological consequences (García Badaracco, 2000; Granieri and Borgogno, 2014). Finally, co-conduction of the sessions by two psychotherapists with a specific clinical and professional expertise ensures greater focus on unconscious emotional content and simultaneous consideration of the intrapsychic, intrafamily, and interpersonal dynamics of the group.

BPG therapy progresses through different phases, each with specific aims (Granieri et al., 2018). In the initial phase (sessions 1–3), clinicians explore through narratives shared with the group how people relate to an ill body and its new needs, as well as anxieties and unconscious affect related to the danger of living in a contaminated site. In this phase, the co-conductors help the group identify a shared and recurring topic [somatopsychic focus (SPF)], a shared image/metaphor that links physical symptoms with emotions, feelings, and fantasies. In the central phase (sessions 4–8), the co-conductors help the group address the SPF through recognition of feelings and fantasies and their connection to their daily life experiences such as physical symptoms and medical treatments. Finally, the concluding phase (sessions 9–12) helps the group reconsider the narrative of the disease including its development among members, eventual absences or deaths, emotions shared with the group, and strategies used to face the disease. Additionally, the group explores fantasies about the end of the therapy and identifies what each member will take away from the work that was done during the sessions.

Under traumatic circumstances, the flow of time can sometimes collapse, leaving the individual stuck in the traumatic event and prematurely withdrawing from a life that has lost its appeal and attractiveness, becoming a sort of black-and-white photograph (Freud, 1915). BPG therapy can be particularly useful in situations where very intense feelings undermine the possibility of ascribing meaning to the experience of the disease. In the contexts of MM and COVID-19, BPG therapy can help patients and caregivers find meaning in the significant changes in their lives related to the disease and medical treatments, allowing them to identify more adaptive strategies and more realistic relational modalities to deal with their situation. Thinking together within the group may help participants to give meaning to the transformations in their lifestyle brought about by the experience of the disease and the related feelings. The psychotherapy group therefore represents a setting where listening of the specific personal modalities through which despair and helplessness related to the catastrophic impact of the

diagnosis are expressed, allows to share, allowing the participant to regain their self-confidence as well as trust in others and hope in life (Ambrosiano, 2016).

## CONCLUSION

MM and COVID-19 have different etiologies but are similar in some important respects, including a clear relationship with their etiologic agents, symptomology, and target organ (respiratory system), and psychological impact. We propose applying what we have learned from MM—specifically, the impact on patients, caregivers, and the general population—to the new challenge of COVID-19. The occupational origin of the disease (predominant in MM but still relevant in COVID-19) suggests the need to develop a surveillance system that includes an individual anamnestic evaluation of occupational risk factors for COVID-19. An occupational surveillance system was recently proposed for monitoring and preventing SARS-CoV-2 transmission in workplaces and improving the effectiveness of the insurance system (Marinaccio et al., 2020a). It will also be important to implement a control system that gives adequate consideration to the occupational dimension of risk to correctly manage vaccination policies (Marinaccio et al., 2020b). The BPG therapy model of intervention developed for MM patients and their caregivers can be successfully adapted to COVID-19 patients and caregivers. Living in asbestos-contaminated sites and in areas most affected by the pandemic both have important impacts on different levels of personal experience including being (health and somatopsychic well-being), belonging (the sense of being part of a community), and becoming (one's expectations for the future) (Fauci et al., 2012; Granieri, 2015). Thus, implementation of an integrated multidimensional intervention by hospitals and other public health services will be useful for addressing the psychological distress and needs of patients and caregivers affected by COVID-19.

## AUTHOR CONTRIBUTIONS

AG conceived of the presented idea. AG, IF, and MB contributed to the interpretation of the data, drafting and critical revision of the manuscript, giving an important clinical, and intellectual contribution. AM, II, and DM contributed to the interpretation of the data and critical revision of the manuscript. All authors agree to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved. All authors contributed to the article and approved the submitted version.

**Background:** Aggressive quarantine and lockdown measures were implemented as protective public health actions during the coronavirus disease 2019 (COVID-19) pandemic. Assessing the psychological effects associated with these measures is an important attempt to inform local policymakers in an early stage. Yet little is known about these effects, specifically depression, among the Palestinians. This study aimed to assess the prevalence and predictors of depression among the Palestinian community during this pandemic.

**Materials and methods:** A cross-sectional web-based survey throughout social media (Facebook and Instagram) was carried out using an anonymous online questionnaire. The validated and standardized depression, anxiety, and stress scale (DASS) was used to measure depression severity. A snowball technique recruiting the general public living in Palestine was conducted. Data were collected between 6 and 16 April 2020, which corresponded to the middle interval of strict massive lockdown in Palestine on 22 March to 5 May 2020. Multinomial logistic regression model was developed to predict depression severity.

**Results:** About 2,819 respondents filled out the questionnaire. Depression prevalence was (57.5%;  $n = 1,621$ ). Out of them, 66% had mild/moderate severity, and 34% had severe/extremely severe degree. Depression severity was negatively associated with age {mild/moderate degree [OR (95% CI) = 0.98 (0.97–0.99)] and severe/extremely severe [OR (95% CI) = 0.96 (0.94–0.97)]} degrees compared with normal degree. Males were significantly less likely to have higher depression than females {mild/moderate degree [OR (95% CI) = 0.69 (0.57–0.85)] and severe/extremely severe [OR (95% CI) = 0.52 (0.40–0.86)]} degree. However, those who reported having inadequate food supply and lesser monthly incomes were more likely to have a higher degree of depression as compared with normal degree. Single persons were significantly more likely to have mild/moderate depression than those in a relationship [OR (95% CI) = 1.31 (1.05–1.64)].

**Conclusions:** High depression prevalence (57.5%) among the Palestinian community during the COVID-19 pandemic is a growing public health concern. It is essential to provide psychological counseling and treatment during and after the pandemic for the

targeted people at high risk (young age/female gender) who were affected psychologically. Strategic long-term policy to address pandemic ramifications, including depression, by implementing comprehensive interventions taking into account socioeconomic disparities, vulnerability, and inequities, is crucial to emerge from this crisis in Palestine.

**Keywords:** COVID-19, depression, Palestine, quarantine, lockdown

## BACKGROUND

Quarantine was adopted as an obligatory means of separation and to restrict the movement of people who have potentially been exposed to a contagious disease and to limit disease spread (1). It has been used for centuries to contain infectious diseases such as cholera and the plague (2). Most recently, quarantine has been used in the coronavirus disease 2019 (COVID-19) pandemic (3).

Separation from loved ones and the loss of freedom during the quarantine are often unpleasant experiences (3), and they create dramatic psychological and emotional effects on some people, such as depression (2). Age, educational level, gender, marital status, living with other adults, having children, and other factors may play a role in psychological problem development such as depression (3). Anxiety and mood disorders are the most common mental health problems in the general population all over the world, and there are important connections between anxiety and depression and the occurrence of viral diseases (4). Therefore, the successful use of quarantine as a public health measure requires us to reduce and manage, as far as possible, the negative effects associated with it (3).

During the COVID-19 quarantine in Southwestern China, nearly 14.6% of study participants had depression, 8.3% had mild depression, 5.2% had moderate depression, and 1.1% had severe depression. The study also found that those who are single or very worried had significantly a higher level of depression than others. But those with “very good” self-perceived health and high income had lower levels of depression than others (4). Another multicenter survey involving 1,563 medical staff found the prevalence of depression to be 50.7% (5).

During the COVID-19 outbreak, Palestine had undergone massive quarantine for nearly 43 days (from 22 March to 5 May 2020). However, the psychological impact of this quarantine and its related lockdown measures among the Palestinian community is unknown. Aggressive quarantine and lockdown measures were implemented globally as precautionary and protective public health actions during the COVID-19 pandemic. Assessing the psychological effects associated with these implemented measures is an important research attempt to inform local policymakers on the evidence in an early stage. Yet no data are available regarding the level of depression among the general population in Palestine, and to the best of our knowledge, no study had evaluated this issue, specifically depression, among the Palestinian general public. This study seeks to assess prevalence and predictors of depression severity among the Palestinian community as the first important step for creating an early targeted intervention and helping people return to normal life.

## MATERIALS AND METHODS

### Study Population, Sample, and Setting

The target population comprised all people who are 18 years or older and currently living in the West Bank, Gaza Strip, and East Jerusalem. We adopted a cross-sectional survey design to find the prevalence of depression among the public and to identify possible risk factors during the pandemic of COVID-19 by using an anonymous online questionnaire. A snowball sampling strategy focused on recruiting the general public living in Palestine during the pandemic was conducted. The online survey was first disseminated on Facebook and Instagram to friends, and they were encouraged to pass it on to others.

### Procedure

As the Palestinian Government recommended the public to minimize face-to-face interaction and isolate themselves at their homes, potential respondents were electronically invited. All of them completed the questionnaires in Arabic through an online survey. Expedited ethics approval was obtained from the Institutional Review Board (IRB) at An-Najah National University (Faculty of Medicine and Health Sciences). Privacy was strictly protected during the procedure. The purposes of the study and information about it were posted on the first page of the questionnaire. All respondents provided online informed consent before starting the questionnaire. The IRB approved our request for a waiver of documentation of this method of obtaining consent. Data collection took place over 10 days (6 to 16 April 2020), which corresponds to almost the middle interval of the massive quarantine in Palestine (22 March to 5 May 2020).

### Survey Development

Previous surveys on the assessment of mental health during quarantine in outbreaks were reviewed (5). The authors included additional questions related to the COVID-19 outbreak in Palestine. The structured questionnaire consisted of questions that covered several areas: (1) informed consent, (2) demographic data, (3) knowledge and concerns about the quarantine, (4) precautionary measures against the COVID-19, and (5) depression, anxiety, and stress scale (DASS) form in Arabic. DASS is an instrument that included 42 self-report items designed to measure the three related negative emotional states of depression, anxiety, and tension/stress. A short version, the DASS21, is available with seven items per scale (6). DASS showed excellent Cronbach's alpha values of 0.81, 0.89, and 0.78 for the subscales of depression, anxiety, and stress, respectively (7).

An Arabic-language version of the DASS was used. The form was adapted from a published study over the psychometric

**Table 1 |** Depression severity original scores and the study re-adjusted scores.

Severity	Depression severity original scores
Normal	0–9
Mild	10–13
Moderate	14–20
Sever	21–27
Extremely sever	+28

**Scores in this study were re-adjusted as:**

Severity	Depression severity re-adjusted scores
Normal	0–9
Mild/moderate	10–20
Sever/extremely sever	+21

properties of an Arabic version of the DASS, in which the results supported the universality of depression, anxiety, and stress across cultures and thus provided initial support for the psychometric properties of the Arabic DASS (8).

A pilot study was performed on a small group of volunteers for feedback to identify ambiguities and difficult questions and to record the time needed to complete the online questionnaire, and therefore, very minor rewording was made to clarify some words and questions related to the COVID-19 pandemic and quarantine.

### Statistical Analysis

DASS contains three subscales, each composed of seven questions. The Depression subscale assesses dysphoria, hopelessness, devaluation of life, self-deprecation, lack of interest/involvement, anhedonia, and inertia. Subjects were asked to use 4-point severity/frequency scales to rate the extent to which they have experienced each state over the past week, as follows:

- 0 = Did not apply to me at all.
- 1 = Applied to me to some degree, or some of the time.
- 2 = Applied to me to a considerable degree or a good part of the time.
- 3 = Applied to me very much or most of the time.

Depression scores were calculated by summing the scores for the seven questions regarding depression in the DASS21 scale. The scores were between 0 and 21, and then they were multiplied by 2, so the final score for each participant was between 0 and 42. Scores and categories are shown in **Table 1** (6).

DASS scores may be presented in five categorical levels. However, in this study, and according to standardized cutoffs, we merged mild with moderate and severe with extremely severe cutoff scores for depression (**Table 1**) to facilitate the multivariate analysis, as some cells showed less than five cases in some categorical independent variables, and this is usually accepted (9).

Data were entered into the 27th version of IBM SPSS (IBM SPSS Statistics for Windows, Version 27.0. Armonk, NY: IBM Corp). In this study, 2,819 individuals completed and returned the questionnaire. Descriptive analysis, median, mean, and standard deviation for continuous variables, and frequencies/percentages for categorical independent variables were conducted. Independent *t*-test was used to test for

significance among continuous variables and the chi-square test for categorical variables. Variables that showed significance in the bivariate analysis (*P*-value <0.05) were included in a multinomial logistic regression model to predict the factors associated with each depression severity degree and presented as odds ratio and 95%CI.

## RESULTS

### Characteristics of the Study Population

In this study, 2,819 individuals completed and returned the questionnaire (**Table 2**). The mean age of respondents was 29.47

years with SD of 10.97. We divided the population into three groups according to age: young (18–35), middle (36–53), and elderly (>53) age groups. Nearly 73.9% were in young age, and only 4% of participants were elderly. More than two thirds (72.6%) of respondents were female. Almost half of them (51.4%) were single. The majority of respondents live in the West Bank (83.5%), and only 9.6% live in Gaza. Around 55.1% ( $n = 1,552$ ) of participants had an income of 2,000–5,000 New Israeli Shekels (555–1,388 USD) per month.

Most of the participants (78.4%) were currently studying in college or have graduated recently. On the other hand, 10% of them are studying a master or doctorate degree. Almost one quarter (24.6%) were smokers, and only 11.8% were health-care workers. About 45.5% reported that they had a high-risk individual living with them currently.

Results showed that 1,144 (40.6%), 1,261 (44.7%), and 1,283 (45.5%) of respondents had low levels of stay-at-home commitment, commitment to inside home precautions, and understanding of quarantine, respectively.

### Quarantine Characteristics of the Population

As shown in **Table 3**, 98% of respondents believed that quarantine is important, and 2,173 (77.1%) expressed that they are afraid of getting the COVID-19 or transmitting it to others. Only 14.9% of respondents had jobs that required them to go outdoors, and only 85 (3%) had at least one of their relatives with confirmed COVID-19. The two most common sources of information about quarantine and precautions were social media and television or radio (59.5 and 18.6%, respectively). Nearly 80.2% admitted that they are properly informed about the quarantine. In addition, 29.3% reported that they had inadequate food supply to withstand the quarantine period.

Quarantine duration ranged from <2 weeks at 6.6% to more than 4 weeks at 35.4%. Nearly 38.2% used to spend between 6 and 10 h outside the home before quarantine, 20.7% spent <2 h, and only 13.6% spent more than 10 h (see **Table 3** for more details).

### Prevalence of Depression in Bivariate Analysis

The prevalence of depression was 57.5% ( $n = 1,621$ ; 38% with mild/moderate depression and 19.5% with severe/extremely severe).

In the bivariate analysis, statistically significant associations were found between depression severity and each of age, sex, social status, residency, geographic area, educational level, monthly income, smoking, and the presence of a high-risk individual ( $P$ -value < 0.05; see **Table 2**). Females represented the majority in all depression degrees as compared with males with 67.5, 75.9, and 78% in normal, mild/moderate, and severe/extremely severe degrees, respectively (**Figure 1**;  $P$ -value < 0.001). Similarly, the young age group (18–35 years) represented the majority in all depression degrees with 65.1, 78.2, and 84.7% in normal, mild/moderate, and severe/extremely severe degrees, respectively (**Figure 2**;  $P$ -value < 0.001).

**Table 3 |** Bivariate analysis of quarantine characteristics with depression severity ( $P$ -value presented was Chi-square significance;  $N=2819$ ).

Self-rating of quarantine commitment	2,819 (100)	Mean = 8.43 SD = 1.9	Mean = 8.55 SD = 1.7	Mean = 8.54 SD = 1.9	0.230

\*It means that the p-value is statistically significant.

Nearly 48.5% of the total refugee camps residents had mild/moderate depression, and 7.3% had severe/extremely severe degree of depression; and this represents the highest percentage distribution as compared with city and village residents among depression severity degrees.

West Bank residents represented the majority among all depression degrees as compared with Gaza and Jerusalem (86.4% of the normal, 82.5% of the mild/moderate, and 79.1% of the severe/extremely severe degrees). Statistically significant associations were found between depression severity and having

enough food supply to withstand quarantine, average hours out of the home before quarantine, and commitment to inside home precautions ( $P$ -value < 0.05; see **Table 3**).

## Multinomial Regression Analysis of Depression Severity Predictors

Multinomial regression model for the variables associated with depression severity is shown in **Table 4**. As shown, depression severity was negatively associated with age {mild/moderate degree [OR (95% CI) = 0.98 (0.97–0.99)]} and {severe/extremely severe [OR (95% CI) = 0.96 (0.94–0.97)]} as compared with normal degree. Males were significantly less likely to have a higher depression degree as compared with females {mild/moderate degree [OR (95%CI) = 0.69 (0.57–0.85)]} and {severe/extremely severe [OR (95%CI) = 0.52 (0.40–0.86)]}. However, those who reported inadequate food supply were associated with a higher degree of depression compared with normal degree. Single persons were significantly more likely to have mild/moderate depression compared with those in a relationship [OR (95% CI) = 1.31 (1.05–1.64)].

Those with a monthly income of <2,000 New Israeli Shekels (<555 USD) were significantly more likely to have mild/moderate depression than those with normal degree and higher monthly incomes [OR (95% CI) = 1.48 (1.11–1.97)]. Those who do not have a high-risk individual living with them were significantly less likely to have severe/extremely severe depression than normal degree [OR (95% CI) = 0.69 (0.56–0.85)]. Moreover, those who reported that none of their relatives were infected with the COVID-19 and those who are not afraid of being infected were inversely related to a higher degree of depression severity (see **Table 4**).

Being not properly informed about quarantine was a significant positive predictor of severe/extremely severe depression compared with normal degree [OR (95% CI) = 1.56 (1.20–2.02)]. On the other hand, those who usually spend lesser hours (2–6 h) out the home before quarantine were significantly less likely to have severe/extremely severe depression compared with more hours (>10 h) and normal degree [OR (95% CI) = 0.59 (0.41–0.85)]. However, those who reported a low level of commitment to inside home precautions were more likely to have mild/moderate depression [OR (95% CI) = 1.20 (1.01–1.43)].

It should be noted that residency, geographic area, educational level, and source of information did not remain significant after adjusting for other variables in the multinomial regression model.

## DISCUSSION

In this study, the prevalence of depression among the Palestinian community during the COVID-19 pandemic was found to be 57.5% (38% with mild/moderate depression and 19.5% with severe/extremely severe). A cross-sectional general population study of 916 Palestinian adults in 2007 reported the 1-month prevalence of major depressive episodes was 10.6% (10). Our study reported a five-fold increase in the prevalence of depression during the COVID-19 in Palestine. This finding represents a

high degree of depression at the general population level in Palestine. Moreover, a recent study in Italy reported a prevalence of 17.3% of depression among the Italian general population during the COVID-19 pandemic (11). In Spain (12), a similar study evaluated the prevalence of depression among the Spanish general population and found that depression was around 19%. Whereas in the UK, the prevalence was 22.12% during the COVID-19 pandemic among the general population (13).

A possible explanation for our finding of a high level of depression could be that in Italy and Spain the prevalence was evaluated in the early stages of the COVID-19 pandemic, while in this study, it has been evaluated at the late stage of the pandemic. Moreover, Palestine is classified as a low- to middle-income country (14) and has a low socioeconomic status with a special geopolitical situation, which could add to the negative mental health effects during the COVID-19 in Palestine. Another study in China (5) reported a prevalence of depression during the COVID-19 for inpatient health questionnaire to be around 50.7%, which is near our findings. This raises an alarming sign in Palestine, as the participants were not COVID-19 patients, and the result is higher than that reported among patients in other countries. We found no study from the Arab world that evaluated depression during the COVID-19 for comparison, and this study could be a starting point for other future studies to cite from the Arab world.

Another important finding in this study was that females were associated with mild/moderate degree and severe/extremely severe degree of depression as compared with males. This is consistent with two studies during the COVID-19 lockdown measures that showed that females were more vulnerable to negative emotional outcomes such as depression (11, 15). The cultural background and the fact that home responsibility relied mainly on females in Palestine could add to more emotional and depressive effects among females during the lockdown measures. Moreover, females are a vulnerable group in the Palestinian community. Furthermore, females are the main component of the young age adult group in this study, and this might partially contribute to the high prevalence of depression among this gender-age group. Interestingly enough, age showed an inverse relationship with depression severity during the lockdown and massive quarantine in Palestine during the COVID-19. Our results are in accordance with those of similar studies in Italy and Spain conducted during the same pandemic (11, 12). It is noteworthy that young adults in the Palestinian community represent university students mainly, and as a result of lockdown, online educational activities were implemented to continue the ongoing academic semester. This group of young adults had to deal with the dramatic changes in requirements to pass the academic semester. At the same time, this group of the young population includes newly graduated adults who are still unemployed or newly employed, so they tend to have less sustained monthly income than older adults. This finding should be taken seriously by decision makers since the young age group is the main productive group in Palestine and worldwide. Therefore, losing productivity might have impacts not only at the personal level but also at the national socioeconomic level of the country.

Those who do not have a high-risk individual inside the home were less likely to have severe/extremely severe depression. This result was also found in the UK (13), which demonstrated that people who have a relative or family member with a preexisting medical condition were more likely to have depressive symptoms.

Monthly income was inversely related to the degree of depression. This is consistent with a study conducted in Southwestern China (4) that reported that a high average household income group had a significantly lower level of depression than a low average household income group due to the economic impact of the COVID-19 and failure to cope with financial problems. In another study in the UK (13), a significant association was also found between loss of income and depression. However, those who reported having inadequate food supply were more likely to have a higher degree of depression compared with normal degree. This may be because those people who reported a shortage of food supply were potentially from low-income group or they lost their jobs as a consequence of lockdown measures. Thus, they had been exposed to a difficult situation without financial support.

Single persons were more likely to have mild/moderate depression than those in a relationship. These findings are congruent with other results that come from China (4). Single persons could be away from their beloved ones, and this might contribute to more depressed emotions among the general population in Palestine. Moreover, those who reported that none of their relatives were infected with the COVID-19 and those who were not afraid of being infected were less likely to have a higher degree of depression severity. All these factors could stimulate another psychological burden on people, which may explain why they showed a significant association with the higher degree of depression. Furthermore, those who usually spend lesser hours (2–6 h) out the home before quarantine were less likely to have severe/extremely severe depression than those who spend more hours (>10 h) and normal degree. This could be because those who used to go outside the home more frequently tend to find more difficulty engaging in inside home activities than persons who usually spend less time outside home.

It is worth mentioning that in our study educational level had no impact on depression severity. This contradicts other similar studies that found a significant association between educational level and depression degree (4, 11, 15). In our study, this could be because those who have a secondary level of education or less were not engaged in online learning, and they are dependent on their parents in the Palestinian community. However, those with a college degree and higher might have higher socioeconomic status and a stable monthly income.

It should be noted that the depression severity may be also attributed to the unclear future and whether or not the adopted governmental plan will overcome the build-up of troubles and consequences of the extreme lockdown. However, we did not investigate these factors in this study, and therefore, further future studies on this perspective might be needed.

Our study could be limited by the sampling technique, and therefore, selection bias might be encountered. For example, it was noticed that 72.8% of the sample were female which might overestimate the depression severity and therefore, our depression rates should be interpreted with caution.

Furthermore, due to social distancing during quarantine, we disseminated the survey on social media, and this might in part exclude people who did not have access to the internet and social media. On the other side, this was the only possible procedure during the lockdown measures, and it was useful in collecting the required information as fast and as safely as possible. This study was a cross-sectional web-based survey, and therefore, recall and/or systematic biases might have been occurred where overestimation or underestimation of some measures might have been occurred due to self-reporting. It should be noted however that this study has several strengths, including a large sample size and the sampling timeframe that corresponded to the peak surge of the COVID-19 cases in Palestine, which had 613 cases and 5 death when this paper was being written (16). Taking into account the worldwide nature of the risk in this pandemic, we strongly believe that these data could provide important and useful information to be generalized to other countries and to future pandemics.

## CONCLUSIONS

High rates of depression and various predictors of its severity among the Palestinian community during lockdown periods of the COVID-19 pandemic were reported. The high prevalence of depression (57.5%) forces the authorities and decision makers to immediately intervene to address the effects of this concerning rise among Palestinians along with the public health measures taking place. Strategic long-term policy to address the pandemic ramifications, including depression, by implementing comprehensive interventions taking into account the socioeconomic disparities, vulnerability, and inequities are crucial to emerge from this crisis in Palestine mainly among the young age group and female gender, who showed more vulnerability to depression.

We strongly believe that this study could help in generating socioeconomic and health initiatives to prevent and manage the pandemic's depression severity. It is crucial for communities to move forward and emerge from the crisis impacts. Furthermore, it is essential to provide psychological counseling and treatment during and after pandemic periods for these groups in Palestine. A post-pandemic assessment of depression among the Palestinian community is recommended to highlight any improvement or deterioration.

## DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/supplementary materials, further inquiries can be directed to the corresponding author/s.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by IRB of An-Najah National University. All respondents provided online informed consent before starting the questionnaire. The IRB approved our request for a waiver of documentation of this method of obtaining consent.

## AUTHOR CONTRIBUTIONS

HA, TA, NY, and MH-Y designed study protocol and drafted the manuscript. HA coordinated the study protocol and conducted the statistical analysis. TA, NY, and MH-Y collected the data. All authors contributed to the article and approved the submitted version.

## ACKNOWLEDGMENTS

We are grateful to all participants in this study for the time they devoted. Sincere thanks to Dr. Adnan Shehadeh, Director of the Center of Excellence in Teaching and Learning at Palestine Polytechnic University, for the professional editing and revision of the English language of this manuscript.

**Objectives:** The aim of this study was to assess coronavirus disease 2019 (COVID-19) anxiety and posttraumatic stress disorder (PTSD) symptoms in the hospital staff, as well as to identify protective factors of COVID-19 anxiety once the coronavirus pandemic was announced in Poland.

**Methods:** 90 healthcare workers from the hospital in Poland completed validated self-report questionnaires assessing self-efficacy, emotional control, and PTSD symptoms; a questionnaire assessing COVID-19 anxiety; and a socio-demographic questionnaire. A multiple linear regression was conducted to assess the effects of gender, being directly vs indirectly exposed to patients, and general self-efficacy on COVID-19 anxiety.

**Results:** The analysis showed that female ( $\beta = -0.271$ ,  $p < 0.01$ ) healthcare professionals indirectly exposed to patients ( $\beta = -0.336$ ,  $p < 0.01$ ) and those who reported lower levels of general self-efficacy ( $\beta = -0.295$ ,  $p < 0.01$ ) have a stronger tendency to experience COVID-19 anxiety [ $R^2 = 0.301$ ,  $F(3,89) = 12.34$ ,  $p < 0.01$ ].

**Conclusion:** The findings show the importance of self-efficacy for dealing with COVID-19 anxiety. The internal coping strategies should be introduced to healthcare workers.

**Keywords:** COVID-19, healthcare workers, disaster, fears, protective factors

## INTRODUCTION

Coronavirus disease 2019 (COVID-19) is thought to be a highly infectious disease. It is primarily transmitted by respiratory droplets and has a similar incubation time and generation time as SARS coronavirus (SARS-CoV) (Wilder-Smith and Freedman, 2020). The first case of COVID-19 had been reported in Wuhan City, China, on 9 January 2020 (Lu et al., 2020). Despite Wuhan City

being locked down within 2 weeks after COVID-19 had been reported, the novel virus has soon reached other provinces in China and neighboring countries. By 11 March 2020, the World Health Organization (WHO) declared COVID-19 a global pandemic. At the time we started writing this article (13 April 2020), there were over 1.4 million confirmed cases of COVID-19 and 116,052 deaths globally; at the time we finished it (12 June 2020), there are 7,616,598 confirmed cases of COVID-19 and 424,227 deaths globally (Khasawneh, 2020; Medonet, 2020; Worldometers, 2020). 215 countries are affected by the novel coronavirus (Worldometers, 2020), including Poland, where the first case of COVID-19 had been reported on 4 March 2020, and the COVID-19 pandemic had been announced on 20 March 2020.

It is worth bearing in mind that since the Ebola virus pandemic back in 1976, COVID-19 pandemic has been the one and only pandemic outbreak from among 25 recognized EVD pandemics, which “spread all over the world” and fulfilled the criteria of a “pandemic” (Espinola et al., 2016; Rabelo et al., 2016; Shultz et al., 2016). Widespread outbreak of COVID-19 has frightened and alerted the whole world. This might be partly due to media, which has been constantly updating the global population with the news on COVID-19 outbreak. Fear behaviors in a situation of a disaster spread rapidly and contagiously (Espinola et al., 2016; Shultz et al., 2016), which has resulted in a global panic (Vellingiri et al., 2020). In Poland, the “pandemic fear” had started before the pandemic was announced. For example, “panic buying” (Sim et al., 2020) had started before the lock-down on 11 March 2020.

COVID-19 affects both the physical and mental health of the affected population (North et al., 2004; Khan et al., 2020; Lai et al., 2020; Super et al., 2020). During a disaster, mental disorders are often diagnosed in an affected population, such as adjustment disorders, depression, posttraumatic stress disorder (PTSD), anxiety disorders, non-specific somatic symptoms, and substance abuse (North, 2002; North et al., 2004; Liu et al., 2006; Tsai et al., 2007; Frankenberg et al., 2008; Hollifield et al., 2008; Wu et al., 2009; Math et al., 2015; Bidzan-Bluma et al., 2020; Lai et al., 2020; Khasawneh, 2020; Rajkumar, 2020; Super et al., 2020).

Researchers have assigned PTSD as the signature diagnosis among post-disaster mental morbidity (North, 2003; Math et al., 2015; Ogińska-Bulik and Kraska, 2017; Moghadam et al., 2020). The main PTSD symptoms are intrusion (reliving the traumatic event over and over again in dreams or memories), avoidance (of feelings, conversations, stimuli, or actions related to the event experienced), and agitation (trouble with focusing, but also falling asleep, general irritability, strong emotional reactions in response to sudden stimuli, constant sense of threat) (World Health Organization [WHO], 1992; Juczyński and Oginiska-Bulik, 2009; Juczyński, 2012; Rybojad and Aftyka, 2018). According to DSM-5 (2013), diagnosis of PTSD includes experiencing repeated or extreme exposure to aversive details of the traumatic events, occurring usually during performance of professional duties. In the case of disasters, this mainly refers to the emergency services (police, military, fire fighters, paramedics) (James, 2011a,b; Ogińska-Bulik, 2013, 2016; Ogińska-Bulik and Juczyński, 2016; Rybojad and Aftyka, 2018). In relation to COVID-19, this applies primarily to the medical staff providing

direct help to the infected patients and those under the threat of developing the disease. However, the incidence of PTSD in these groups is highly diversified and depends on factors such as the scope of exposure, social support, and training (James, 2011a,b; Ogińska-Bulik, 2013; Ogińska-Bulik and Juczyński, 2016). In particular, demographic characteristics such as age and gender are associated with different rates of PTSD, with younger people and women more likely to develop this stress disorder. Interpersonal and psychological characteristics of the individual, such as social support and self-esteem, have also been implicated in the onset and course of PTSD (Adams and Boscarino, 2006).

The medical personnel, including paramedics, physicians, nurses, obstetricians, nursing aids, psychologists, but also medical analysts, radiology professionals, and cleaning, transport, and technical staff, are all involved in a particular way in preventing the consequences of COVID-19 pandemic and performing crisis interventions. Healthcare workers should be regarded as a highly exposed group with a higher risk of psychiatric symptoms during the COVID-19 pandemic. The risk factors among healthcare workers include female gender and being a frontline worker among others (Vindegaard and Benros, 2020).

Among Chinese healthcare workers exposed to COVID-19 (from clinics or wards for patients with COVID-19 in multiple regions of China), women, nurses, individuals living in Wuhan, and frontline healthcare workers have been shown to have a high risk of developing unfavorable mental health outcomes. They reported experiencing symptoms of depression, anxiety, insomnia, and distress, especially female nurses (Lai et al., 2020).

Personal and social resources are constituting means of efficient coping with a threat. Studies have confirmed a positive meaning of the possibility to express emotions when faced with a disaster. Personal resources of an individual play a crucial role in emotional expression. These include the sense of personal control, self-efficacy, resourcefulness, sense of humor, optimism, valuation, and coping with distressing events (Adams and Boscarino, 2006; Doliński, 2006; Ranieri et al., 2020). Medical profession representatives are expected to have psychological resilience, whose significant aspect is experiencing emotions and expressing them in a certain way. Experiencing emotions is usually accompanied by somatic changes, mimic and pantomimic expressions, and specific behavior (Dąbrowska-Chołostakow and Kocbach, 2018). Emotions are related to self-control, which is defined as demonstrating a behavior consistent with the norms accepted by an individual or with social norms. Self-control involves reactions initiated by a subject, by means of which he achieves congruence among his own emotional states, thought and affective feelings, and the accepted internal norms (internalized rules of functioning) or the external ones (socially approved rules) (Wagner and Heatherton, 2013). It is emphasized in the literature that suppressing emotions is an unfavorable phenomenon, because it may lead to intensification of the experienced emotions or their lingering in the form of emotional tension (Doliński, 2006).

Self-efficacy allows to assess the situations accurately and seek efficient ways of coping with the encountered difficulties and obstacles (Juczyński, 2000, 2012). People with high self-efficacy can maintain relatively stable emotions even under pressure

(Bihlmaier and Schlarb, 2016). Self-efficacy also increases concentration and self-control (Przepiórka et al., 2019; Xiao et al., 2020). Low sense of self-efficacy is related to anxiety and sense of helplessness, while high sense of self-efficacy is related to the higher level of positive emotions (these persons assess distressing stimuli more often as a challenge than a threat), which favors taking up challenges, defining aims, and achieving successes in fulfilling them (Maddux and Lewis, 1995; Juczyński, 2012; Schwarzer, 2015).

Currently, there are no studies conducted on the psychological resources, including emotional control and self-efficacy, of healthcare workers during the COVID-19 pandemic. At the time of the COVID-19 pandemic, the workplace environment is not supportive in Polish hospitals because Polish healthcare centers suffer from acute lack of the necessary protective measures, including protective masks, disposable gloves, protective coats and coveralls, and disinfecting liquids. This makes healthcare workers particularly vulnerable to developing unfavorable mental health outcomes, including PTSD. Based on the previous studies, it seems that the sense of self-efficacy and emotional control (of anger, anxiety, depression) may be related to the functioning of the hospital staff, including the intensity of PTSD, after the COVID-19 pandemic was announced.

The aim of this study was to assess the psychological resources, including coping self-efficacy and emotional control (of anger, anxiety, depression) of hospital staff with reference to the coronavirus anxiety and PTSD symptoms after the coronavirus pandemic was announced.

This is the first study to investigate the psychological resources of healthcare workers during the COVID-19 pandemic, and the first study to assess psychological outcomes of the COVID-19 pandemic on healthcare workers in Europe.

## MATERIALS AND METHODS

### Study Group

The study group consisted of 90 healthcare workers from a district hospital in Kościerzyna, Pomeranian region, Poland. The staff included paramedics, physicians, obstetricians, nursing aids, psychologists, medical analysts, radiology specialists, cleaning, transport, and technical crews. Descriptive characteristics of the study participants are described in **Table 1**.

### Research Procedure

The study was conducted in the hospital on 22 March 2020—2 days after the coronavirus pandemic had been announced in Poland. Considering that the lockdown-type control measures in Poland started before the pandemic was announced (first lockdown-type control measures had started on 10 March 2020), the panic had also started well before the pandemic was announced.

The research project was reviewed and approved positively by the Ethical Committee (decision no. 29/2020) at the Institute of Psychology at the University of Gdańsk, Poland. Participants in the current study were obtained with a cooperation of a gatekeeper, which allowed access to the hospital. Participants

**TABLE 1** | Descriptive characteristics of the study participants.

Variables	N = 90
Gender	
Males	N = 23 (25.6%)
Females	N = 67 (74.4%)
Direct vs indirect exposure to patient	
Direct	N = 66 (73.3%)
Indirect	N = 24 (26.7%)
Specialization	
Yes	N = 48 (53.3%)
No	N = 42 (46.7%)
Age	M = 45.66 (SD = 9.70)
Number of years in the profession	M = 19.373 (SD = 11.29)

included in the study were hospital workers, without any psychiatric diagnosis in the past to the present, who agreed to participate in the study. Exclusion criteria included DSM-5 psychiatric diagnoses (American Psychiatric Association, 2013) and taking psychotropic medications. Psychiatric diagnoses were performed by a psychiatrist.

Recruitment of the participants involved a general conversation about the pandemic, which was meant to encourage the respondent to take part in the study. After agreeing to take part in the study, individual meetings were scheduled. During the meetings, participants were asked to fill out the questionnaires.

The following research tools were used:

1. Author's own survey including socio-demographic data
2. Author's own three-item anxiety scale concerning anxiety about coronavirus.

The respondents were asked to assess, on a scale of 0–10, how strong are their fears of COVID-19 in relation to: worries about themselves (I am worried about myself), worries about loved ones (I am worried about my loved ones), and fear of losing their job (I am worried about losing my job and poverty). Responses for all three items were summed up to create a composite measure in which higher scores reflect greater anxiety concerning the consequences of COVID-19. This is an author-designed tool, which has been standardized in relation to Hamilton Anxiety Rating Scale (HAM-A). Scores of 15 and above correspond with HAM-A scores of 18 and above, which is a commonly used cutoff score of anxiety disorders in clinical studies (Hamilton, 1959; Małyszczak et al., 1999; Kocjan, 2016).

A one-factor structure of the tool was tested via confirmatory factor analysis (CFA). Model's fit statistics show very good fit: CFI = 0.99, RMSEA = 0.001. Scale reliability in the current study was assessed using the Cronbach's alpha. The results of this measure equaled 0.77.

In addition, the measurement of COVID-19 anxiety was supplemented with a single item assessing concerns about coronavirus infection, i.e., "Are you worried about catching the coronavirus?" Study participants reported their concerns on a five-point scale: (1) Definitely not; (2) Probably not; (3) Probably

yes; (4) Yes; and (5) Definitely yes. On the scale, scores of 3 and above indicated fear of catching COVID-19; hence, we selected 3 as a cutoff score.

Considering a relatively small number of participants ( $N = 90$ ), we used a dichotomic classification of fear of COVID-19 for both scales. For the dichotomic classification, we used the cutoff scores and assigned 0 = no fear, 1 = fear. This could result less likely to creation of biased estimates than are more unbalanced dichotomies (Pedhazur and Schmelkin, 1991; Borz and Döhning, 2006).

General Self-Efficacy Scale (GSES), which is a 10-item psychometric scale that is designed to assess optimistic self-beliefs to cope with a variety of difficult demands in life. The scale was originally developed in German by Jerusalem and Schwarzer (1992). The total score a person can get is between 10 and 40 points. The higher the score, the higher the self-efficacy, which translates into greater self-confidence and better ability to cope with a difficult situation. Sten scores 10–24 points were regarded as low, 30–40 points as high, and 25–29 points as average.

A Polish version (Juczyński, 2012) has been shown to be reliable and valid (Cronbach's alpha equaled 0.85). Additionally, scale reliability was assessed by the author using the test–retest method (after 5 weeks) and equaled 0.78 (Juczyński, 2012); in the present study, Cronbach's alpha resulted to be 0.86.

The Courtauld Emotional Control Scale (CECS) (Polish version), which is a 22-item questionnaire developed to measure the extent to which individuals report suppressing emotions of anger, anxiety, and depressed mood. Subscales have been shown to be consistent with these primary emotions: anger, depressed mood, and anxiety. The total emotional control index is within 21–84 points. The higher the result, the more enhanced the suppression of negative emotions. The Polish version was found to be a reliable and valid method. The following Cronbach's  $\alpha$  coefficients were obtained: for the control of anger 0.80, depression 0.77, anxiety 0.78, and for the total emotional control index 0.87 (Juczyński, 2012), with our data Cronbach's alpha for the total emotional control index equaled 0.76.

Impact Event Scale-Revised (IES-R)—Polish version (Juczyński and Oginiska-Bulik, 2009) is a self-report measure that assesses a subjective psychological distress caused by a traumatic event. The principal component analysis identified three factors

(Intrusion, Hyperarousal, and Avoidance), which are closely associated with PTSD symptoms. The cutoff point is 30 points.

The Polish version was found to be a reliable and valid method. The overall scale reliability measured with Cronbach's alpha is 0.92; in the present study, Cronbach's alpha resulted to be 0.94.

## Data Analyses

Descriptive statistics were computed for the characteristics of the sample consisting of frequencies and percentages for categorical variables and means and standard deviations (SDs) for scale variables (Table 1). Parametric assumptions were tested before conducting parametric tests. Differences in levels of anxiety concerning the consequences of COVID-19 between males and females; professionals directly vs indirectly exposed to patients; and professionals with vs without specialization were assessed via  $t$ -test.

Before analyzing the correlation between variables, we assessed the normality of the distribution of variables on the basis of skewness and kurtosis (see Table 2).

The criterion set was  $< 2.0$ .

As there were no clear deviations from the normal distribution, we used the Pearson's  $r$  coefficient. Bivariate associations between study variables were assessed via Pearson's correlation coefficient  $r$  (Table 2).

A multiple linear regression was conducted to ascertain the effects of gender, being directly vs indirectly exposed to patients, and general self-efficacy on the anxiety concerning the consequences of COVID-19. We followed the hypothesis, and CECS is not the significant predictor, so we did not include it in the regression model.

## RESULTS

The majority of the respondents ( $N = 62$ ; 68.9%) reported being worried of catching COVID-19. The majority of the respondents ( $N = 84$ , 93%) also demonstrated a subjective distress caused by COVID-19 (only six individuals did not report them). The mean General Self-Efficacy GSES was relatively high in the studied group of respondents. The mean score of Control of Negative Emotion CECS suggests that the respondents had an average suppression of negative emotions. Table 2 contains descriptive

**TABLE 2** | Means, standard deviations, and correlation matrix of the study variables.

Variables	<i>M</i>	<i>SD</i>	<i>Skew.</i>	<i>Kurt.</i>	1	2	3	4	5	6
1. Age	45.66	9.70	−0.51	−0.32						
2. Number of years in the profession	19.37	11.29	0.05	−0.85	0.790**					
3. Fear of catching COVID-19	3.97	1.09	−0.63	−0.93	0.031	0.061				
4. Anxiety concerning the consequences of COVID-19	19.49	8.10	−0.20	−1.06	0.114	−0.040	0.478**			
5. GSES	30.66	3.82	0.66	1.45	−0.040	−0.090	−0.331**	−0.322**		
6. CECS overall	49.74	9.31	0.37	−0.03	−0.304**	−0.160	−0.040	0.030	−0.160	
7. PTSD overall (IES-R)	62.16	18.21	0.01	−0.70	0.239*	0.209	0.488**	0.348**	−0.253*	−0.140

$N = 90$ .

\* $p < 0.05$ .

\*\* $p < 0.01$ .

statistics and a correlation matrix (Pearson's correlation) of the variables studied.

Further analysis showed that women reported higher levels of anxiety concerning the consequences of COVID-19 ( $M = 20.82$ ,  $SD = 7.53$ ) than men ( $M = 15.61$ ,  $SD = 8.23$ ),  $t(88) = 2.76$ ,  $p < 0.01$ ; the difference is moderate (Cohen's  $d = 0.66$ ) (equal variance assumed  $F = 0.24$ ,  $p = 0.63$ ). Contrary to expectations, healthcare professionals directly exposed to patients reported lower levels of anxiety concerning the consequences of COVID-19 ( $M = 17.40$ ,  $SD = 7.92$ ) than those who were indirectly exposed to patients ( $M = 24.11$ ,  $SD = 6.53$ ),  $t(88) = 3.92$ ,  $p < 0.001$ ; the difference was high (Cohen's  $d = 0.92$ ) (equal variance assumed  $F = 1.20$ ,  $p = 0.23$ ). Healthcare workers with specialization obtained significantly lower mean scores for anxiety concerning the consequences of COVID-19 ( $M = 16.27$ ,  $SD = 7.32$ ) than workers without specialization ( $M = 22.57$ ,  $SD = 7.67$ ),  $t = 3.98$ ,  $p < 0.001$ ; the difference was high (Cohen's  $d = 0.84$ ) (equal variance assumed  $F = 0.31$ ,  $p = 0.58$ ). There were no significant differences between healthcare workers with and without specialization when PTSD symptoms overall score was compared ( $t = 1.56$ ,  $p = 0.12$ ).

## Linear Regression Analysis

A multiple linear regression was conducted with SPSS Statistics to ascertain the effects of gender, being directly vs indirectly exposed to patients, and general self-efficacy on the anxiety concerning the consequences of COVID-19. The results of multiple regression analyses showed a significant main effect of all predictors on the anxiety concerning the consequences of COVID-19, suggesting that female ( $\beta = -0.271$ ,  $p < 0.01$ ) healthcare professionals indirectly exposed to patients ( $\beta = -0.336$ ,  $p < 0.01$ ), who reported lower levels general self-efficacy ( $\beta = -0.295$ ,  $p < 0.01$ ) have a stronger tendency to respond with anxiety regarding the consequences of COVID-19 [ $R^2 = 0.301$ ,  $F(3,89) = 12.34$ ,  $p < 0.01$ ].

## DISCUSSION

The aim of this study was to assess the psychological resources, including coping self-efficacy and emotional control (of anger, anxiety, depression) of hospital staff with reference to the coronavirus anxiety and PTSD symptoms, once the coronavirus pandemic was announced in Poland. The study was conducted shortly after the restriction period in Poland has started, and it investigated the subjective assessment of COVID-19 threat and PTSD symptoms in the hospital staff, as well as identified protective factors of fear of COVID-19.

The COVID-19 pandemic was perceived by the group of hospital personnel (medical, technical, and maintenance staff) as a genuine threat. Majority of the respondents were worried of catching COVID-19. According to the stress-adaptation model, the experience of fear and stress is defined as a universally experienced response to extraordinary life circumstances (Maudner et al., 2003; Valdez and Nichols, 2013). The fear of catching the coronavirus may also stem from the high awareness of the hospital staff that the virus may be

absorbed by the cells of the mucus membrane in the eyes, nose, cheek—after which it changes its genetic code, multiplies, and transforms its own cells into the cells of the intruder. The virus is invisible and may be everywhere—in a patient's breath, on his clothes, items in his possession, and on everything he touched. It is easily transmittable. The hospital personnel might thus perceive the virus as a genuine invisible threat to them and all persons they get in touch with (including their close friends and relatives). This could explain their real fear of coronavirus. The perception of one's own situation as threatening may deepen insecurity. Usually, at the time of pandemic, infection monitoring procedures and public health recommendations are modified frequently. The changes may be introduced on a daily or even hourly basis, which explains the increased level of insecurity in the medical personnel. It seems that media broadcast also intensifies insecurity and anxiety. Research also suggests that the staff lacks both planning and strategic solutions for the community at various levels at the time of disasters, which also intensifies insecurity and anxiety when facing a threat (Roudini et al., 2017). Moreover, when faced with a disaster, individual fear behaviors spread rapidly and contagiously, among groups of persons who share the fear and observe the behaviors of each other (Espinola et al., 2016; Shultz et al., 2016). Finally, the fear of COVID-19 may also be related with stigmatization of healthcare workers, others' fear of contact with those treating patients with COVID-19 (Ramaci et al., 2020). We could observe similar fear-related behaviors in the years 2013–2016 during the West Africa Ebola Virus Disease Outbreak (Espinola et al., 2016; Rabelo et al., 2016; Shultz et al., 2016).

Widespread outbreak of COVID-19 is associated with psychological distress and symptoms of mental illness (Bao et al., 2020; Rajkumar, 2020; Super et al., 2020; Vindegaard and Benros, 2020). Work-related mental health impairment is recognized as a real problem in the context of helping responders, including health professionals, due to adverse health outcomes after a severe disaster (Neria et al., 2011; Farooqui et al., 2017; Nukui et al., 2018). Recent studies have shown that among healthcare workers depression and anxiety rates were higher (Chen et al., 2020; Mo et al., 2020) compared to administrative staff (Lu et al., 2020; Zhang et al., 2020) and non-frontline workers (Liang et al., 2020; Vindegaard and Benros, 2020), during the COVID-19 pandemic (Xu et al., 2020). We observed differences between workers directly exposed to patients and those indirectly exposed to patients. Despite the fact that workers directly exposed to patients are more prone to being directly exposed to COVID-19, they experienced coronavirus-related worries less frequently than workers indirectly exposed to patients, as well as healthcare workers with specialization obtained significantly lower mean scores for anxiety concerning the consequences of COVID-19 than workers without specialization. This could be explained by their awareness of having a job which is strongly socially desirable, as well as awareness of their own skills and the sense of self-efficacy. Some research has shown contradicting results, i.e., female nurses in Wuhan working in the front-line medical staff were twice more likely to suffer anxiety and depression than the non-clinical staff (Lai et al., 2020; Lu et al., 2020). In those studies, however, studied nurses have had close contact

with COVID-19 patients. In the present study, the medical staff could potentially have had a direct contact with patients infected with COVID-19, yet there were no cases of COVID-19 registered in the hospital.

In the current study, gender was another variable that turned out to be a significant predictor to respond with anxiety regarding the consequences of COVID-19. Some studies have revealed that female gender and younger age are some of the risk factors of anxiety (Norris et al., 2002; Frankenberg et al., 2008; Math et al., 2015; Sohrabizadeh et al., 2016; Vindegaard and Benros, 2020). Younger persons and women are also more likely to develop that stress disorder when faced with a disaster (Adams and Boscarino, 2006). Similarly, disaster rescue workers are at high risk of developing psychiatric morbidity (Stellman et al., 2008).

In the current study, the vast majority of the participants (apart from six respondents) declared PTSD symptoms. A mass threat is a potentially traumatic event (PTE) that threatens or overtly endangers the physical and/or psychological health, well-being, and integrity of a population and that is perceived and experienced, both individually and collectively, by persons comprising the population at risk. PTEs, regardless of whether they result in physical harm, have the capacity to produce psychological distress and, with severe or prolonged exposure, PTSD (Espinola et al., 2016). It is worth emphasizing that not all respondents declared being anxious of COVID-19, and not all of them had the PTSD symptoms. Although researchers have assigned the PTSD as the signature diagnosis among post-disaster mental morbidity, the incidence of PTSD reported in literature ranges from 4 to 60% (Pietrzak et al., 2012; Brooks et al., 2019). The level of PTSD symptoms was correlated with age, sense of self-efficacy, and fear of catching COVID-19 and anxiety concerning the consequences of COVID-19. There was no significant relationship between gender and PTSD symptoms scores.

Nowadays, the workplace environment is not supportive in Polish hospitals, especially at the time of COVID-19 pandemic, because currently Polish healthcare centers suffer from acute lack of the necessary protective measures, including protective masks, disposable gloves, protective coats and coveralls, and disinfecting liquids. We assumed that emotional control would be a significant factor protecting against the PTSD symptoms and fear of COVID-19. The obtained results do not confirm this assumption. Only age negatively correlated with emotional control. Younger age supported the control of negative emotions, which could be due to greater adherence to the professional workplace norms, which favor emotional control and discourage expressing negative emotions (anger, anxiety, depression) when at work in a hospital. The control of negative emotions decreased with age. The obtained results are consistent with Averill's (2004) review. According to Averill (2004), the diversity of emotions experienced by a person results from the possession of various cognitive emotional programs of responding to events. Cognitive emotional patterns are inborn, but they develop and change under the impact of life experiences. Emotions are a kind of social role. Controlling them means being emotionally correct, which is a condition of high emotional intelligence (Averill, 2004). The fact that the hospital staff

do not always control negative emotions or admit much more easily to it may be due to the general life experience growing with age. Expressing negative emotions is beneficial and recommended in various psychotherapeutic approaches (Salovey et al., 2002).

We assumed that the sense of self-efficacy will be a significant resource in the light of the COVID-19 pandemic. The GSES scores were negatively correlated with fear of catching the coronavirus as well as anxiety concerning the consequences of COVID-19. The sense of self-efficacy of hospital personnel is based primarily on their education, practical skills, and expert knowledge, so even lack of external resources, such as protective masks they have, face shields, goggles, disposable gloves, protective coats and coveralls, and disinfecting liquids, does not lower the sense of self-efficacy in all hospital staff groups. Anxiety has been shown to increase sensitivity to work pressure and the working environment and has a negative effect on self-efficacy because it reduces positive behaviors and initiative (Bandura and Adams, 1977; Miller et al., 2006; Xiao et al., 2020).

## Strengths

The main strength of the study is that it was conducted 2 days after the COVID-19 pandemic had been announced in Poland, which controls the limitations that often arise in retrospective studies. Furthermore, it was conducted in a non-artificial environment—at the workplace, with direct researcher–respondent contact. The study group consisted of the staff from one hospital, who were directly, as well as indirectly, exposed to patients. Personnel not commonly involved in research, such as maintenance workers, were also included in this study.

## Limitations

The limitations of this study include a sample that is limited to the personnel in only one hospital in the Pomeranian region, Poland, which makes it impossible to generalize the conclusions to hospital staff from other hospitals. Moreover, the current study investigated symptoms and/or signs of PTSD rather than PTSD. It is hence impossible to ascertain whether the respondents suffered from PTSD or only experienced the symptoms of PTSD. In order to diagnose PTSD, a full psychiatric assessment would need to be conducted.

Conducting the study just 2 days after the COVID-19 pandemic had been announced in Poland can be a strength as well as a limitation. Considering that the media broadcast has been intensifying insecurity and anxiety since the first case of COVID-19 had been reported in Wuhan City, it seems that the “coronavirus fear” in Poland had started before the pandemic was announced, yet this is only an assumption. Symptoms of PTSD usually manifest within the first 3 months after the trauma, hence not enough time might have passed for some of the respondents to manifest PTSD symptoms. It is also difficult to ascertain without a psychiatric examination whether the respondents had PTSD symptoms or acute stress disorder (ASD) symptoms. PTSD refers to the long-term aftermath of trauma (when the symptoms last longer than a month), while ASD refers

to the initial traumatic symptoms that arise immediately after a traumatic event (Bryant et al., 2000a,b; Bryant and Harvey, 2002). PTSD can follow ASD, but it can also occur even when ASD does not develop.

## CONCLUSION

The findings show the importance of self-efficacy for dealing with COVID-19 anxiety. The internal coping strategies should be introduced to healthcare workers as a part of the psychological preparation and health management to increase the psychological resilience of the hospital staff. Research has shown (Stueck, 2007, 2009; Stueck and Villegas, 2008; Stueck et al., 2019; Parker et al., 2020) that stress reduction methods combined with body orientation, e.g., breathing meditation and Autogenic Training, has a positive effect on self-efficacy. It seems that introducing a modern biocentric and psychological disaster management approach into hospitals could prepare the hospital staff to better deal with a pandemic or crisis.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethics Board for Research Projects at the Institute of Psychology, University of Gdansk, Poland. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

MoB and IB-B contributed to conceptualization, methodology, formal analysis, writing, and original draft preparation. AS-W contributed to conceptualization, investigation, and project administration. MS contributed to conceptualization, writing, and original draft preparation. MaB contributed to conceptualization, methodology, formal analysis, writing, original draft preparation, and supervision. All authors contributed to manuscript revision, read, and approved the submitted version.

## FUNDING

Unmasking Reflexivity in HR  
Managers During the COVID-19  
Lockdown in Italy.  
Front. Psychol. 11:588128.  
doi: 10.3389/fpsyg.2020.588128

This paper explores how some Italian HR managers narrate the changes imposed by the COVID-19 threat in the workplace. Events since December 2019 have presented exceptional circumstances to which HR managers have reacted in very different ways. This study explored how HR managers came to introduce organizational changes aimed at coping with the emergency, as well as how employees were involved in those organizational changes. The article is based on a thematic analysis of some interviews with Italian HR managers whose companies decided to switch working from home on a massive scale. We wanted to offer some reflections on the actions taken by a few HR managers and Italian companies to keep working at a time when most workers were forced to respect the lockdown.

**Keywords:** organizational change, crisis management, HR managers' reflexivity, qualitative approach, thematic analysis

## INTRODUCTION

Over the weekend before Monday 10 March 2020, Italian society, its companies, and economy stopped almost entirely. Offices, factories, and shops were closed. Traveling around the country by car or train was forbidden, and street police checks and heavy fines were introduced for those who did not respect the rules. During that period of quarantine, from the beginning of March to the beginning of May, many changes took place in the workplace. Which of these changes will remain, and which will be abandoned? In this situation, what happened to managers, workers, and jobs?

When the lockdown quarantine began, the glittering white-collar office towers designed by architects fell empty and a large-scale unplanned experiment began. Politicians, the media, and workers called it "smart working." To be precise, however, this was not "smart working"<sup>1</sup>. What was witnessed and experienced was working from home or working at a distance. In those months, millions of Italian workers stayed away from their workplace. The pandemic made it necessary to organize numerous activities, requiring interpersonal collaboration through video-based business meetings. Facebook, Microsoft, and Google decided to resort to remote working on a massive scale, until after the summer. Some firms went even further and for example, at the social media company, Twitter employees were allowed to work remotely indefinitely. Working from home was one of the

<sup>1</sup>Throughout this article, we call it "smart working" because this is the term which has been used by the press in Italy to describe this particular way of working. However, it was not the "true smart working" which involves the possibility of carrying out work activities in places other than the company headquarters or the home (for example on a train, in a park, in a library). It was not even teleworking which, to be such, requires the intervention of the company in the employee's home in order to create a specific space where the work activity is carried out.

many possible ways to react to the emergency, which involved a transition for millions of workers who had never experienced this way of working before.

This study aims to explore how some Italian HR managers narrate the changes imposed on the workplace by the restrictions of the COVID-19 pandemic. What has happened in the world since December 2019 has been an exceptional event to which HR managers have reacted in very different ways. We were interested in understanding how HR managers came to introduce organizational changes aimed at coping with the emergency, as well as how employees were involved in those organizational changes. The article is based on a thematic analysis of some interviews with Italian HR managers whose companies decided to resort to working from home on a massive scale. We wanted to offer some reflections on the actions taken by a few HR managers and Italian companies to keep working at a time when most of the workers were forced to respect the lockdown.

## THEORETICAL FRAMEWORK

### The Crisis Management

This paper draws on theories of crisis management to understand how companies and HR managers deal with exceptional situations/events. According to Giust-Desprairies (2005), a crisis presents itself as an unexpected event, upsetting the *status quo*. From a psycho-sociological perspective, several aspects characterize the experience of a crisis: emotional overload; a sense of uncertainty and loss; disorientation, and disengagement. At the organizational level, crisis usually brings to the fore certain issues, needs, and expectations that were previously overlooked; the framework and knowledge used for orienting thoughts and actions lose significance and relevance and people feel continuously threatened. Consolidated leadership and balances of power vacillate and conflicts and divergent opinions may suddenly emerge. Coordination systems get jammed. Crisis confuses people, and decision-making can be blocked, or instead dominated by reactive and impulsive stances. People often ask themselves what makes sense. The individual and collective imaginary seem to “freeze,” and the future appears as a never-ending present, characterized by a continuous escalation of emergency (Hsiu-Ying Kao et al., 2020; Galuppo et al., 2019). The COVID-19 emergency can be narrated by HR managers as either an irreversible crisis or as a temporary one. In the former, it is represented as a tsunami, which changes (and changes radically) ways of working, managing human resources, and imagining the development systems for evaluating people. According to this perspective, the world (and global business) will never be the same after the pandemic. In the situation in which the crisis is seen as temporary, there is a risk that the change will only be superficial, and the transformation generated by the threat is temporary: it is an ephemeral transition.

It is useful to ask how organizations and HR managers can learn from a crisis. One suggestion comes from theorists in the field of organization studies who have studied critical reflexivity. We are thinking, in particular, of the works of Cunliffe (2003), Alvesson (2003), Ripamonti and Galuppo (2016),

Ripamonti et al. (2016, 2018), and Caetano (2015) who emphasize the important role and contribution of reflexivity to management and organizational learning (Cassell et al., 2019). As Cassell et al. (2019) wrote, the literature on this topic outlines a variety of benefits that come from reflexivity, including “enabling us to think about our thinking, and in questioning our own taken-for-granted beliefs and those of others” (p. 3). Managers and employees can learn to cope with extraordinary situations - crisis or emergency situations - that involve stopping and/or slowing down (Stewart, 2007) without making a rapid assessment and taking action, without discarding what is not entirely comprehensible or fully understood (Benozzo and Gherardi, 2019). Although difficult, situations that are anxiety-provoking and confusing can be fruitful and enriching.

The themes evoked by the COVID-19 crisis are linked to literature on crisis management, and this literature has pointed out two important issues which organizations face:

- *Influencing external stakeholders.* This issue relates to how external communication with stakeholders is managed, including which messages to send them to indicate the organization’s ability to manage the unexpected crisis event. Usually, in the context of a crisis, great attention is paid to how stakeholders react to a critical event and to how information about the organization involved is managed.
- *Internal HR management dynamics.* This issue focuses on how the organization manages three specific moments: the pre-crisis, crisis management, and the post-crisis event. The possibility of learning from this crisis management process depends on the cognitive and emotional skills and abilities of the managers involved (Pearson and Mitroff, 1993; Alpaslan et al., 2009; Williams et al., 2017).

The ability of HR management to place issues connected to taking care of people at the center of the business strategy makes it possible to implement adequate, suitable responses to environmental requirements (Bader et al., 2019). Taking care of employees is also connected to how HR management influences sensemaking processes (Weick, 1999; Velasco et al., 2013). Some authors (Hewett et al., 2017) have argued that there can be significant differences in perception of the same event between the various groups of company population. Often, the way that a critical event is interpreted can be different between managers and employees and generate situations of conflict.

In literature on crisis management, one of the central themes is internal communication. As Hewett et al. (2017) have pointed out, this means that, when dealing with critical situations, HR management must ensure that communication is transparent, clear, and authentic. This should ensure that messages regarding the aims and procedures of HR policy are correctly understood by line managers and that these are then passed on to collaborators. A positive perception of the action taken by management in the face of a problematic situation has a positive impact on organizational performance (Pombo and Gomes, 2019).

## Crisis Management in the Period of COVID-19

COVID-19 is a crisis event of exceptional nature since it has affected all organizations, thereby creating a negative impact on every single organization simultaneously. In this scenario, our focus is on the role of HR management, which the literature on crisis management has always identified as being the most significant factor in influencing the capacity of an organization to react in the face of critical events. We concentrated attention on the management actions implemented by the HR department. Our research question was aimed at understanding how HR departments gave meaning to what was happening and how they built people management strategies to cope with the crisis. The issue of the relationship with stakeholders was left in the background, since COVID-19 is an event that, for the first time, has affected every organization simultaneously and brought turbulence to the whole system, meaning that organizations were left to themselves to manage internal problems. It was thus impossible to devote time and resources to dealing with external stakeholders, who were themselves having to cope with the same dramatic problems.

### The Management of Human Resources

The issues raised by the COVID-19 situation that HR management has had to deal with can be summarized as follows:

#### Stress Management

This has become a priority in the period of COVID-19. A study published on March 23, 2020, of 1257 healthcare workers in 34 hospitals in China (Lai et al., 2020) found a high prevalence of mental health symptoms among workers. Rates of psychological suffering were high: 50.4% had symptoms of depression, 44.6% of anxiety, 34% of insomnia, and 71.5% of psychological distress. The perception of not being able to respond to the increasing demands of the job during the COVID period generates a feeling of performance anxiety (Shanafelt et al., 2020). This feeling may cause a collapse in motivation and performance when the stressors exceed people's endurance (Vogel and Bolino, 2020).

#### Management of Internal Communication

Clear, transparent communication is the primary goal during periods of crisis. Some recent studies (Garfin et al., 2020; Rao et al., 2020) on the effect of people's repeated exposure to communication regarding the COVID-19 pandemic suggested that ambiguous messages cause increased anxiety and stress. In the COVID-19 situation, it was impossible to transmit clear messages and unambiguous responses to questions such as: "What will happen if someone is infected? Would it be possible to work from home with the same level of protection?" (Dragging et al., 2020). However, despite this lack of information, HR managers had to adopt a position and continue to give directives to company staff.

#### Generating a Supportive Atmosphere in the Workplace During the Crisis

Hou et al. (2020) studied the mental health of healthcare workers in China during the period of COVID-19. The latest research on the global pandemic indicates that the worker's perception of

social support is a protective factor that helps to contain stress. When workers are convinced that their colleagues can help them, their resilience capacity increases (Hou et al., 2020).

All these tensions have been interpreted in different ways by different organizations. Some managers have focused on ways of reassuring people. Some of the proposals reported in the literature include meditation, yoga, and stress management courses (D'Angelo et al., 2018). These experiences might have a positive influence on how future emergencies are dealt with (Hou et al., 2020). Other organizations have devoted their energy to creating a reassuring organizational environment. Yet others have tried to insist on internal communication, sending reassuring messages to their employees. A wide variety of actions have been implemented to try to deal with the pandemic, but the choices of which actions to implement depend on the meaning which the managers (and in particular those in charge of HR) attributed to the COVID-19 pandemic as an event. The specific function attributed to HR managers is to manage relations with personnel.

### The Reflexive Function in HR Management

The COVID-19 emergency can be narrated by HR managers as either an irreversible crisis or as a temporary one. In the former approach, it is represented as a huge and sudden change, which will radically change ways of working, managing human resources, and imagining the development systems for evaluating people. According to this perspective, the world (and global business) will never be the same as before the pandemic.

In the latter narration, when the crisis is seen as temporary, there is a risk that changes will only be apparent or superficial, the transformation generated by the threat is temporary, and that this is an ephemeral transition. Once the crisis has been overcome, the organizational structure folds back on itself, because organizations are characterized by inertia, by a lack of flexibility (Gagliardi, 1986). In this second case, the role of the HR manager is to use logical arguments to convince people and contain their anxiety. In this case, there is no deep leaning or change and a return to normal is desired. Unfortunately, and paradoxically, in this situation, this mindset is not aware that normal behaviors are exactly what generated the crisis.

It is useful to ask how organizations and HR managers can learn from a crisis. Organization studies on reflexive practice, in particular of the works of Cunliffe (2003), Alvesson (2003), Ripamonti et al. (2016), and Caetano (2015), emphasize the important role of reflexivity to management and organizational learning (Cassell et al., 2019). As Cassell et al. (2019) wrote, there is literature that outlines a variety of benefits arising from reflexivity, including "enabling us to think about our own thinking, and in questioning our own taken-for-granted beliefs and those of others" (p. 3).

We refer to reflexive practice by identifying it as the ability to generate new perspectives and insights (Alvesson et al., 2008) and create scope for re-constituting the self (Cunliffe, 2003). Recently, the concept of reflexivity has been utilized in a whole series of organization studies (Chia, 1996; Holland, 1999; Weick, 1999; Antonacopoulou and Tsoukas, 2002; Alvesson, 2003; Alvesson et al., 2008; Cunliffe, 2009; Segal, 2010; Xing and Sims, 2012) to describe that process that allows people to think about

themselves in their workplace by implementing a strategy of distancing themselves from the contingent situation. The aim is to activate a kind of thinking about which assumptions are used when implementing specific organizational actions (Lewis and Kelemen, 2002; Vince, 2002; Johnson and Duberley, 2003; Schippers et al., 2008; Jordan et al., 2009).

Reflexivity can be thought of as an “internal conversation” that organizational actors use to think about events that occur and to overcome the obstacles they encounter (Archer, 2007; Kakavelakis and Edwards, 2012). Through reflection, people evaluate their social contexts, imagine possible alternatives for their actions, and work with others to make organizational actions happen. In Archer’s perspective, reflexivity is an actor’s ability to build strategies for action. Strategies that take into account the actor’s position within a social system, to be able to act through tactical and strategic thinking. In this paper, we connect the concept of reflexivity to Emirbayer and Mische’s concept of agency (1998) – the ability to influence the surrounding world based on one’s ability to interpret the peculiarities of the context in which one finds oneself – which brings a temporal perspective to the discussion.

According to Emirbayer and Mische (1998), agency can refer to three temporal orientations, in the past (iteration), future (projectivity), and present (practical evaluation). In their own words, all “three of these constitutive dimensions of human action are found at various levels, within each concrete action” (Emirbayer and Mische, 1998: 171). In any given situation, however, one of these predominates, while the other two are present in a latent state. In the case of iteration, the authors refer to the selective reactivation of past thought patterns by organizational actors. Projectivity, on the other hand, involves the reconfiguration of acquired thought patterns to deal with plans. Practical evaluation concerns people’s ability to organize action in response to problems and requirements emerging in the present (Emirbayer and Mische, 1998).

We may encounter an iterative type of reflexivity that tends to select practices or thoughts from the past to deal with emerging problems. We may also encounter a kind of reflexivity centered on the present, and aimed at understanding which implicit assumptions are being used to deal with contingent problems. We may also have a style of forward-looking reflexivity, adopted to organize future strategic action.

The type of strategies chosen by HR managers therefore depends on their reflexive capacity and priorities. Bringing into play an iterative agency mainly involves thinking about which models from the past can be used to deal with the critical situations developing today. Using an approach centered on projective agency (forward-looking agency) means recognizing that the crisis has reconfigured the organizational field of action. It, therefore, becomes necessary to completely redesign how the work and the organization are conceived to guarantee survival in the medium and long term. Implementing a “practical” style of agency means placing oneself in the present and taking actions that solve strictly topical problems. In our opinion, where one positions oneself in one of these three types of agency also depends on the type of reflexive

thinking to which the protagonists on the organizational scene gain access.

The priorities for action are identified by each manager’s reflexive capacity, which might favor a way of managing that is either oriented toward the past, reorganizing the present, or one which is forward-looking and focused on creating new work scenarios. For HR managers, the potential for achieving distance from the critical situation of COVID-19 depends on their critical and reflexive capacity.

## METHOD

The present research aimed to explore how HR managers made sense of the COVID-19 crisis, with specific regard to people management and its related changes and challenges. The study takes the form of a brief qualitative research report, whose preliminary findings are based on 10 semi-structured interviews conducted with Italian HR managers whose companies decided to resort to large-scale smart working. These multifaceted data allowed us to gain initial insights into how HR managers from different contexts spoke about the situation and made meaning from the challenges it presented.

Given the exceptional nature of the ongoing event, in the course of our research, we met up with HR managers who were willing to undertake an interview. It was not possible to proceed with a statistical sampling that took into account variables such as age or gender of the interviewees or the size of the organization. The participants in the study work in companies in the North of Italy and were identified thanks to the researchers’ network of acquaintances and by word of mouth. This process generated a convenience sample. All the interviewees gave written consent to the recording the interview and to participating in the research. All the interviews were transcribed verbatim.

Since we do not consider the narratives used by the participants in our study as representative of the HR managers’ narratives during COVID-19 lockdown in Italy, other studies are needed in this field, such as those that take into account the opinions of managers working in different or similar sectors.

The semi-structured interviews consisted of a series of open questions, organized into five main sections: a brief overview of the organization; how the organization was dealing with the current crisis; the role of HR in the COVID-19 emergency; perceived challenges, resources and criticalities in “managing people” during the crisis; expectations and predictions about the future.

## Data Analysis

Data were analyzed using a theoretical thematic analysis (Braun and Clarke, 2006), driven by the research question. The analysis aimed to identify the main themes and meanings through which the HR managers’ narratives could be organized and interpreted. The analysis was conducted as follows: in a first phase, after becoming familiar with the data, we organized them through an open coding process, in which we were driven by the research question and by the “sensitizing concepts” described in the theoretical framework (Maguire and Delahun, 2017). We then

organized the codes into broader themes that were consistent with the research question. These themes were reviewed several times, by going back and forth to the coding process. The next section presents the themes discussed by HR managers during the interviews.

The first theme regards the time orientation of managers' actions. Managers described their commitment to cope with the present situation and to make decisions about the future. Some of them seemed focused on the present, and on the task of defending the company and its employees from threat, by trying to limit permanent damage to the organization's capacity for survival. From the reflections of other HR managers, the belief emerged that, due to the huge crisis, the real battle was with the future and opportunities to introduce changes that might increase the ability of the company to develop.

The second area, on the other hand, distinguished between two different ways of reacting to the emergency, one conservative and the other transformative. The former tended to emphasize the possibility of re-establishing the pre-COVID situation, and it thus becomes important to devote the maximum amount of energy to keep the organization alive and wait for the crisis to pass. The latter way of reacting expressed the conviction that we are witnessing a reconfiguration of today's world of working. The thoughts of these managers were to focus on opportunities to anticipate the transformational lines which will guide new ways of working and thinking about these organizations.

Bearing in mind these themes, we tried to reconstruct the routes of meaning which guided the managers' behaviors while they were coping with the COVID-19 emergency. Altogether, three lines of development were identified, based on the managers' shared priority and attention to the initial impact on the companies, during the 2 months when the pandemic first began.

Starting from this collective and generalized attention to contain the emergency damage, we singled out various tendencies

in the development of the managers' behaviors, which were directed in very different ways. The hypothesis is that each of these tendencies is the basis of a similar number of relationship models and expresses the different forms of reflexivity of the HR managers."

The following discussion captures details emerging from the data analysis, summarized in **Table 1**.

## RESULTS

### Surviving and Support

Analysis of the data provided a fascinating insight into the efforts of HR managers to deal with the impact that COVID-19 had on their employees. The first focus, also because of the number of citations and categories which emerged, regards a fundamental question that guided all the HR managers on how to support the women and men within their organization. Instead of various concerns regarding the hard aspects of the organization, this first category emphasizes individuals and the actions that must be activated with maximum priority in order to limit the emotional impact of COVID-19 and to preserve people's psychological and physical health.

The supportive actions conceived by the HR chiefs regard four main topics:

#### 1. The stress impact arising from the increased workload

Since working from home has a stronger impact in terms of time and stress than office working, it is essential to support people, firstly, by recognizing the value of this additional work and then eventually by adjusting the workload (Gozzoli et al., 2018).

"Today we are seeing a significant increase in the total workload, which is crushing us [...]. We need to think about regulations to reduce the possibilities of creating alienation.

**TABLE 1** | Different forms of reflexivity of the HR managers.

	Interview extracts	Role of human resources (employees)	Type of reflexivity	Type of agency	Time orientation
Surviving and Support	"We have set up a system of psychological support with psychologists who are assisting us with helping staff who have experienced the death of a colleague in the company to work through the grief. We introduced this psychological support system about a week ago. Obviously, I can't talk about what people were saying, but they were telling me that the real issues at the moment are anxiety, anguish and fear."	To comply with HR managers' rules for coping with emergencies	Problem-oriented reflexivity	Practical evaluation	Present
Back to the past! The old reassuring models	"There was a shift of focus: first there were inspection activities, involvement-style, and then we . . . took action emphasizing the safety issue; we did a huge job on safety awareness. There was rethinking about the role of leaders, from controlling safety sanctions to safety services."	To adapt themselves to the demands from top managers	Blocked reflexivity	Iteration	Past
New organizational scenarios	"Using robotics and IT in order to limit physical contact, and automation, are all trends that would have happened anyway, but which are now speeding up. As always, there are activities that disappear, and others that are on the rise."	To adapt themselves to the role required by the models proposed	Blurred reflexivity	Iteration	Future
Crossing the Bermuda Triangle with bearings	"We trained influencers to prepare people to return to the office and help them to understand how we can help build a new way of working."	Make a contribution to understand how to bring about a new way of organizing	Projective reflexivity	Projectivity	Future

Having started with 150 requests for help before the pandemic, now we are receiving 1000 requests. At the people support level, the emergency situation has meant that requests for help have multiplied. It's an incredible situation, an enormous number of questions in need of an answer!"

## 2. People and time management

In this second area, the focus is on time management. It is not easy to restructure an individual's work life and to plan daily work from home. The timing of work and the overlap of different aspects of work and personal life are a great source of stress and difficulty. One of the themes is the struggle to separate working time from the time when we usually do not work, compared with traditional organizations, work is becoming more pervasive: "I know people who start work at 6.00 in the morning. The main topic is how to organize time."

## 3. Limiting employees' fear

The third category of supportive actions regards the handling of fear, the spread of COVID-19 having generated a common dread, which leads management to take responsibility for it. Actions directed at overcoming fear usually involve specialized figures such as psychologists.

"We have set up a system of psychological support with psychologists who are assisting us with helping staff who have experienced the death of a colleague in the company to work through the grief. We introduced this psychological support system about a week ago. Obviously, I can't talk about what people were saying, but they were telling me that the real issues at the moment are anxiety, anguish, and fear."

This first group of managers seems to deploy an agency linked to the present and oriented toward tackling the practical problems posed by the pandemic. Emirbayer and Mische (1998) use the term "practical evaluation" to describe this type of agency, which is strongly anchored in the present and designed to find solutions that can make it possible to survive in the contingent situation. This is the first form of reflexivity which, though anchored to the imminent threat of situations, can still maintain a minimum distance to activate a form of thinking open to "problem-solving" and bringing into play all the resources which the organization has available.

## Back to the Past! the Old Reassuring Models

This cluster comprises the portion of respondents whose description of the crisis emphasizes the tragic aspect of the events which were unfolding and highlights the need to limit effects through strong actions on the part of HR. Therefore, HR was re-established as playing a central role involved in guiding people in the right direction and, at the same time, containing and limiting psychological breakdown in employees.

The key shift is that this critical situation brought about a radical change in the balance between people and the organization, a change that has the potential to produce undesirable results, such as lack of engagement, reluctance to respect burdensome new safety rules, and diverse kinds of opportunistic behavior. As such, it is only possible to overcome

the crisis by establishing a strong, authoritative leadership, which people can look to as a point of reference. This is all reminiscent of certain old-fashioned management models that still exert a reassuring, seductive power. The way through the crisis involved escaping into the past and re-evoking cultural lifelines which are attractive for their apparent clarity and the central role attributed to the company's directors. In this cluster, there was an absence of research areas and detailed study to understand which elements might be needed to cope with the crisis.

"There was a shift of focus: first there were inspection activities, involvement-style, and then we ... took action emphasizing the safety issue; we did a huge job on safety awareness. There was rethinking about the role of leaders, from controlling safety sanctions to safety services."

This is where we can place those managers who express a form of iterative agency, based on resorting to a managerial style that is obsolete, but endowed with strong emotional appeal. In this group of managers, it would seem to be impossible to put any real distance in place from the situation they are experiencing to make room for "reflexive thinking" and produce thinking of a questioning and exploratory nature. The reaction of these managers seems to be based on the irresistible attraction of emotionally reassuring models of the past, even when these are oversimplified and historically outdated (Benozzo and Colley, 2012).

## New Organizational Scenarios

In this third category, the themes raised in the interviews centered on a significant reconfiguration of work organization, starting from different data assumed as strong points of reference. What emerged was a responsive vision that focused on enhancing organization in the medium to long term. Furthermore, the objective was to adopt changes and modifications with regard to hard organizational aspects which would make it possible to adapt to new scenarios, all the while avoiding any radical processes of change.

The basic idea here is that once the critical phase is over, organizations will re-establish the "status quo" before COVID-19, with a few changes in ways of working, but nothing radical. The managers included in this cluster reflect on what the organizations will be like in the future and do not expect any fundamental transformations. They indicate that the crisis will have significant consequences for the financial situation of the companies, and also that if the economic recovery is slow, there will be an impact on staff numbers. Organizations will therefore be dealing with two stages (slow recovery and permanent/final recovery) connected to economic stability, which will likewise be guaranteed by downsizing companies.

The respondents' leading hypothesis is that it will be necessary to identify innovative organizational models, which will make it possible to rethink work organization, for example in an asynchronous modality. Employees will not be allowed to work all together in the same office or workspace, smart working will be widespread, and input from the IT sector will be crucial to provide the necessary support for these new remote modes of working. In short, new organizational models will have to be found which can keep pace with organizational change. The fundamental concept of this cluster is that the main task that

people will face is that of adapting. The new modes of working will require a recalibration of timing and patterns of interaction that will not always cater to individual sensitivities and needs.

“Using robotics and IT to limit physical contact, and automation, are all trends that would have happened anyway, but which are now speeding up. As always, there are activities that disappear, and others that are on the rise.”

Even though these managers employ future-oriented thinking, the question they ask themselves leaves little room for the contribution of other people in helping to design how the work organization might be changed. They pin their hopes completely on IT, which will find new modes of working thanks to technologies capable of regulating how people interact in a new way. The thinking involved in redesigning the future is delegated to IT engineers and planners. It would appear, then, that here the managers are deploying a projective agency, but one in which reflexive thinking is depleted in its creative force.

## Crossing the Bermuda Triangle With Bearings

The third pertinent area regards exploring unexpected scenarios. Assuming that the ongoing situation represents a profound change, the productive modalities and the timing of working have reached a point of no return. Work organization has its roots in production that adopt synchronous modalities and working in-person. It will be necessary to shift toward asynchronous productive models with an accompanying reduction in face-to-face people collaboration. This means that fundamental questions emerge regarding just how that legacy of relationships, upon which work organizations are historically based, can be preserved.

Trust-based relationships between people and a sense of organizational belonging are the foundations upon which companies build their competitive advantages. Acknowledging that the big question is how to identify innovative asynchronous organizational scenarios, the next challenge is how to preserve the legacy of trust between people. The concepts of this cluster regard the possibility of finding organizational devices that would allow people not to lose their central place in the work process.

By way of example, several HR directors thought about making so-called “company influencers” available, namely a coach who could support staff in the process of returning to work and help maintain involvement and commitment. The key issue was how to reflect on new conditions of cooperation to return together to a job that will be different. The main characteristic of this fourth cluster is that none of the HR managers had the answers to the questions outlined above and the only chance of finding them is to highlight some potential areas for future research paths that are emerging from the activation of people within the organization. Indeed, a contextual hypothesis could be identified so as to continue to enable them to work together.

“We trained influencers to prepare people to return to the office and help them to understand how they can help (is that right? or how to build?) a new way of working.”

Here we find a form of projective agency, and reflexivity is projected into the future. In our opinion, it is here that we find

the highest form of reflexive thought capable of projecting people out of the contingent situation. The questions which guide the managers’ thoughts are strongly projected into the future, and they are linked to a potential fundamental reshaping of the way of working. They lead in turn to new questions that cannot be resolved in the short term because they need time and space in order to be addressed, and they are questions that are difficult to answer on one’s own, using pragmatic thinking. They can only be addressed by bringing into play a kind of imaginary thinking constructed together with one’s colleagues.

## DISCUSSION

The present study interviewed a group of HR directors who responded to the impact of the COVID-19 crisis. They were all in charge of managing various workplaces, departments, and factories. Two main issues were raised during the interviews. The first is related to how managers coped with feelings of *uncertainty* in the crisis. The second regards the link between change management and reflexivity.

### Uncertainty

The role of the people in the scenarios outlined above led us to identify three types of managerial behaviors in respondents. We should point out that the first “survival and support” cluster is common to all of the respondents. All responses showed a great deal of attention to people and to the possibility of “defending” and “supporting” them using every available tool during the COVID-19 pandemic.

This study identified three types of managerial behaviors that pointed to a different conception of the processes of organizational change and the role of people. The first type of behavior occurs over a brief timespan and expresses a style of thought that is unable to accept the change taking place. The impact of the emergency generates a “freezing” of thinking and a collapse into a never-ending present, in which the only way out is to escape into a reassuring mythical past in which the re-appearance of old management models centered around the “strength” of the manager seems to provide relief (Alfes et al., 2019). The second type of behavior projects itself into the future, placing its trust in the hope that collaboration between IT and management engineers will produce new organizational models that can deal with the new emerging challenges. The third type of behavior, “Travelling with bearings” is when a person projects themselves into an uncertain future that will require a radical shift in the way we organize how people work. The uncertainty is mitigated by a series of essential points that guide HR directors:

- The challenge of adhocratic models. It is impossible to rely on abstract modeling. T-New ways of working must be identified starting from the challenges proper to each specific context.
- The challenge of asynchronous work. In the future, work will be done remotely, and this will require some profound reflection on how to rethink the relational legacy of organizations.

- The challenge of people. People will have a central role to play in identifying new sustainable working conditions. Relying on abstract models or falling under the spell of the old paradigms will not enable us to rise to the challenge of creating innovative modes of working.

## Manager Reflexivity

What emerges from this study is that HR managers reacted in very different ways to the spread of COVID-19 and these differences seem to be connected to the managers' ability to reflect upon the situation in progress. In particular, we make use of the concept described by Cassell et al. (2019) who, emphasizing the benefits of reflective thought, points to people's capacity for meta-thinking as being critical in enabling them to construct a complex representation of the work situation they are experiencing. This ability to face a crisis or emergency by achieving some detachment from the contingent events and expanding their reflective capacity is not evenly spread among managers. Most of our respondents exhausted their reflexive efforts either by resorting to management actions that were focused on surviving in the current situation or by using defense mechanisms that were focused on escaping to the past or projecting into a-historic future, represented by the abstract modeling of theoretical organizational models. Only a small minority of respondents (Traveling the Bermuda Triangle cluster) showed that they were able to activate reflective thought and question their strategies of problem-posing and problem-setting, projecting their managerial action into an uncertain future, in which it will be necessary to promote the involvement of all the people present in the organization to find possible forms of innovation, through widespread participation.

In our opinion, these different positions have a series of implications for how to manage human resources in times of crisis. Approaches such as "Escape to the past..." and "New organizational scenarios" which seem to be able to "tidy things up" and reassure people in a chaotic situation, may end up preventing managers from staying in touch with reality and listening to people and to their experiences, which can vary enormously.

While on the one hand the remaining approaches, "Surviving and support" and "Crossing the Bermuda Triangle," can create uncertainty and conflicts between opposing claims, stances, and modes of experiencing and interpreting the crisis; they seem at the same time to offer managers greater opportunities to have a handle on the situation and the people involved. They can produce truly "alternative" ways of coping with the crisis, creating and strengthening new abilities to learn from experience, to be used not only in the short term but also in the medium and long term.

## REFERENCES

Alfes, K., Shantz, A. D., Bailey, C., Conway, E., Monks, K., and Fu, N. (2019). Perceived human resource system strength and employee reactions toward

It seems to us, then, that this pilot study can offer initial suggestions to managers who are still involved in tackling the crisis generated by the impact of COVID-19. The first suggestion is to listen to people and to remember to bear in mind that different people react to a crisis in different ways. The second recommendation is to devote the right amount of time and space to build (together with the employees) a "framework" of meaning where colleagues can place themselves, to take charge of (and make sense of) the experiences of everyone. This might mean not offering any immediate and univocal answers, nor clear indications, and might also mean listening to conflicting positions and opposing interpretations, which, if they are to be resolved, need to be heard and given some legitimacy.

## Limitations and Indication for Further Research Studies

This research was carried out over a short period, and it was possible to investigate in real-time how HR managers gave meaning to the COVID-19 emergency at the very moment in which Italy was entering lockdown. In light of these conditions, this study was able to consider only a limited sample of subjects and was therefore exploratory, and further investigation is necessary, using a bigger and wider-ranging sample of managers and companies to analyze how they responded to the crisis, the implications of reflexivity, and the social and organizational impact in the medium and long term. Furthermore, follow-up research could also monitor which management strategies are being implemented in the phases after lockdown and the consequences of these approaches.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

The novel coronavirus disease (COVID-19) has become a global pandemic, causing substantial anxiety. One potential factor in the spread of anxiety in response to a pandemic threat is emotion contagion, the finding that emotional experiences can be socially spread through conscious and unconscious pathways. Some individuals are more susceptible to social contagion effects and may be more likely to experience anxiety and other mental health symptoms in response to a pandemic threat. Therefore, we studied the relationship between emotion contagion and mental health symptoms during the COVID-19 pandemic. We administered the Emotion Contagion Scale (ESC) along with a measure of anxiety in response to COVID-19 (modified from a previous scale designed to quantify fear of the Swine Flu outbreak) and secondary outcome measures of depression, anxiety, stress, and obsessive-compulsive disorder (OCD) symptoms. These measures were completed by a large ( $n = 603$ ) student sample in the United States. Data were collected in the months of April and May of 2020 when the fear of COVID-19 was widespread. Results revealed that greater susceptibility to emotion contagion was associated with greater concern about the spread of COVID-19, more depression, anxiety, stress, and OCD symptoms. Consumption of media about COVID-19 also predicted anxiety about COVID-19, though results were not moderated by emotion contagion. However, emotion contagion did moderate the relationship between COVID-19-related media consumption and elevated OCD symptoms. Although limited by a cross-sectional design that precludes causal inferences, the present results highlight the need for study of how illness fears may be transmitted socially during a pandemic.

**Keywords:** pandemic (COVID-19), media effect, anxiety, COVID-19, emotion contagion

## INTRODUCTION

The novel coronavirus disease (COVID-19) is a viral respiratory infection that was identified in Wuhan, China in late 2019. COVID-19 was officially declared a pandemic on 11 March 2020 (World Health Organization, 2020) and has spread rapidly across the globe. The United States recently reached a grim milestone of 200,000 COVID-19-related deaths (CDC, 2020). COVID-19 has had a severe impact on healthcare systems, economic activity, and has caused widespread social disruption. The effects of COVID-19 on mental health and emotional well-being are likely to be enormous as well. A recent survey by the U.S. Census Bureau found that one-third of Americans are showing signs of clinical anxiety or depression related to COVID-19 (National Center for Health Statistics, 2020).

It is critical to study the factors that relate to impaired mental health and emotional symptoms in response to COVID-19 to understand how the public responds to pandemic illness threats. Existing research has investigated factors related to mental health symptoms in response to illness threats such as the H1N1 “Swine Flu” influenza (Tausczik et al., 2012; Wheaton et al., 2012), Zika virus (Blakey and Abramowitz, 2017), SARS (Xie et al., 2011), and Ebola (Blakey et al., 2015; Thompson et al., 2017). This work has largely suggested that pandemic illness threats are associated with widespread anxiety and worry among the public. Importantly, anxiety about one’s health can be helpful and adaptive in moderation, as it can focus attention and promote utilization of health-protective behaviors (e.g., handwashing and maintaining social distance). However, for some individuals, anxiety in response to a pandemic threat can become excessive and maladaptive (Asmundson and Taylor, 2020). Excessive anxiety can be debilitating and lead to severe impairment in functioning. In addition, some individuals may develop excessive behavioral responses to prevent infection. For example, past work (Brand et al., 2013) has linked anxiety about pandemic illnesses to extensive washing and cleaning compulsions, which are hallmark symptoms of obsessive-compulsive disorder (OCD), a psychiatric disorder that can be disabling when severe (American Psychiatric Association, 2013).

Research suggests that fear about an illness and associated behavioral changes can also spread virally (Asmundson and Taylor, 2020). For example, media reports about serious contagious illnesses can lead to threat-based reactions as has been shown historically, including in reports that link mass panic about the 1665 London plague to newspaper articles, prompting officials to shut down printing presses (Defoe, 2016). Similarly, consumption of media reports about more recent pandemic illness outbreaks has also been associated with anxiety symptoms (Xie et al., 2011; Tausczik et al., 2012). The mechanisms by which media reports lead to anxiety and other emotional reactions to a pandemic require further study. In particular, work is needed to determine which factors predispose certain individuals to experience these symptoms. One potential factor that has not received sufficient empirical attention is the construct of emotion contagion.

Emotion contagion, a construct from the field of social psychology, refers to the well-established finding that the emotion and affective behavior experienced by one individual may be influenced by that of others through conscious or unconscious pathways (Hatfield et al., 1993). For example, seeing other people cry at a funeral may provoke sadness and tearfulness in oneself. A large body of work in the field of social psychology supports the social transmission of emotion in laboratory experiments (Hatfield et al., 2014). Recent experimental work also suggests that emotional states can be transferred to others via social media (Kramer et al., 2014). Susceptibility to emotion contagion has been investigated as an individual difference variable, as some are more likely to take on social emotions than others. Evidence to support the notion that individuals differ in their tendency to be influenced by the emotions expressed by other people comes from data showing large individual differences in self-reported emotional contagion (Doherty, 1997; Sonnby-Borgström, 2002). In addition, self-reported susceptibility to emotion contagion has been linked to brain areas in the mirror neuron system for emotions (Lawrence et al., 2006; Pfeifer et al., 2007) as well as the ability to detect authentic facial emotions (Manera et al., 2013).

Several forms of emotions appear to be socially contagious, including happiness, anger, and anxiety (Behnke et al., 1994). However, data suggest that negative emotions are particularly transmissible among strangers (Paukert et al., 2008). Recent empirical work shows that individuals higher in emotion contagion have more stress reactivity in response to traumatic events (Trautmann et al., 2018). Thus, it is possible that people who are more in tune with the pervasive emotions of others may be particularly affected during the COVID-19 outbreak.

Whereas the majority of work on emotion contagion has focused on personal interactions, recent work has determined that emotions can be transmitted digitally (Coviello et al., 2014; Goldenberg and Gross, 2020). This is particularly important given that social media is ubiquitous in the present moment and many adults get their news through social media. As the virus has spread across the world, it has garnered significant media attention. Based on past research, this media exposure is likely to increase anxiety about COVID-19, but this effect might be especially strong for individuals higher in susceptibility to emotion contagion.

The present study sought to investigate the relationship between susceptibility to emotion contagion, media usage, and emotional responses to the COVID-19 outbreak in a large sample of adult residents of the United States during the early phase of the illness threat. We explored the novel hypothesis that individuals higher in emotion contagion would have heightened concerns about COVID-19 as well as more other mental health symptoms (anxiety, depression, stress, and OCD symptoms). Given that consumption of media about COVID-19 and utilization of social media may also heighten anxiety about the virus, we conducted a regression analysis controlling for these factors. Finally, we tested the possibility that emotion contagion might potentiate the relationship between media use and concern about COVID-19 via moderation analysis. As a secondary set of outcomes, we also evaluated other mental health variables including symptoms of depression, anxiety, stress, and OCD.

## MATERIALS AND METHODS

### Participants

Participants ( $n = 603$ ) were recruited from psychology classes at Florida International University (FIU) and were English-speaking residents of the United States. There were no other inclusion/exclusion criteria. The total sample consisted of 528 females (87.6%) and 71 males (11.8%). Three individuals (0.5%) selected “prefer not to say” when asked about gender identity and one respondent (0.2%) left the question blank. The sample had a mean age of 22.92 years ( $SD = 4.83$ , range 18–48). Race-ethnicity was assessed via two separate questions. On the first question, participants were asked to check a box to identify with a race: 63.0% selected “White/Caucasian,” 17.6% selected “Black/African American,” 4.1% selected “Asian/Pacific Islander,” 14.3% selected “other,” and 1.0% left the question blank. On a separate question, participants were asked “are you of Hispanic/Latino descent” and 74.3% selected yes.

### Procedure

Data were collected from 5 April to 13 May 2020, which comprised some of the early months of the COVID-19 outbreak in the United States. The FIU student sample was recruited from psychology classes and completed the survey in exchange for course credit. Data were collected via an online survey that was built using the online survey tool, Qualtrics. The first page of the survey comprised the study consent form. On the following pages, participants completed the set of self-report questionnaires listed below (in a fixed order), as well as a series of demographic questions. The study was reviewed and approved by the institutional review board (IRB).

### Measures

#### Emotion Contagion Scale (ECS; Doherty, 1997)

The ECS is a 15-item self-report scale that assesses the tendency to “catch” the emotions expressed by others. Items on the ECS assess susceptibility to the social transmission of five basic emotions: anger, fear, sadness, happiness, and love. Items are scored on five-point Likert scales from *not at all* (1) to *always* (5). The ECS has good psychometric properties and is commonly used in research studies. In the current study, the item stems for certain items on the scale were modified to include examples of how emotions could be transmitted online (e.g., “I cry at sad videos on social media”). In the present sample, the scale had good internal consistency ( $\alpha = 0.88$ ).

#### COVID Threat Scale (CTS)

The COVID-19-threat Scale is a nine-item, self-report inventory that was created for the present study by adapting a questionnaire developed to assess anxiety in response to the H1N1 “Swine Flu” influenza (Brand et al., 2013). Items utilize a five-point Likert Scale from *not at all* (1) to *very much* (5) to assess threat-perceptions of COVID-19. Items assess threat-related perceptions about the extent to which COVID-19 may spread across the United States, concerns about becoming ill or family members becoming ill, and changes in behavior (e.g., excessive handwashing). A tenth item assessing perception that COVID-19

would become a pandemic was not analyzed because COVID-19 was officially declared a pandemic by the WHO. The full scale appears in the **appendix** and analysis of the factor structure of the scale appears in the data supplement. Higher scores reflect greater anxiety and threat-related behaviors in response to COVID-19. The scale had acceptable internal consistency in this sample ( $\alpha = 0.76$ ).

#### Depression Anxiety Stress Scales 21 (DASS-21; Antony et al., 1998)

The DASS-21 is a short form of the original 42-item DASS (Lovibond and Lovibond, 1995). The scale is comprised of three separate subscales, measuring self-reported depression, anxiety, and stress on a 0–4 point scale. The DASS-21 subscales have strong evidence of reliability and construct validity (Henry and Crawford, 2005). The three subscales of the DASS demonstrated good internal consistency in the present study (range in  $\alpha$ 's = 0.85–0.90).

#### Obsessive-Compulsive Inventory-Revised (OCI-R; Foa et al., 2002)

The OCI-R is an 18-item self-report questionnaire that assesses six dimensions of OCD symptoms: (a) washing, (b) checking/doubting, (c) obsessing, (d) neutralizing, (e) ordering, and (f) hoarding. Participants rate the degree to which they are bothered or distressed by OCD symptoms in the past month on a five-point scale from *not at all* (0) to *extremely* (4). OCI-R total scores have demonstrated excellent psychometric properties and validity (Foa et al., 2002). Reliability in the present sample was excellent ( $\alpha = 0.92$ ). Reliability for the OCI-R subscales was as follows: hoarding = 0.84, checking = 0.68, ordering = 0.87, ordering = 0.78, washing = 0.79, and obsessing = 0.84.

#### Social Media Utilization

For the purposes of the present study, participants were asked a simple question “How much time per day you spend on social media?” on a six-point ordinal response scale. Categories were scored as *not at all* (1), *a few minutes* (2), *about an hour* (3), *between 1 and 3 h* (4), *between 3 and 8 h* (5), *more than 8 h* (6). Similarly, participants were asked “How much time per day do you spend reading, watching or listening to news about the coronavirus?” which was answered on the same time per day response scale. The time frame for these questions was “recently” (i.e., “within the past week”).

#### Statistical Analysis

We first computed correlation coefficients among the study measures to assess the relationship between emotion contagion, media use, and the primary (concerns about COVID-19) and secondary outcomes (anxiety, depression, stress, and OCD symptoms). Next, we tested the hypothesis that emotion contagion would predict the degree of fear of COVID-19 controlling for exposure to COVID-19 media and social media utilization. To do this, we entered the ECS scores, social media consumption (per day), and COVID-19-media consumption as predictor variables in a simultaneous regression predicting concern about COVID-19, as indexed by CTS scores. Finally, we

tested the possibility that emotion contagion might potentiate the relationship between media use and concern about COVID-19 via moderation analysis conducted through the PROCESS SPSS macro (Preacher and Hayes, 2008). Subsequent supplementary analyses similarly tested for moderation effects among the secondary outcomes (anxiety, depression, stress, and OCD symptoms). Finally, as a sensitivity analysis, we tested both whether scores on study measures differed by study enrollment time period via independent samples *t*-tests and whether enrollment period affected primary regression results. Statistical analyses were run using the IBM SPSS (Version 23, Armonk, NY, United States).

## RESULTS

### Correlations

**Table 1** presents the correlations among study measures. As shown in the table, greater susceptibility to emotion contagion was significant and positively correlated with concern about COVID-19 ( $r = 0.32, p < 0.001$ ), depression ( $r = 0.12, p < 0.01$ ), anxiety ( $r = 0.27, p < 0.001$ ), stress ( $r = 0.29, p < 0.001$ ), and OCD symptoms ( $r = 0.29, p < 0.001$ ). Emotion contagion susceptibility was weakly yet significantly correlated with daily social media consumption ( $r = 0.13, p < 0.01$ ) and consumption of media related to COVID-19 ( $r = 0.12, p < 0.01$ ). Similarly, concern about COVID-19 was also weakly yet significantly correlated with hours per day of self-reported daily social media consumption ( $r = 0.11, p < 0.01$ ) and consumption of media related to COVID-19 ( $r = 0.21, p < 0.001$ ).

### Regression Results

COVID Threat Scale scores were slightly negatively skewed ( $-0.75$ ) and leptokurtic ( $0.87$ ) but did not violate normality assumptions for regression analysis (skew and kurtosis  $< 1$ ). Regression diagnostics indicated no problems with multicollinearity; the data met the assumption of independent errors (Durbin-Watson value = 2.05) and the histogram of standardized residuals indicated that the data contained approximately normally distributed errors, as did the normal P-P plot of standardized residuals. The data also met the assumptions of homogeneity of variance and linearity.

Results showed that the overall model (which included gender, time per day using social media, consumption of COVID-19 articles, and ECS scores) accounted for 14% of the variance in concerns about COVID-19, which was significant ( $R^2 = 0.14, p < 0.001$ ). Inspection of the individual regression coefficients revealed that the ECS was a significant individual predictor of concerns about COVID-19 [ $b = 0.14 (SE = 0.02), p < 0.001$ ], as was time per day consuming articles about COVID-19 [ $b = 0.83 (SE = 0.20), p < 0.001$ ]. Time per day using social media was not a significant predictor in the model [ $b = 0.17 (SE = 0.19), p = 0.37$ ], nor was participant gender [ $b = 0.50 (SE = 0.63), p = 0.43$ ].

### Moderation Effects

We explored the possibility that emotion contagion might moderate the relationship between excessive concern about

COVID-19 and both general social media utilization and COVID-19-related media consumption. Separate analyses were run considering the two media utilization questions as independent variables.

In the first regression model, concern about COVID-19 (CTS scores) was set as the dependent variable, daily consumption of media pertaining to COVID-19 was set as the independent variable, and emotion contagion was set as the moderator. Results found significant main effects for emotion contagion [ $b = 0.86 (SE = 0.19), p < 0.001$ ] and COVID-19-related media consumption [ $b = 0.14 (SE = 0.02), p < 0.001$ ] but the interaction term was not significant [ $b = -0.01 (SE = 0.02), p = 0.51$ ].

In the second regression model, concern about COVID-19 (CTS scores) was set as the dependent variable, daily utilization of social media was set as the independent variable, and emotion contagion was set as the moderator. Results found significant main effects for emotion contagion [ $b = 0.15 (SE = 0.02), p < 0.001$ ]. The main effect for daily use of social media was not significant [ $b = 0.30 (SE = 0.19), p = 0.13$ ] and the interaction term was not significant [ $b = -0.002 (SE = 0.02), p = 0.88$ ].

### Supplementary Analyses

As a secondary analysis, we explored predictors of the other mental health outcome variables (DASS-21 subscales and OCI-R scores). These analyses are presented in full in the **Supplementary Material**. Overall results showed that emotion contagion was an independent predictor of each of the DASS-21 subscales and of OCI-R scores. Daily consumption of information related to COVID-19 also predicted all secondary outcomes, while daily time on social media predicted DASS-21 Depression and DASS-21 Stress but not OCI-R or DASS-21 Anxiety. There was only one significant moderator: ECS scores moderated the relationship between consumption of COVID-19 information and OCI-R scores such that the strength of this association increased along with increasing ECS scores (see **Figure 1**). Analysis of OCI-R subscale scores revealed that emotion contagion predicted each of the OCI-R subscales. Moreover, ECS scores moderated the connection between consumption of COVID-19 media and four OCI-R subscales (washing, checking, neutralizing, and hoarding), as well as the connection between daily social media use and two OCI-R subscales (obsessing and hoarding) suggesting the emotion contagion may be more relevant for the connection between specific OCD symptoms and media use domains (see **Supplementary Material** for details).

### Analysis by Study Enrollment Period

Given that data collection spanned from 5 April to 13 May 2020, we investigated whether responses varied by date of enrollment. The median response date was 13 April and we divided the participants based on whether they had completed the survey in the first or second half of responses. The two groups of participants (early vs. late responders) did not differ in terms of time per day on social media ( $t = -0.81, p = 0.42$ ), consumption of media about COVID-19 ( $t = -1.04, p = 0.30$ ), or CTS scores ( $t = -0.72, p = 0.47$ ). Regression results predicting CTS scores were similar in both enrollment

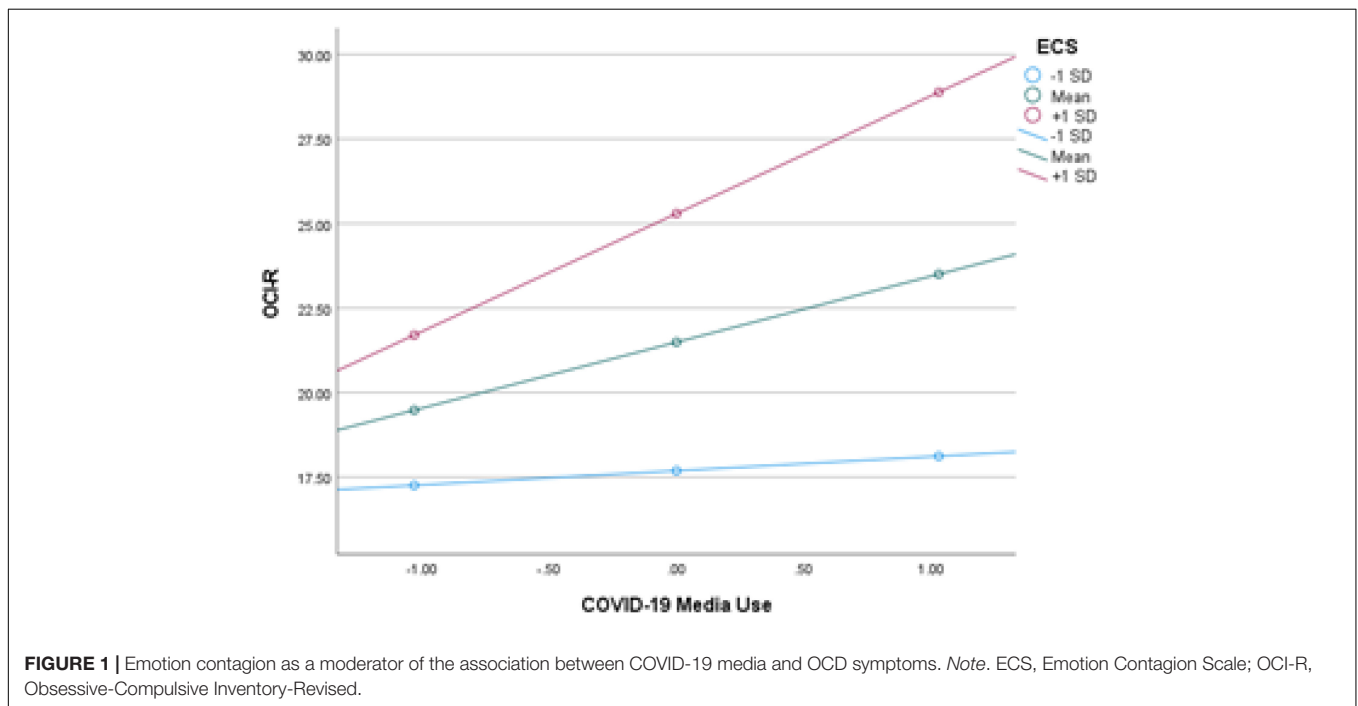

**TABLE 1 |** Correlations among study measures.

	ECS	CTS	DASS-D	DASS-A	DASS-S	OCI-R	Time/day COVID-19	Time/day social media
ECS	–							
CTS	0.32**	–						
DASS-D	0.12*	0.17**	–					
DASS-A	0.27**	0.23**	0.71**	–				
DASS-S	0.29**	0.28**	0.78**	0.79**	–			
OCI-R	0.29**	0.24**	0.53**	0.59**	0.58**	–		
Time/day COVID-19	0.12*	0.21**	0.14*	0.21**	0.17**	0.17**	–	
Time/day social media	0.13*	0.11*	0.14*	0.14*	0.15**	0.12*	0.18**	–

\* $P < 0.01$ .

\*\* $P < 0.001$ .

Note. ECS, Emotion Contagion Scale; CTS, COVID-19 Threat Scale; DASS, Depression Anxiety Stress Scale; OCI-R, Obsessive-Compulsive Inventory-Revised.

**FIGURE 1 |** Emotion contagion as a moderator of the association between COVID-19 media and OCD symptoms. Note. ECS, Emotion Contagion Scale; OCI-R, Obsessive-Compulsive Inventory-Revised.

periods (see **Supplementary Material**). These results suggest that concerns about COVID-19 were stable during the study period, and may have become widespread even before data collection began. Similarly, scores on the DASS-21 subscales and OCI-R did not differ by enrollment period (all  $p$ 's > 0.26).

## DISCUSSION

We investigated emotional responses during the COVID-19 pandemic outbreak in the United States in a large student sample and tested the possibility that individuals with greater susceptibility to emotion contagion would experience more distress and symptomatic behavior. Results were in line with our hypothesis: individuals with greater levels of susceptibility to emotion contagion had greater levels of anxiety about COVID-19, more depression, anxiety, and stress, and

greater levels of OCD symptoms. These findings are discussed in detail below.

Although the magnitude of the associations was modest, our overall findings suggested that individual differences in susceptibility to emotion contagion tracked with emotional symptoms, such as anxiety about the virus and maladaptive behavioral responses (i.e., OCD symptoms). This finding is in line with past work showing that individuals higher in emotion contagion experience more stress responses to traumatic events (Trautmann et al., 2018). In this case, the COVID-19 outbreak itself represents a form of community stressor, causing widespread anxiety and worry in the public. Those high in emotion contagion are likely more attuned to the emotional experiences of others and thereby experience heightened anxiety.

We also considered the possibility that general social media use and consumption of media about COVID-19 in particular would also be relevant to predicting degree of anxiety

around COVID-19. Furthermore, we considered that emotion contagion might act as a moderator for these relationships. Results showed that consumption of media about COVID-19 significantly predicted degree of COVID-19-related anxiety but this relationship was not moderated by emotion contagion. One prior report found that degree of emotion contagion moderated stress response following exposure to a traumatic film but this took place under laboratory conditions and with a highly controlled stressor (Trautmann et al., 2018), whereas our measure of exposure to media on COVID-19 was retrospective and uncontrolled. Therefore, it is possible that under more controlled conditions, a significant moderation effect would have emerged.

Alternatively, it is possible that the link between emotion contagion and fear of a pandemic is independent of exposure to media articles, as other pathways may connect these variables (e.g., information provided via family and friends). Nevertheless, our results linked both media consumption and emotion contagion to concern about COVID-19. This result is in line with research on past pandemics, which found positive associations between consuming media reports about the outbreak and anxiety (Xie et al., 2011; Tausczik et al., 2012). We also found that susceptibility to emotion contagion was related to concern about the spread of COVID-19, as well as other mental health outcomes (depression, anxiety, stress, and OCD symptoms). Emotion contagion was somewhat more strongly associated with concern about COVID-19, anxiety, and stress, and less strongly linked with depression, which may relate to anxiety being the predominant emotion experienced by the public during this time (National Center for Health Statistics, 2020).

In our supplemental analysis, we did find that the link between consumption of media about COVID-19 and OCD symptoms was significantly moderated by emotion contagion such that this association was stronger for individuals higher in emotion contagion. To the extent that OCD symptoms (e.g., compulsive washing and cleaning) might relate to the virus that causes COVID-19, it is possible that proneness to socially transmitted emotions enhanced the link between consumption of alarming articles about COVID-19 and increased OCD symptoms. However, caution is warranted in interpreting this finding because it was conducted as a secondary analysis and the cross-sectional nature of the data preclude drawing causal inferences. In addition, our sample was non-clinical, and therefore, future research is needed in clinical populations.

Hours per day of social media use weakly yet significantly related to concern about COVID-19, but this relationship did not reach significance in our regression model controlling for gender and consumption of COVID-19 related media. Among the secondary outcomes, time interacting with social media did predict symptoms of depression and stress, but not anxiety or OCD symptoms. Emotion contagion did not moderate the link between social media use and the mental health outcome variables. This result suggests that simply using social media may not robustly be linked with all mental health outcomes during a pandemic threat. Rather it may be important to consider the content of social media with which one interacts. Emerging work has suggested that the mental health effects of social media use may be highly variable, with some forms of social media use

linked to deleterious mental health outcomes, while other social media use (e.g., that which encourages belongingness and social connection) may improve mental health outcomes (Clark et al., 2018). Thus, future research with more fine-grained analysis of social media utilization is needed.

## LIMITATIONS

Present results should be interpreted in light of several important study limitations. First, all data were collected online utilizing a cross-sectional design in which participants completed measures at a single time point. Thus, our results are not able to firmly establish cause and effect relationships. For example, we cannot determine whether media exposure increased anxiety or whether individuals with heightened anxiety were more likely to seek information and therefore spent more time engaging with media. A more powerful design would be a longitudinal study to follow individuals low and high in emotion contagion to compare their utilization of social media and trajectories for anxiety and stress in response to a pandemic threat. Similarly, other variables (such as neuroticism) should be considered as potential third variables explaining the associations between observed relationships. Unfortunately, neuroticism was not assessed in our survey, representing an important future direction for research. In addition, all data were collected via self-report surveys, and reliance on self-report questionnaires may have inflated the relationship between variables due to shared methods variance. Future study using mixed methods approaches including interviews would add methodological diversity to measurement. Finally, the data were limited to a student sample (that was mostly female). Therefore, future research is needed to replicate these findings in other samples, including among clinical samples of individuals experiencing anxiety disorders who may be particularly affected by fears of pandemic illness threats (Dennis et al., 2020), as well as samples with greater numbers of male participants. Given that the results of some of the present analyses were statistically significant but of small magnitude, their clinical significance requires further study.

## CONCLUSION

Notwithstanding these limitations, the present report highlights the possibility that emotion contagion effects may contribute to emotional reactions during a pandemic illness outbreak, such as COVID-19. We found that those who were higher in susceptibility to emotion contagion experienced more concern about the spread of COVID-19, more anxiety, stress, and depression and greater OCD symptoms. Together, these data suggest that maladaptive emotional experiences may be socially contagious during a pandemic threat.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Institutional Review Board at Florida International University. The participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

MW and AP conceived of the idea for this study. AP sought and received approval from the local IRB and coordinated data collection. MW and GM conducted the statistical analysis. All authors contributed to the final write up and all reviewed and approved the submission.

Handwashing is important in preventing infectious diseases like COVID-19. The current public health emergency has required rapid implementation of increased handwashing in the general public; however, rapidly changing health behavior, especially on this scale, is difficult. This study considers attitudes and affective responses to handwashing as possible factors predicting COVID-19 related changes to handwashing behavior, future intentions, and readiness to change during the early stages of the pandemic in the United States. Income was explored as a potential moderator to these relationships. To explore these issues, data from 344 community participants were analyzed. Results indicate that stronger affective responses toward handwashing relate to increases in handwashing since the outbreak of COVID-19, and both attitudes and affect uniquely predict handwashing intentions. Income significantly moderated the relationship between affect and readiness to change. Those with low income were more influenced by both affective responses and attitudes. These results suggest messages targeting both cognitions and affective responses are needed to increase the handwashing behavior during a global pandemic and these variables are critical in increasing readiness to change in low-income individuals.

**Keywords:** COVID-19, behavioral intentions, handwashing, readiness to change, affective responses, emotion, attitudes

## INTRODUCTION

Due to the rapid spread of the SARS-CoV-2 virus, it was critical that Americans quickly implemented health behaviors such as social distancing and frequent handwashing. This implementation is, perhaps, easier said than done, as rapid implementation of behavior change is notoriously difficult to achieve in many health domains. With the backdrop of a global pandemic, it was unclear how Americans would response to this need for behavior change, or what factors may be influential. Handwashing was not only among the first behaviors recommended to the public, remaining visible to the public throughout the course of the pandemic, but it is also central to the prevention of the spread of SARS-CoV-2 (West et al., 2020). As such, it is logical to explore it as a target behavior. The present study builds on emerging literature (Williams et al., 2018) and hypothesizes that affective and cognitive variables are critical and distinct predictors of behavior, behavioral intentions, and readiness for behavior change. Further, as disparities have been seen in the potential risk to those who have lower

incomes (Koma et al., 2020; Raifman and Raifman, 2020), income will be explored as a potential moderator.

Factors related to behavioral intentions and change have been widely explored, however the rapidity of the change due to the pandemic in the United States is unprecedented, and it is unclear what factors will be most influential on behavior and intentions. Cognitive variables, such as attitudes, have long been established as consistent predictors of behavioral intentions in models such as the Theory of Planned Behavior (Ajzen, 1991), and attitudes have previously been found to significantly predict prevention-related behavioral intentions related to the Ebola epidemic (Gamma et al., 2017). Determining behavioral intentions, however, may give an incomplete picture of actual behavior. Readiness to make behavioral changes may help to fill this gap, as it has also been found to be uniquely predictive of the actual behavior in other domains (Biller et al., 2000; Geller et al., 2004). Attitudes have also been found to predict individuals' temporal readiness to change, or stage of change (Ronda et al., 2001). The present study seeks to confirm that attitudes continue to predict behavior, intentions, and readiness to change during a rapidly moving pandemic with diverse and intense health-related messaging and personal relevance.

Alongside attitudes, affective responses to health behaviors have recently been acknowledged as important predictors of health behaviors (Schuettler and Kiviniemi, 2006; Rhodes et al., 2009; Kwan and Bryan, 2010; Ferrer et al., 2016). For example, the Behavioral Affective Association Model (BAAM; Kiviniemi and Klasko-Foster, 2018) contends that affective associations with health behavior are a critical and often underappreciated determinant of action. The BAAM identifies cognitive variables (e.g., perceived norms) and affective variables (e.g., positive feelings) as independent predictors of intentions and health behaviors (e.g., Brown-Kramer and Kiviniemi, 2015). In line with such models, studies indicate that affective variables can be separate predictors of health actions and intentions from cognitive variables, such as attitudes (Lowe et al., 2002; Kiviniemi et al., 2007; Conner et al., 2013; Geers et al., 2017). For example, using simultaneous regression analyses, Lawton et al. (2009) found that affective and instrumental attitudes were separate significant predictors of intentions to perform 11 different health behaviors, including alcohol consumption, flossing, and sunscreen use. Similarly, Murray et al. (2019) recently found that affective associations with physical activity and perceived barriers to physical activity were separate and simultaneous predictors of physical activity in cancer survivors. Interestingly, in these studies, the affect variables were generally a stronger predictor of health intentions and behavior than the cognitive variables. It now appears that behavior change interventions can be optimized if they specifically target changing emotions as well as attitudes (for a review, see Williams et al., 2018). Based on this emerging database, it is predicted in the present study that affective responses to handwashing will be distinctly predictive of behavior and intentions. While there is little evidence to date on the impact of affective responses on the stages of change, affect is inherently tied to the processes of change (e.g., dramatic relief; Prochaska et al., 2008), and thus it is also predicted that affective response will be uniquely

predictive of readiness to change handwashing behavior during the early stages of a global pandemic.

While attitudes and affect are expected to drive handwashing behavior, intentions, and readiness to change, it is possible that the influence of these predictors varies with important social factors. One possibility, explored here, is that income moderates these effects. It is well documented that income and factors related to income are determinants of health (USDDS, 2020). Emerging data suggests that monetarily impoverished communities are most impacted by COVID-19. A recent analysis of the Behavioral Risk Factor Surveillance System data by Koma et al. (2020) from the Centers for Disease Control and Prevention (CDC) revealed that lower income was associated with more risk factors for becoming seriously ill with COVID-19 in the United States (also see Raifman and Raifman, 2020). In addition to low-income being associated with risk factors related to COVID-19 such as diabetes (Bird et al., 2015), chronic kidney disease (Nicholas et al., 2015), and heart disease (Lemstra et al., 2015), low income may also increase risk due to behavior. Those living in low-income areas have been found to be less likely to follow stay home directives (Chiou and Tucker, 2020), perhaps due to the lack of time off, job requirements, or being unable to forego income. Furthermore, income plays a particularly strong role in perceptions of information about healthy behaviors in the United States: Those with high income are more positive about their health and health care than those with low income (Hero et al., 2017). As low income can relate to riskier behavior and less responsiveness to health care information, positive changes in affective responses and attitudes for these individuals may result in greater benefits. Understanding the impact of income on the processes behind key health behaviors would shed light on psychological factors involved in the different paths of low- and high-income individuals and may highlight directions for more targeted intervention. As such, income will be explored as a moderator of the relationship between both attitudes and affect and the dependent variables of handwashing behavior, intentions, and readiness to change. It should be noted that there is some overlap in the data presented in the current study and a paper by Matkovic et al. (2020), including demographic items, handwashing attitudes, affect, intentions, and readiness to change. However, while the study by Matkovic and colleagues focused on differences in variables in response to a message intervention manipulation, this study focused on modeling the relationships among variables including attitudes, affect, and intentions, in order to better understand the pathways these variables take in affecting behavior. While there is an overlap in the data used, separate *a priori* hypotheses were made and separate analyses were run for each study.

## MATERIALS AND METHODS

### Participants

Community participants ( $N = 344$ ) were recruited from Prolific, an online participant recruitment system at the end of March 2020, just as stay home and shelter in place orders began to

be issued in many states. Participants ranged in age from 18 to 74 ( $M = 32.69$ ,  $SD = 11.60$ ), and were fairly evenly distributed by gender, with 54.1% identifying as women, 43.9% identifying as men, and 1.5% identifying as another gender or preferring not to disclose their gender. Participants lived in the United States at the time of survey completion and represented 44 of the states. Participants were 68% White, 16% Asian/Asian-American, 5% Black, 5% Latinx, and 6% two or more races. Participants were compensated for participating in the study.

## Measures

Participants completed measures through the Qualtrics survey platform and provided information about their handwashing attitudes, affective responses, intentions, and readiness to change.

### Demographic Items

Demographic items, including age, gender, race and ethnicity, and household income, were included at the end of the study. A series of items relating to geographic location, cases of COVID-19 occurring in near proximity, and risk factors related to COVID-19 were also collected at this time. Of interest in the present study, household income was collected as a multiple-choice item in which participants indicated their household income in \$9,999 increments. Eleven options were provided, with the final choice indicating "\$100,000 or more." Of the respondents, 52.6% fell in the income range of \$20,000 and \$79,999, and 19.80% reported household incomes \$100,000 or more.

### Handwashing Attitudes

Handwashing attitudes were assessed using two items presented on a 7-point Likert scale ranging from *strongly agree* to *strongly disagree*. The items asked participants to rate how important and effective handwashing is in preventing disease, reading "Handwashing is effective in preventing disease" and "Handwashing is important." The two items showed acceptable internal consistency with a Spearman-Brown coefficient of 0.78, and were averaged together to create a single bipolar attitude toward handwashing measure, ranging from negative to positive.

### Handwashing Affect

Five items that assessed affective responses related to handwashing were measured in order to capture the strength of these affective responses. Items included both positively and negatively valenced affective states, including anger, pride, guilt, annoyance, and feeling in control. Example items include "I am angry when others do not wash their hands" and "I am proud of washing my hands." Items were scored on a 7-point Likert scale ranging from *strongly disagree* to *strongly agree*. The five items had a high level of internal consistency ( $\alpha = 0.83$ ). As such, the five items were averaged together to create a single bipolar affect toward handwashing measure.

### COVID-19 Handwashing Behavior Change

COVID-19 related handwashing behavior change was calculated by asking participants to self-report the number to times they

washed their hands daily before the outbreak of COVID-19 and then after the outbreak of COVID-19. Both items allowed participants to enter a numeric response into an open response item. Analyses were conducted on the post-COVID-19 handwashing behavior while controlling for self-reported pre-COVID-19 handwashing behavior.

### Handwashing Intentions

Handwashing intentions were assessed using six questions that targeted the intention to wash one's hands in scenarios recommended by health organizations, such as "after blowing your nose, coughing or sneezing" and "after touching surfaces outside of the home, including money." The final item asked about intention to wash one's hands for at least 20 s each time. The scale demonstrated a high level of internal consistency ( $\alpha = 0.80$ ).

### Readiness to Change

Temporal readiness to change, or the stage of change that a participant is in, was simply assessed with a single item modeled after the work of Glanz et al. (1994). Participants were asked to select an option that best reflected their intention to wash their hands for 20 s multiple times per day. Response options included "I do not intend to do this," "I have thought about doing this, but do not yet plan to," "I intend to do this, but have not done it yet," "I am actively doing this," and "This is something that I have done for a long time, and intend to continue doing to prevent disease."

## Procedure

The present study was conducted as part of a larger project on COVID-19 and was approved by the University of Toledo Institutional Review Board. All procedures were conducted in compliance with the guidelines of the American Psychological Association. Participants were eligible for inclusion if they were at least 18 years old and resided in the United States. Before responding to the measures used in the present study, participants first were shown one of five brief handwashing messages for other purposes. The dependent variables in the present study, COVID-19 related handwashing behavior change, and readiness to change, did not differ based on the message shown. Only handwashing intentions were impacted by this message manipulation, and specifically, only one group differed from the other four. This group was excluded from the analysis of behavioral intentions to ensure that the message manipulation did not impact the present findings. It should be noted that the analyses produce similar results when they are conducted with all participants by controlling for message condition. Participants then completed the previously described measures on their attitudes, affect, intentions, and readiness to change related to handwashing. Finally, participants concluded their participation by completing demographic items.

## RESULTS

**Table 1** provides the means, standard deviations, and bivariate correlations for the measures of handwashing attitudes, affect,

intentions, behavior, and readiness to change. Notably, affect and attitudes were both positively correlated with COVID-19 related change in handwashing behavior, intentions, and readiness to change.

Given the correlations between variables, relative weights analyses (RWA; Johnson, 2000; Tonidandel et al., 2009) were used to determine the relative importance of attitudes and affect in explaining their relationship with the dependent variables of behavior change, behavioral intentions, and readiness to change. In RWA, predictor variables are transformed into orthogonal variables that are maximally related to the original predictors to determine the amount each predictor contributes to the total predicted variance and considers a predictor's direct effect (Johnson and LeBreton, 2004). The results from each analysis is described below and a summary of the findings can be found in Table 2.

### COVID-19 Handwashing Behavior Change

Changes in the number of times per day participants washed their hands before and after knowledge of COVID-19 was first assessed. Both the pre- and post-COVID-19 handwashing variables displayed considerable positive skew. As such, a natural log transformation was applied to both variables. Analyses were run both pre- and post-transformation. Both results were significant and produced similar findings. The transformed

variable was used in the presented analyses. In an RWA, when controlling for handwashing behavior prior to COVID-19, affect, but not attitudes was found to be a significant predictor of COVID-19-related handwashing behaviors.

### Handwashing Behavioral Intentions

Mirroring the first RWA, analyses were also run with behavioral intentions as the outcome variable. The results suggest that handwashing attitudes and affect are distinct significant predictors of handwashing intentions, with affect emerging as the stronger of the two predictors.

### Readiness to Change

Again, similar to the previous analyses, an RWA was used to determine the relationship between handwashing attitudes, affect, and readiness to change. The RWA indicated that, similar to handwashing behavior, only affect was a significant predictor of readiness to change.

### Income

Next, moderation analyses were conducted using the PROCESS macro for SPSS (Hayes, 2017) to determine if income moderated the relationship between attitudes and affect, and handwashing behaviors, intentions, and readiness to change. Analyses revealed

TABLE 1 | Means, standard deviations, and correlations of the variables.

	N	M	SD	1	2	3	4	5	6

<b>Readiness to change</b>							
Handwashing attitudes	0.18	0.11	0.031	-0.001	0.078	25.795	
Handwashing affect*	0.21	0.28	0.088	0.028	0.170	74.205	

\*indicates statistical significance determined by 95% CI.

b and β represent unstandardized and standardized regression coefficients, respectively; RW, raw relative weight; CI-L, lower bound of confidence interval used to test significance of RW; CI-U, upper bound of confidence interval used to test RW; RS-RW, rescaled relative weight shown as the percent of predicted variance in the outcome variable attributed to each predictor variable. Handwashing behavior n = 342; Behavioral intentions n = 277; readiness to change n = 344.

income to be a significant moderator ( $b = -0.03$ ,  $SE = 0.01$ ,  $p = 0.006$ ) of the relationship between affect and readiness to change,  $F(3, 335) = 7.71$ ,  $p < 0.001$ ,  $R^2_{\text{change}} = 0.02$ . Specifically, stronger affective responses resulted in greater readiness to change for low-income Americans, but not high-income Americans (see **Figure 1**). Income did not moderate the effects on behavioral intentions or handwashing behavior.

## DISCUSSION

The COVID-19 pandemic is the first of its kind occurring in modern times. As such there is limited data available to understand and make sense of the way that individuals respond to and react during a time of disease-related crisis. Gaining an understanding of public behavior provides the opportunity to better intervene at the preventative level, allowing for proven biomedical and epidemiological strategies to be more widely utilized and adopted. Behavioral research focused on COVID-19 is therefore critical in order to empower governments and health care organizations to intervene in the current pandemic and prepare for future events.

The present study begins to disentangle the relationships between both cognitive and affective variables on key health behaviors at an early stage of a rapid public health crisis. The RWAs considering the relative weights of attitudes and affect in predicting COVID-19 handwashing and readiness to change revealed handwashing affect to be a relatively stronger predictor of actual handwashing than handwashing attitudes. This advantage of affect over attitudes was more pronounced on the measure of readiness to change handwashing behavior. These findings add to emerging affective science database which indicates that cognitive variables, such as attitudes, are typically better predictors of behavioral intentions, and that affective variables are more closely related to the actual behavior (Williams et al., 2018). These findings highlight the importance of considering the affective impact of interventions, as affective variables may be the driving factor behind actual behavior change and readiness to make those changes.

Despite this finding, cognitive variables should not be dismissed. Actionable interventions for behavior change often

necessarily focus on changing participant intentions, which are often directly predictive of behavior. The present study provides evidence for the unique impact of both cognitive and affective variables on behavioral intentions in the context of a pandemic, and highlights the importance of targeting both variables for intervention. As predicted, attitudes toward handwashing were found to be significant predictors of handwashing behavioral intentions. Also, in support of our hypotheses, affective responses were found to better predict handwashing behavioral intentions beyond the impact of attitudes, in that the relative importance of affect was stronger than that of attitudes. This lends support to past studies demonstrating that affective constructs are distinct from cognitive variables, and additionally shows that this is true even during times of increased attention to health due to an abundance of health-related messaging and high personal relevance. Importantly, these data suggest that handwashing interventions should target both attitudes and affect.

Beyond these findings, it was also demonstrated that household income significantly interacted with handwashing affective responses when predicting readiness to change, but not when predicting past behavior change or behavioral intentions. Low-income individuals showed lower readiness to change than high-income individuals when they had weak affective responses; however, their readiness to change was higher than high-income individuals when they had strong affective responses. One possible explanation for this moderation occurring for readiness to change, but not COVID-19 related behavior change or intention, may be that while participants of all income levels display similar intentions to change, temporal readiness to change, as captured in participants' stage of change, may capture forecasts of future internal and external barriers that impede enactment of this intention, and strong affective responses may work to overcome these barriers.

## Limitations and Suggestions for Future Research

The current results should be understood in light of the study's limitations. The present data is cross-sectional and self-reporting in nature. The behavior change variable utilized in the present study was self-report in nature and future research should include other measurements. This variable also addresses past behavior, as opposed to future behavior change, which does not allow for the causal influence of intentions on the behavior to be explored. Relatedly, the measure of attitudes used in the present study was limited to two items due to the need for brevity. While care was taken to use items that would capture participants' attitudes, it is possible that results may be biased by having a more robust, 5-item measure of affect. Relatedly, income was employed as a moderator due to its established connection to health behavior and perceptions, as well as to emerging data that it is a risk factor for becoming seriously ill from COVID-19. Income, however, is an overarching societal-level variable, like age and education, that can be linked to many specific psychological processes. As such, additional work is needed to clarify the important moderating effect derived from income.

Given the promising present results, however, future studies should also aim to determine how other cognitive variables,

such as perceived susceptibility, subjective norms, and perceived control impact handwashing intentions, readiness to change, and behavior.

While the present study determined that income level moderates the relationship between affect and readiness to change, future studies should consider the influence of affect and attitudes as mediators of the demographic predictors of COVID-19 preventative behaviors. Future work should also aim to differentiate the impact of positive and negative affective responses, as differences can manifest in their predictive ability (Geers et al., 2017), and should also consider differences in self-conscious and hedonic affective states. For example, while not a primary focus of this study, both self-conscious and hedonic affective states were included in the measure of affect used here. *Post hoc* exploratory analyses found that these states significantly differed from one another, with hedonic states being rated as stronger. Upon examination, it appears that these types of affect were also distinct predictors of intentions, while only hedonic emotions were predictors of readiness to change. These results are in line with the findings of Giner-Sorolla's (2001) findings that hedonic affect was more accessible than self-conscious affect in situations related to self-control. Since these analyses were *post hoc*, future studies are needed to explore the impact of different types of affective states on health behaviors.

## Conclusion

While extensive research has been devoted to understanding variables related to preventative health behaviors, little is known about how these variables perform in the United States during a pandemic, such as COVID-19. The present results provide initial evidence that cognitive and affective variables are distinct predictors of behavioral intentions and demonstrates the moderating role of household income in predicting readiness to change. This suggests the promise of interventions targeting

both attitudes and affect for increasing handwashing behaviors and suggests that these types of interventions may be particularly efficacious in low-income communities.

## DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found at: [osf.io/bdx8g](https://osf.io/bdx8g).

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by University of Toledo Institutional Review Board. The patients/participants provided their written informed consent to participate in this study.

Hospital Preparedness, Resilience,  
and Psychological Burden Among  
Clinical Nurses in Addressing the  
COVID-19 Crisis in Riyadh, Saudi  
Arabia. *Front. Public Health* 8:573932.  
doi: 10.3389/fpubh.2020.573932

In the continuous effort to minimize the devastating effects of coronavirus disease (COVID-19) and to curb the spread of the disease, hospital preparedness and resilience play significant roles in the psychological well-being of clinical nurses given that their work demands immediate action to adapt and adjust to stressors. Thus, this study investigates the hospital preparedness, psychological burden, and resilience of clinical nurses in addressing COVID-19 in Riyadh, Saudi Arabia. A total of 281 clinical nurses participated in the survey from April 2020 to June 2020. Results show that clinical nurses perceived a high self-assessed COVID-19 hospital preparedness (49.65,  $SD = 2.30$ ); high self-assessed nurses' resilience (4.03,  $SD = 0.36$ ); and most have normal levels of depression, anxiety, and stress. The variables were predicted to be statistically significant ( $F_{18,262} = 4.14, p = 0.001$ ) and accounted for 16.8% of the variance in the nurses' perception of hospital preparedness ( $R^2 = 0.221$ ; adjusted  $R^2 = 0.168$ ). The regression analysis was statistically significant ( $F_{30,250} = 6.71, p = 0.001$ ) and accounted for 38% of the variance in nurses' resilience ( $R^2 = 0.446$ , Adjusted  $R^2 = 0.380$ ). The predictors of depression, anxiety, and stress show that the overall relationship was statistically significant at ( $F_{23,257} = 6.71, p < 0.001$ ), ( $F_{23,257} = 6.675, p 0.000$ ), and ( $F_{23,257} = 6.692, p 0.000$ ) with 31.9% of the variance ( $R^2 = 0.375$ , Adjusted  $R^2 = 0.319$ ), 31.8% of the variance ( $R^2 = 0.374$ , Adjusted  $R^2 = 0.318$ ), and 31.9 % of the variance ( $R^2 = 0.375$ , Adjusted  $R^2 = 0.319$ ), respectively. The findings of this study helps in improving the continuing education program, psychological support, and mental health program to ensure that the needs of clinical nurses are addressed during the outbreak of a disease.

**Keywords:** clinical nurses, COVID-19 crisis, hospital preparedness, nurses' resilience, psychological burden

## INTRODUCTION

In December 2019, Wuhan, China reported the first case of the coronavirus disease (COVID-19) (1). Saudi Arabi was among the first countries that implemented precautionary measures [e.g., stopping direct flights between Saudi Arabia and China (2); suspension of Umrah pilgrims; and banning of inbound travel from countries with active COVID-19 cases (3)] to prevent the entry of

the disease. However, despite the early implementation of the safety measures by the Saudi Arabia government, the first COVID-19 case was reported on March 2, 2020 because of the undeclared travel history of one traveler from Iran (3). The emergence of COVID-19 in Saudi Arabia resulted in the implementation of stricter rules to prevent the spread of the disease. The Saudi government totally suspended Umrah, Mosques were closed, schools and universities shifted to online learning, travel ban was ordered to all affected countries, and quarantine became mandatory for passengers. Individuals who were infected with COVID-19 were offered free hospitalization (4). As of June 7, 2020, Saudi Arabia has an approximate total of 101,914 COVID-19 patients with 712 deaths (5). This number is expected to increase further if the disease remains uncontrolled. The increasing number of COVID-19 cases puts health professionals at risk for the disease. The nursing staff at the frontlines are at most risk of becoming infected with the disease as the human transmission becomes evident with close contact to the carrier source. The unprecedented increase in the number of COVID-19 patients, person under investigation (PUI), and person under monitoring (PUM) necessitates a response from hospital management through the implementation of guidelines and procedures within a facility in coordination with the local authorities.

Hospital preparedness is integral in maintaining health services and controlling the spread of COVID-19. It involves the prevention, containment, management, monitoring, and identification of persons with COVID-19 or those exposed to them by implementing facility protocol (6). These measures include the training of healthcare personnel (HCP) on infection prevention and control policies, rapid identification, and isolation of patients confirmed or suspected to have COVID-19; placement of patients in appropriate isolation rooms; transmission-based precaution with the use of the appropriate personal protective equipment (PPE); moving a patient with confirmed or suspected COVID-19 within the facility; hand hygiene; environment cleaning; and limiting visitor access (7). Chopra et al. (8) projected that the large influx in the cases will continue to challenge bed capacity, equipment, and HCP in hospitals. The American Nurses Association (ANA) (9) emphasized the importance of the proper implementation of protocols and guidelines in managing COVID-19. During the early phase of the COVID-19 pandemic, no hospital has a well-established clinical protocol or treatment; resources, such as PPE, are limited (10); and the work load of nurses increased (11). These factors can result in mental health problems, such as stress, physical and mental fatigue, and irritability, among nurses (10).

Resilience is defined as the ability to face adverse situations while remaining focused and optimistic for the future (9). This attribute is considered vital for clinical nurses who are continually confronted with competing priorities and a complex healthcare system. With the ongoing pandemic and already stretched nursing staffing, clinical nurses are pushed to the edge with even higher work demands. The shortage of PPE increases the threat to their well-being (12). In Wuhan, China, nurses increase the resilience of their colleagues by comforting and helping each other (13). Gratitude from the public also improves

nurses' resilience with praiseworthy feedback and positive image (14). At this moment, nurses' resilience is essential for them to respond to this adversity favorably.

The increasing workload and negative effects of a pandemic may give rise to psychological burden among clinical nurses. As a result, their work performance may decline (15). Nurses are working extensively to ensure that the needs of the patients are attended. As nurses help in the journey of addressing this disease, maintaining and improving of their mental health are as important as improving their knowledge and skills on how to defeat the virus. The normal daily activities of nurses are already very stressful (16) and often have a negative effect on their mental health. The COVID-19 outbreak is a stressful situation that causes fear and anxiety among HCP because they have high likelihood of acquiring the disease. HCP in China have been infected with the disease, and many of them are exposed because of the shortage in PPE (13). In a study conducted in Wuhan, China, nurses were found to experience a severe degree of mental health symptoms (17). The unfortunate avoidance of family members and friends due to stigma, lack of PPE, the physical strain of PPE, preparing and keeping up-to-date with the best practices against COVID-19, and the risk of acquiring COVID-19 cause psychological burdens to nurses (18). In the unending continuous to minimize the devastating effects of COVID-19 and to curb the spread of the disease, resilience plays a significant role in the psychological well-being of clinical nurses given that their work demands immediate action to adapt and adjust to stressors. Thus, this study focuses on understanding hospital preparedness, psychological burden, and resilience of clinical nurses in addressing COVID-19.

## AIM OF THE STUDY

This study aims to determine the predictors of hospital preparedness in managing COVID-19 patients and the psychological burden and resilience among clinical nurses in addressing the COVID-19 crisis in Saudi Arabia. It also seeks to determine the effects of hospital preparedness in managing COVID-19 patients to nurses' resilience and hospital preparedness in managing COVID-19 patients and nurses' resilience to the psychological burden of clinical nurses in addressing the COVID-19 crisis in Riyadh, Saudi Arabia.

## METHOD

This cross-sectional design was conducted in two government hospitals in Riyadh Region, Saudi Arabia from April 2020 to June 2020.

### Sampling and Sampling Technique

This study was conducted in two government hospitals in Riyadh, Saudi Arabia. Hospital A is a training hospital, whereas hospital B is a non-training hospital. Both hospitals are COVID-19 designated facilities. These hospitals provide various medical and nursing services for emergency, outpatient, inpatient, and homecare patients. These hospitals also have infectious control

and Middle East respiratory syndrome coronavirus (MERS-COV) policies and guidelines, infectious units, and mental health programs for their employees. The study population was composed of Saudi and non-Saudi clinical nurses who met the study inclusion criteria of being employed in the research site hospital. The inclusion criteria for the respondents of the study included nurses who are on active duty during the COVID-19 crisis and license nurse practitioners in Saudi Arabia who are willing to be part of the study. The exclusion criteria were nurses who are on leave during the COVID-19 crisis and those who refused to participate in the study. The study had a total of 281 respondents, and convenient sampling technique was applied. The actual power after *post-hoc* analysis of the G\*Power program (version 3.1.9.4) using the *t*-test model, two predictor variables, medium expected effect size ( $d = 0.5$ ), and a 5% level of significance is 0.99.

### Data Gathering Instrument

Demographic data were obtained to describe the respondents. Three instruments were used to obtain data: (1) Hospital Preparedness Assessment Tool, (2) the Depression, Anxiety, and Stress Scale—21 (DASS-21), and (3) the Resilience Scale for Nurses. The researcher received approval for the use of DASS-21 and Resilience Scale for nurses.

### Hospital Preparedness Assessment Tool

This hospital preparedness assessment tool was adapted from the Control for Disease Control and Prevention (CDC) protocol. The element of this protocol is “infection prevention and control policies and training for HCP, the process for the rapid identification and isolation of patients with confirmed or suspected COVID-19, patient placement, transmission-based precaution, movement of a confirmed or suspected COVID-19 patient within the facility, hand hygiene, environment cleaning, monitoring, and managing HCP, and visitor access and movement within the facility” (18). The questionnaire includes YES or NO questions, wherein the staff nurses will determine if the item is present or being practiced in their workplace. The scale level content validity index (S-CVI) score averaging method of the tool based on the evaluation of five experts, which include nurse supervisors, nurse educators in the hospital, and a nurse infectious manager, is 1. According to Polit and Beck (19), a S-CVI score of 1 with 3–5 experts is valid.

### DASS-21

DASS-21 is a tool used to measure the psychological burden of nurses in addressing COVID-19. DASS-21 is a 21-item self-administered questionnaire used to assess depression, anxiety, and stress with 7 items. The “depression” part of the DASS-21 measures low mood, motivation, and self-esteem; the “anxiety” part focuses on physiological arousal, perceived panic, and fear; and the stress part involves tension and irritability. Cronbach's  $\alpha$  revealed a result of 0.84 to 0.92 for DASS-Anxiety, 0.90–0.95 for DASS-Stress, and 0.96–0.97 for DASS-Depression (20). To determine DASS severity rating, the score of every statement for each scale (e.g., depression, anxiety, and stress) were added. The total score of the items in each group (e.g., depression,

anxiety, and stress) were compared with the severity rating of the three scales to determine their severity labels. If the total score of the items in depression subscale is 0–4, 5–6, 7–10, and 14 and above, then it is interpreted as normal, mild, severe, and extremely severe, respectively. Meanwhile, if the total score of the subscale stress is 0–3, 4–5, 6–7, 8–9, and 10 and above, then the severity label is normal, mild, moderate, severe, and extremely severe, respectively. In the stress subscale, a total score of 0–7, 8–9, 10–12, 13–16, and 17 and above is considered normal, mild, moderate, severe, and extremely severe.

### Resilience Scale for Nurses

The Resilience Scale for Nurses is composed of 22 items validated by Ihara et al. (21). The tool has four principal factors that consist of positivity in nursing, which has eight items; interpersonal skills, which has five items; having an anchor in personal life, which has five items; and response to novelty, which has four items. The overall Cronbach's alpha of RSN is 0.84, “positivity in nursing” is 0.87, interpersonal skills is 0.77, “having an anchor in personal life” is 0.76, and a “response to novelty” is 0.63 (22).

### Data Gathering Procedure

A letter of request for permission to conduct a study was forwarded to the research committee of the institution. Upon approval, an abstract was presented for review by the Research Ethics Committee at the Ministry of Health (MOH), Saudi Arabia. Upon ethics approval, a letter was presented to the Nurse and Medical Director of the participating institution. The list of staff nurses was obtained from the head nurse and/or supervisor of the hospital. The researchers/research assistant explained the importance, procedure, and advantages of the study before asking the respondents to sign the consent form. Once permission has been given by the potential respondent, the researcher/research assistant administered the questionnaire to them. The respondent was informed that indicating his/her name is optional, but a tracking number is included to ensure that no respondent was given the questionnaire more than once.

The questionnaires were distributed in the ward assignment of the nurses. The researcher/research assistant distributed three questionnaires to those willing to partake in the study. The respondents were instructed to answer the questionnaire personally and to contact the researcher for any clarifications, concerns, or problems encountered while answering the tool. For busy respondents, the data gathering tool was retrieved after 2 days or depending on the time set by the respondent and researcher. Once the questionnaire has been received by the researcher, it was checked for any missing data. If any item was left without any answer, then the researcher will ask the respondent to answer the missing item(s). The results were analyzed after the data were tallied and tabulated. The collected data were kept in a folder file with a security code in the personal computer of the primary researcher. Only the primary researcher can access the secured folder file.

### Ethical Consideration

The University Research Committee and the MOH of Saudi Arabia ensured the ethical conduct of the study. Confidentiality

was maintained by avoiding data that could associate the response of the respondent to their identity. The aims, purpose, and process of research were discussed with the respondents. Respondents were allowed to ask questions and withdraw from the study if they feel that their rights were being violated. Perceived coercion was avoided by ensuring the absence of an existing power relations between the researchers and the respondents or by using a middleman to contact the respondents. The respondent was also informed that no additional data apart from the survey information will be taken.

## Statistical Analysis

Data related to the descriptive data form and the scales used were evaluated in SPSS 23 program version 22.0. Sociodemographic data were presented with mean, percentages, and frequency analysis. The predictors of hospital preparedness, resilience, and psychological burden of nurses, hospital preparedness predicting nurses' resilience, and hospital preparedness and nurses' resilience predicting psychological burden were evaluated using linear multiple regression analysis.

## RESULTS

A total of 281 clinical nurses in Riyadh, Saudi Arabia participated in the study. More than half of the respondents are from hospital A (77.94%). Most of the respondents are females (85.8%), Bachelor of Science in Nursing (BSN) graduates (84.7%), and Christians (75.8%). The mean age was 33.25 ( $SD = 6.38$ ). The largest group of respondents include Filipinos (58.7%) as compared with Saudi national Nurses (12.1%). Most of the respondents are Emergency Room (ER) nurses (31.7%), and more than half have provided care for a confirmed COVID-19 case (65.2%). The mean years of experience of the nurses were 10.66 ( $SD = 6.37$ ). The mean of the self-assessed degree of confidence of nurses on the government response to COVID-19 was 8.07 ( $SD = 1.82$ ), 8.17 ( $SD = 1.47$ ) for public authorities, and 8.34 ( $SD = 1.47$ ), and 8.46 ( $SD = 1.53$ ) for hospital administration and nursing administration, respectively indicating high level of confidence (Table 1).

## COVID-19 Hospital Preparedness, Resilience, and Psychological Burden of Nurses

The results of the descriptive analyses of the clinical nurses' perception of COVID-19 hospital preparedness, resilience, and psychological burden in Riyadh, Saudi Arabia are presented in Table 2. Most clinical nurses perceived a high self-assessed COVID-19 hospital preparedness, as evidenced by the mean score of 49.65 ( $SD = 2.30$ ). Furthermore, all COVID-19 hospital preparedness subscales were rated as high.

The clinical nurses perceived a high self-assessed resilience, as shown by the mean of 4.03 ( $SD = 0.36$ ). The subscales of resilience, namely, "Positivity in nursing" (4.60,  $SD = 0.41$ ), "Interpersonal skills" (4.09,  $SD = 0.51$ ), "Having an anchor in personal life" (4.05,  $SD = 0.48$ ), and "Response to novelty" (3.99,  $SD = 0.76$ ), were also perceived as high by the clinical nurses.

**TABLE 1 |** Demographics ( $n = 281$ ).

Variables	n	%
<b>GENDER</b>		
Female	241	85.8
Male	40	14.2
<b>EDUCATIONAL ATTAINMENT</b>		
Diploma	43	15.3
BSN	238	84.7
<b>NATIONALITY</b>		
Saudi	34	12.1
Filipino	165	58.7
Indian	82	29.2
<b>MARITAL STATUS</b>		
Single	107	38.1
Married	174	61.9
<b>RELIGION</b>		
Muslim	43	15.3
Christian	213	75.8
Hindi	25	8.9
<b>CLINICAL AREA</b>		
ER	89	31.7
ICU	30	10.7
OPD	25	8.9
Medical-Surgical Ward	82	29.2
Isolation ward	31	11.0
Operating Room	24	8.5
<b>PROVIDED CARE FOR CONFIRMED COVID-19 CASE</b>		
No	123	43.8
Yes	158	56.2
<b>PROVIDED CARE FOR SUSPECTED COVID-19 CASE</b>		
No	257	91.5
Yes	24	8.5
	Mean	SD
Age	33.25	6.38
Year of experience	10.66	6.37
Degree of confidence on the government	8.07	1.82
Degree of confidence on the public health authorities	8.17	1.47
Degree of confidence on the hospital administration	8.24	1.47
Degree of confidence on the nursing administration	8.46	1.53

The percentage of respondents with a normal level of depression is 51.2% ( $n = 144$ ), 36.3% ( $n = 102$ ) have normal level of anxiety, and 82.2% ( $n = 231$ ) have normal level of stress while addressing COVID-19 crisis. Meanwhile, 23.5 ( $n = 66$ ) of the respondents have moderate depression, 19.5% ( $n = 55$ ) perceived a mild degree, and 5.7% ( $n = 16$ ) had severe depression during the COVID-19 crisis. In terms of anxiety, 37.4% ( $n = 105$ ) have moderate anxiety, 12.1% ( $n = 34$ ) have severe anxiety, 7.5% ( $n = 21$ ) have extremely severe anxiety, and 6.8% ( $n = 19$ ) have mild anxiety during the COVID-19 crisis. Furthermore, during the COVID-19 crisis, 8.5% ( $n = 24$ ) of the respondents have moderate stress, 5.7% ( $n = 16$ ) have mild stress, 2.85% ( $n = 8$ ) have severe stress, and ~0.7% perceived extremely severe stress.

**TABLE 2** | Results of the descriptive analyses of the different variables ( $n = 281$ ).

Variable	Mean	SD	
COVID-19 Preparedness of the hospital	49.65	2.30	
Infection prevention and control policies and training for healthcare personnel	6.92	0.27	
Process for rapidly identifying and isolating patients with confirmed or suspected COVID-19	11.30	0.95	
Patient placement	9.46	0.83	
Transmission-Based Precautions	3.85	0.53	
Movement of patients with confirmed or suspected COVID-19 within the facility	2.88	0.51	
Hand hygiene	1.95	0.30	
Environmental cleaning	4.66	0.74	
Monitoring and managing healthcare personnel	2.94	0.29	
Visitor access and movement within the facility	5.70	0.70	
Resilience	4.03	0.36	
Positivity in nursing	4.60	0.41	
Interpersonal skill	4.09	0.51	
Having an anchor in personal life	4.05	0.48	
Response to novelty	3.99	0.76	
Depression	9.53	6.49	n (%)
Normal			144 (51.2)
Mild			55 (19.6)
Moderate			66 (23.5)
Severe			16 (5.7)

Extremely severe			21 (7.5)
Stress	10.12	7.27	
Normal			231 (82.2)
Mild			16 (5.7)
Moderate			24 (8.5)
Severe			8 (2.8)
Extremely severe			2 (0.7)

## Multiple Regression Analysis on the Nurses' Perception of Hospital Preparedness

Multiple regression analysis was used to determine the predictors of hospital preparedness in Riyadh, Saudi Arabia during the COVID-19 crisis, as perceived by staff nurses. The variables were predicted to be statistically significant ( $F_{18,262} = 4.14$ ,  $p = 0.001$ ) and accounted for 16.8% of the variance in the nurses' perception of hospital preparedness ( $R^2 = 0.221$ ; adjusted  $R^2 = 0.168$ ). As presented in **Table 3**, hospital, gender, clinical area, provided care with confirmed cases, and degree of confidence on the government effort against the pandemic were revealed

as significant factors for predicting the nurses' perception of hospital preparedness. Specifically, nurses who work in Hospital B have a lower mean score of 1.15 ( $p = 0.020$ ,  $CI = -2.12, -0.19$ ) as compared with those working in Hospital A. A point increase in female respondent mean score indicates a decrease in the mean score of male respondents of 1.32 ( $p = 0.001$ ,  $CI = -2.08, -0.56$ ). Similarly, medical-surgical (MS) ward nurses and operating room (OR) nurses have a lower mean of 1.30 ( $p = 0.004$ ,  $CI = -2.19, -0.41$ ) and 2.50 ( $p < 0.001$ ,  $CI = -3.75, -1.26$ ) than the mean score of ER nurses, respectively. The nurses who provided care to patients with COVID-19 perceived a higher mean score of 1.22 ( $p = 0.003$ ,  $CI = 0.41, 2.03$ ) as compared with those who did not provide care to patients with COVID-19. A point increase in the degree of confidence of clinical nurses on the ability of the government to control COVID-19 cases corresponds to a 0.25 ( $p = 0.039$ ,  $CI = 0.01, 0.49$ ) increase in the perceived hospital preparedness of nurses in Riyadh, Saudi Arabia.

## Multiple Regression Analysis of Nurses' Resilience

Multiple regression analysis was conducted to examine the predictors of clinical nurses' resilience during the COVID-19 crisis. The regression analysis was statistically significant ( $F_{30,250} = 6.71$ ,  $p < 0.001$ ) and accounted for 38% of the variance in nurses' resilience ( $R^2 = 0.446$ , Adjusted  $R^2 = 0.380$ ). As presented in **Table 4**, age, years of experience, area of assignment of nurses, degree of confidence on the public health authorities and hospital administration, and the hand hygiene subscale of hospital preparedness were revealed as significant factors for predicting nurses' resilience. Specifically, the addition year in the age of the respondent corresponds to 0.02 ( $p = 0.027$ ,  $CI = 0.00, 0.03$ ) increase in nurses' resilience. The years of experience had a positive influence on nurses' resilience by 0.03 ( $p = 0.001$ ,  $CI = 0.05, 0.02$ ). The result observed on nurses assigned in the MS and isolation wards had decreased mean scores of 0.16 ( $p = 0.42$ ,  $CI = -0.25, -0.01$ ) and 0.16 ( $p = 0.020$ ,  $CI = 0.30, -0.03$ ), respectively, as compared with the mean score of ER nurses. The increase in the degree of confidence of nurses on the government resulted in 0.06 ( $p = 0.001$ ,  $CI = -0.09, -0.02$ ) decrease in the perceived nurses' resilience. A point increase in the degree of confidence of nurses in hospital administration corresponds to 0.10 ( $p = 0.002$ ,  $CI = -0.16, -0.04$ ) decrease on nurses' resilience. A point increase in the degree of confidence of nurses on the public health authorities resulted in 0.14 ( $p < 0.001$ ,  $CI = 0.10, 0.18$ ) increase in the nurses' resilience. As to the hospital preparedness subscale, a point increase in the mean score of hand hygiene corresponds to 0.31 ( $p < 0.001$ ,  $CI = -0.46, -0.15$ ) decrease on nurses' resilience.

## Predictors of Depression, Anxiety, and Stress

Multiple regression analysis was conducted to examine the predictors of depression of clinical nurses during the COVID-19 crisis in Riyadh, Saudi Arabia. The regression model accounted 31.9% of the variance in depression ( $R^2 = 0.375$ , Adjusted  $R^2 = 0.319$ ), and the overall relationship was statistically significant

**TABLE 3** | Result of the multiple regression analysis on the nurses' perception of hospital preparedness ( $n = 281$ ).

The dependent variable was the nurses' perception of hospital preparedness.  $\beta$  is the unstandardized coefficients; SE-b is the Standard error.  $R^2 = 0.221$ , Adjusted  $R^2 = 0.168$ .

\*Significant at 0.05, \*\*Significant at 0.01, \*\*\*Significant at 0.001.

( $F_{23,257} = 6.692$ ,  $p < 0.001$ ). As presented in **Table 5**, gender, educational attainment, nationality, marital status, religion, area of assignment of nurses, degree of confidence on the government, public health authorities and hospital administration, and nurses' resilience were revealed as significant factors for predicting the nurses' psychological burden. Specifically, nurses in Hospital B have a higher depression mean score, by 3.09, than those in Hospital A. Depression score was negatively correlated to age and degree of confidence in public health authorities, which decreased by 0.44 for every increase in age and by 1.17 for every increase in the degree of confidence of nurses to public health authorities. Females have a lower mean score than males by 2.55. Diploma nurses have a lower mean score than BSN by 4.36. Similarly, Filipino and Indian nurses have a lower mean score than Saudi national nurses by 7.10 and 8.97, respectively. Single nurses also have a lower mean score than married nurses by 2.63. Nurses who did not provide care to a COVID-19 patient has a lower mean score by 2.12 than those who provide care to a COVID-19 patient. A point increase in the degree of confidence of nurses on the public health authorities corresponds to a 1.17 decrease on the nurse's depression mean score. Meanwhile, a point of increase in the degree of confidence of nurses on the government and hospital administration resulted in 0.88 and 1.36 increment in the depression mean score of nurses. Isolation ward nurses' depression mean score is higher by 4.35 than ER nurses.

A point of increase in the nurses' resilience corresponds to a decrease of 4.09 depression mean score of nurses.

As to the predictors of the anxiety of clinical nurses during the COVID-19 crisis in Riyadh, Saudi Arabia, the regression analysis was statistically significant ( $F_{23,257} = 6.675$ ,  $p < 0.001$ ) with 31.8% of the variance in anxiety ( $R^2 = 0.374$ , Adjusted  $R^2 = 0.318$ ). **Table 5** shows that with other variables held constant, female nurses' anxiety mean scores are lower by 2.86 than those of male nurses. Similarly, nurses with diplomas had a lower mean than BSN nurses by 5.52. Filipino and Indian nurses' anxiety mean scores were lower than Saudi national nurses by 6.17 and 8.78, respectively. MS, isolation ward, and OR nurses have higher anxiety mean scores than ER nurses by 2.20, 2.57, and 4.17, respectively. Nurses who provide care to confirmed COVID-19 patients have lower anxiety mean scores than those who do not provide care to COVID-19 patients by 4.76. A point increase in the degree of confidence of nurses in public health authorities and nursing administration led to a decrease of 0.99 and 1.38 of the anxiety mean score, respectively, whereas a point increase in the degree of confidence of nurses on the hospital administration corresponds to 2.59 increase in the anxiety mean score of nurses.

With regards to the predictors of the stress of clinical nurses during COVID-19 crisis in Riyadh, Saudi Arabia, the regression analysis was statistically significant ( $F_{23,257} = 6.692$ ,  $p < 0.001$ ) with a 31.9% of the variance in stress ( $R^2 = 0.375$ , Adjusted

$R^2 = 0.319$ ). **Table 5** shows that with other variables held constant, nurses with a diploma had lower stress mean score than BSN nurses by 4.44. Filipino and Indian nurses' stress mean scores were lower than Saudi national nurses by 7.14 and 8.82, respectively. Single nurses have a lower mean score than married nurses by 4.55. Isolation ward and OR nurses have higher stress mean scores than ER nurses by 4.80 and 5.37, respectively. Nurses who provide care to confirmed COVID-19 patients have lower stress mean scores than those nurses who did not provide care to COVID-19 patients by 5.47. A point increase in the degree of

confidence of nurses in public health authorities corresponded to a decrease of 1.30 in anxiety mean score, whereas a point increase in the degree of confidence of nurses on the hospital administration corresponds to a 2.64 increase in the anxiety mean score of nurses.

## DISCUSSION

The finding of this study shows that clinical nurses in Riyadh, Saudi Arabia have high perception of hospital preparedness in

combating COVID-19. This finding implies that the hospital is playing its role in preventing and controlling the disease. The hospital is complying with the policies and guidelines set by the WHO and CCDC in response to COVID-19. The guidelines and policies are implemented properly to ensure that staff, patients, and visitors are protected. The finding of the study further shows that the preparedness of the hospital is based on the immediate action executed by the government in response to COVID-19. The government has allocated sufficient funds to ensure hospital readiness in terms of personnel, medicines, availability of equipment, such as hospital beds and ventilators, and other necessary medical supplies, were secured (22). The Saudi government took further extra measures to lessen the consequences of the COVID-19 crisis, which include rapid identification and isolation of confirmed or suspected COVID-19 patients. Currently, no effective medicines or vaccines have been discovered to control and manage COVID-19. For

this reason, isolation and identification of symptomatic and asymptomatic persons with COVID-19 can reduce the spread of the virus (23). Thus, early prevention and control are vital in containing COVID-19.

The finding of this study also shows that during this unprecedented crisis, nurses' resilience is very high, thereby showing their ability to adopt in a very stressful situation. The positive characteristics of the respondents that lead to high resilience include age, years of experience, and degree of confidence in public health authorities. As a person ages, their resilience increases, especially in problem-solving and capability to handle emotional problems (24). During the COVID-19 pandemic, as nurses age, their ability to adjust and adapt to the changes in their work became more evident. The years that nurses have spent providing care to infectious and non-infectious patients have contributed to the development of their resilience. This view is supported by Hart et al. (25) who found

that competence, flexibility, adaptability, hardiness, and sense of coherence in nurses increase resilience. The actions of the public health authorities by providing guidelines and policies to combat COVID-19 have also helped nurses to fulfill their roles and functions. The policies and guidelines issued by the health authorities help nurses to cope and adjust amid the COVID-19 crisis. These policies and guidelines strengthen the ability of the nurses to protect themselves and deliver services in response to COVID-19 while increasing their competence and confidence in dealing with COVID-19 patients. Being competent and confident are strategies to cope, deal, and handle immediate stressors and enhance resilience (26). The novelty of this disease has also helped nurses to be more engaged in understanding and learning up-to-date information to prevent and control COVID-19. This action is considered a part of the health coping strategies that improve their resilience (27). Nurses use their nursing knowledge and skills to adapt psychologically and prevent psychological burden. This notion is evident in the findings of this study on the increased number of nurses who have normal levels of depression, anxiety, and stress.

Although many studies have proven that most nurses experience psychological burden during a pandemic (17), the findings of our study show otherwise. Most of the nurses in our study did not experience depression, anxiety, and stress. This finding is associated with the positive support received by nurses from the government, society, and their families. The support from their family and the society help nurses increase their sense of pride and professional identity (28). Therefore, the inspiration received by nurses from their support system contributes to their psychological adaptation and adjustment during this pandemic.

However, although most of the nurses in this study have normal psychological status, male Saudi national nurses, as well as Christian, Hindu, and nurses providing direct care to COVID-19, were found to be predictors of nurses' psychological burden. Male nurses have a higher mean score than the female nurses, indicating that the former is more prone to psychological burden during this pandemic than the latter. This finding could be associated with the role of males in the family in Asian countries. Males are usually the breadwinners and provide the needs of their family. The fear of spreading the disease to their loved ones and the financial impact of this pandemic are factors that could increase the psychological burden of male nurses. However, this assumption needs further investigation in future studies. Saudi nurses are prone to psychological burden because of the following reasons: contagion and spreading the virus to their families and friends because they are living with them unlike foreign nurses who live in accommodations provided by the hospital. This finding is consistent with that in China, where Chinese nurses experience fear, depression, anxiety, and stress due to COVID-19 (17).

Christians and Hindu have higher mean depression, anxiety, and stress scores than Islamic nurses because of poor religious coping. According to Carver (29), religion is a coping mechanism used to promote positive well-being. During this pandemic, everyone wants to address their spiritual need by attending

church services or consulting with clergies or priests. In Saudi Arabia, the practice of other religious gatherings or services is not allowed, except for Islam. The practice of praying together as a coping mechanism is not allowed. This conflict between religious practices and orientation and culture in Saudi Arabia affects religious coping, thereby increasing their psychological burden. According to Cruz et al. (30), religion is an effective coping mechanism for psychological burden. Religion provides an avenue to cope with a stressful situation and positive support from religious core group members. This view prompted Cruz et al. (31) to posit that the development of a safe working place for Saudi and non-Saudi nurses where they can freely practice their spirituality would be advantageous.

Nurses working in the MS, Isolation, and OR wards have higher psychological burden than ER nurses. MS and OR ward nurses are usually not exposed to COVID-19 patients and have limited clinical experience in providing care to a patient with an infectious disease as compared with isolation ward and ER nurses. Providing care to COVID-19 patients also requires comprehensive and specific management (32). These identified factors increase the psychological burden of MS and OR ward nurses. The experience of an isolation ward nurse has a high mean score in the psychological burden than an ER nurse because of their prolonged exposure to COVID-19 patients. Most patients are admitted at the isolation ward, which predisposes nurses to be more susceptible to contagion. The feeling of being infected increases the psychological burden of nurses (32).

The findings show that nurses' high resilience decreases the mean score of depression and implies that nurses can cope with stressors during this global pandemic and help prevent depression. Self-confidence, calmness, relaxation, and cheerfulness (33) are positive contributors to the emotional stability of nurses. Thus, the finding implies that positive emotions should be strengthened in the psychological dimension to prevent psychological burden.

## LIMITATION OF THE STUDY

The respondents of the study include clinical nurses. Thus, the findings may not be generalized to the other population with different experiences and perceptions in the clinical settings. Nevertheless, it can be replicated. In addition, participants in this study were limited to two settings because of the COVID-19 pandemic. For better representation, future researchers should conduct a wider scale setting. The use of cluster sampling is also recommended to ensure that each facility will have an allocated proportion to generate representativeness of the sample size. The data were gathered using a self-report questionnaire. Thus, the report bias cannot be controlled. There is also limitation in interpreting the psychological burden of the clinical nurses. Since, DASS-21 is not a measure of clinical diagnoses, which means it cannot diagnose depression, anxiety, or stress. Instead, DASS-21 can determine the presence and severity of stress, anxiety, and depression.

## CONCLUSION AND IMPLICATIONS

This research is significant for nursing administrators and staff nurses because it can help them identify the strained aspects of hospital preparedness that need to be improved to strengthen their workplace in the prevention, control, management, and containment of COVID-19. The development of hospital protocols in the handling of confirmed or suspected COVID-19 patients is also effective.

In clinical areas, the findings of this study can help hospital administrators and nursing leaders to identify the strengths and weaknesses of hospital preparedness for confirmed or suspected COVID-19 patients. The hospital can be guided in designing a continuing education program that would enhance hospital preparedness for confirmed or suspected COVID-19 patients.

Nurses have low psychological burden and high resilience. The finding of this study would be of great help in developing psychological support and mental health program to be implemented in times of crisis.

The results of this study may potentially support the scarce data available on hospital preparedness for confirmed or suspected COVID-19 patients, psychological burden, and resilience. The results of this quantitative endeavor can also serve as basis for other similar future research that aim to explore the same topic. This study fills a gap in the literature on hospital preparedness for confirmed or suspected COVID-19 patients, psychological burden, and resilience.

The COVID-19 pandemic caught the entire world off guard. Israel, similar to all other nations, was forced to cope with the unknown. “Flattening the curve” of infections has become a common term among specialists and decision makers, while explaining restricting measurements taken toward the population. Israelis, who had previously learned to deal with life under constant security threat, are now facing a new reality. The purpose of the study was to check how Israelis are psychologically affected by and coping with the COVID-19 pandemic. The study included 925 Israelis divided into three groups: ages 18–29, 30–59, and 60–88. The data were collected between March 31 and April 8, 2020, when it was already clear that this is a global plague, the country’s borders were closed, and the government’s directive for citizens was to remain at home while imposing limitations on the public and private sectors. The current study examined psychological distress among the three age groups as well as the associations between levels of distress, resilience, and coping strategies. Levels of distress were measured via the BSI-18 that measures anxiety, depression, and somatization. Resilience was measured using the Connor-Davidson CD-RISC scale. Coping was measured by the short version of the COPE. Psychological distress was associated with being in a younger age group, being a woman, having economic concerns, use of emotion and problem focused coping, and lower resilience. The study also found that concern for the health of family members was the strongest concern among all age groups but was highest among the younger age group. It was also found that those in the younger age group suffered from higher levels of depression, anxiety, and somatization compared to the older age group. The middle age group suffered from elevated levels of anxiety and somatization compared to the older age group. Although the older age group was the most vulnerable to the coronavirus, in this study age was found to be a protective factor from psychological distress. The results of the study suggest the need to consider the younger age group as a risk group, which hence needs to be addressed as the focus of intervention programs. It appears that the concern for their loved ones takes a heavy toll on the younger generation, and this should be considered a major source of stress.

**Keywords:** coronavirus, psychological distress, age, coping, resilience

## INTRODUCTION

The 2019 Coronavirus (COVID-19) pandemic caught the whole world “off guard.” It first emerged in late December 2019 in Wuhan, China, and spread nationwide between December 2019 and early 2020 (1). On January 30, 2020, the World Health Organization (WHO) declared the COVID-19 outbreak a public health emergency of international concern. Israel was not spared. On January 30, Israel banned all flights from China, expanding this 2 weeks later to include more Asian countries. On March 12 all universities, schools, and kindergartens were closed, switching to remote study methods. On March 19, Israeli Prime Minister Benjamin Netanyahu declared a national emergency. Israelis were not allowed to leave their homes, unless absolutely necessary. Excluding essential services (food shops, pharmacies, and banks), which remained open, everything was closed. The restrictions were toughened during the days leading up to the closure, which was a prohibition on leaving one’s house for a distance of more than 100 m, meetings with others who do not live in the same household, and so on. The national unemployment rate rose from 3.4 to 27% in April. Mandatory face masks outside the home was introduced on April 12, and the restrictions were gradually lifted from April 19 until the Israeli economy resumed its routine.

The current study was conducted during the peak of the closure, from March 30 to April 8. At this time there was a real concern that the pandemic would get out of hand and Prime Minister Benjamin Netanyahu, together with the Ministry of Health and its Director General appeared on television almost every evening in order to explain the severity of the pandemic and warned of a forecast of thousands of casualties and tens of thousands inflicted if the closure would not be maintained. The concern that it would not be possible to provide a medical response and that the crisis was threatening to overwhelm the Israeli healthcare system was reiterated. The rate of those diagnosed with Coronavirus rose from 4,695 cases on March 30 to 9,404 by April 8, and the number of deaths rose from 12 on March 30 to 73 on April 8.

Israeli society is used to coping with crisis situations that include war and security threats, but Israel last coped with a pandemic event of global dimensions in the 1950s, in the case of the polio pandemic.

Research on how Israelis cope with security threats indicates processes of habituation after periods of tension and anxiety (2, 3). These processes were observed both in mental and physical contexts. For example, Levav et al. (4) examined health service use among the general population in response to terrorism. They found that, with few exceptions, the residents did not seek increased help from psychiatric services during the study period. In another study, Ponizovsky et al. (5) looked at the association between psychological distress and mortality. Supporting their assumption that Israelis are conditioned to adjust to these life stresses, they found that exposure to security threats (i.e., war, combat, and terror) had no association with overall mortality or cause-specific mortality.

Nonetheless, the coping of Israeli society with a non-security threat with features of a pandemic, such as the situation formed

following exposure to COVID-19, has hardly been studied [e.g., (6, 7)]. Hence, the purpose of the current study is to examine psychological distress, coping processes, and resilience of Israeli society at the height of the pandemic and of the period of social restrictions.

A review of 24 studies documenting the psychological impact of quarantine (“the separation and restriction of movement of people who have potentially been exposed to a contagious disease,” p. 912) was carried out by Brooks et al. (8). The studies were conducted across 10 countries and included people with SARS (11 studies), Ebola (five), the 2009 and 2010 H1N1 influenza pandemic (three), Middle East respiratory syndrome (two), and equine influenza (one). One of these studies related to both H1N1 and SARS. Most studies reviewed reported negative psychological effects, including symptoms of psychological stress, anxiety, insomnia, anger, irritability, emotional exhaustion, depression, and post-trauma. Stressors also included longer quarantine duration, infection fears, frustration, boredom, inadequate supplies, inadequate information, financial loss, and stigma.

Research-based evidence on the mental health effects of the current pandemic began to arrive particularly from several studies conducted in China, where the pandemic began, as stated (1, 9). The first nationwide survey of psychological distress among Chinese people in the COVID-19 epidemic was conducted by Qiu et al. (1). They found that almost 35% ( $N = 52,730$ ) of the respondents experienced psychological distress, with significantly higher psychological distress among women and among individuals between 18 and 30 years of age or above 60. Going forward, a systematic review conducted by Xiong et al. (10) shows that although early studies from China documented higher distress among older adults, later studies from Western countries usually found lower rates of distress among older adults relative to other age groups. Similar findings were also found among Israeli older adults (7).

However, studies suggest that exposure to stressful life events retains a stable equilibrium without reactive psychopathology. A consistent body of research suggests that a majority of those who were exposed to stressful and traumatic events retain a stable equilibrium without reactive psychopathology (11, 12). The growing focus on health promotion and well-being, shifting emphasis away from pathogenic to salutogenic factors provides an opportunity to examine the role of resilience and the coping strategies in health.

Different operational definitions and corresponding methodology for measuring resilience have been offered (13). Connor and Davidson (14) define resilience as a personality trait that embodies the personal qualities that enable one to thrive in the face of adversity. In other words, it is a set of protective factors (e.g., close relationships with family and community, optimistic outlook, embracing challenges) allows an individual to have a positive response to adverse events (14). Reference to resilience as a personality trait is expressed in the questionnaire authored by them, named *The Connor–Davidson Resilience Scale* (14) that is used in this study, as well as in others [e.g., (15)]. Research findings note that trait resilience is a relatively stable personality feature (16), that was found to be associated with

lower levels of distress (e.g., depression, anxiety, sleep disorders, and PTSD) and better physical and mental health (12, 14, 16, 17).

Resilience has been associated with coping strategies, in the context of adverse events (18). In the current study, we use the notion proposed by Lazarus and Folkman (19, 20) that coping strategies are cognitive and behavioral efforts to manage specific external and/or internal demands appraised as taxing or exceeding the resources of the person dealing with stressful situations and events. Coping strategies may yield either positive or negative results. They were found to be an important feature, which moderates the association between exposure to stress and mental health in various contexts (21, 22). Lazarus and Folkman (19) suggested two major forms of coping: problem-focused (dealing with stress sources and taking proactive steps to change them) or emotion-focused (serving to reduce the emotional stress resulting from such situations) [See also: (23)].

Use of problem-focused strategies usually shows more negative correlations with distress, and indicates good mental health (24, 25) and higher levels of resilience (22, 26). In contrast, greater use of emotion-focused coping is highly correlated with high levels of psychological distress [e.g., (24, 27–29)].

However, the distribution of coping strategies is not so dichotomous (30). Several studies have shown that both coping strategies were positively correlated with pathogenic (e.g., PTS symptoms) as well as with salutogenic factors (e.g., resilience, post traumatic growth) (3, 22). It was also found that emotion-focused strategies may also be beneficial in situations perceived as uncontrollable or in the absence of a viable solution (e.g., terrorism exposure and security threats) (31–34). In these cases, it even might be better to use emotion-focused coping, since this strategy may reduce the negative psychological effects of the scenario/event without confronting it directly (30).

The Coronavirus revealed different risk levels for different age groups, with a higher risk for people aged 60 or older. Studies on nation-wide populations indicate that age is a major factor in addressing mental health outcomes (35). Therefore, in the current study we aim to examine the levels of psychological distress and concern about health and financial situation during this special period among different age groups, as well as the relations to resilience and coping strategies across ages and for specific age groups. Three age groups were examined: older adults (60+), middle group (59–30), and younger (22–33). The age groups were selected based on former studies that utilized similar age group examinations of mental health outcomes (1, 35).

We hypothesized that participants would report high concerns for their own and their families' health regarding the COVID-19 pandemic, as well as high concerns for the financial implications of the COVID-19 pandemic. Furthermore, we hypothesized that a higher level of health concerns and psychological distress would be reported by the older adults age group compared with the other age groups, since this age group was at the highest risk of dying after contracting the virus. Finally, negative correlations were hypothesized between the level of psychological distress, and resilience and problem-focused coping, and a positive correlation between level of distress and emotion-focused coping.

## METHOD

### Participants

Nine hundred and twenty-five participants took part in the study. They were divided into three groups: younger, aged 18–29,  $N = 189$  (20.4%); middle, aged 30–59,  $N = 473$  (51.1%), and older adults, aged 60–88,  $N = 263$  (28.4). Most of the respondents in the middle aged and older adults groups had children (90.3 and 97%, respectively). Only 13.8% of the younger group had children. Among those with children, they had up to 11 children, with a greater number of children in the older adults group ( $M = 3.05$ ,  $SD = 1.18$ ) than in the middle aged group ( $M = 2.73$ ,  $SD = 1.42$ ), with the younger group having the fewest children ( $M = 0.35$ ,  $SD = 0.082$ ) ( $F_{(2,854)} = 223.70$ ,  $\eta^2 = 0.344$ ,  $p < 0.001$ ).

As seen in **Table 1**, there were 71% females, with no meaningful gender differences by age group. Most participants in the middle age and older adults groups were married or in a steady relationship (about 80%), while most participants in the younger group were single (61%), a significant difference. Most respondents had an academic education, yet to a higher extent in the middle aged group (75%) than in the younger (60%) or older groups (57%).

### Measurements

#### Personal Data

Data were gathered regarding gender, age, religiosity, level of education, number of children, age of youngest child, type of residential town, residential region.

#### Coronavirus Objective and Subjective Exposure

This measure was devised for the current study. Questions were asked regarding the current time—during closure due to COVID-19. Did you contract the Coronavirus? Were you admitted to a hospital or quarantined at home because you were ill with the virus? Did someone from your family contract the Coronavirus? Did you continue working during the closure? Who is currently at home with you?

Three additional questions related to respondents' degree of concern during this period. Participants were asked to rate on a 5-point scale (1 = not at all to 5 = very much): How concerned are they that their health will be affected due to contracting the Coronavirus? How concerned are they that their family members will be affected by contracting the Coronavirus? And how concerned are they about their financial situation due to the Coronavirus crisis?

#### Coping Strategies: Measured by the COPE Scale (36)

The scale assesses two major coping strategies: problem-focused (15 items) and emotion-focused (15 items). The scale has been used extensively in Hebrew [e.g., (27, 37)]. Participants were asked to rate the extent to which they used each coping option to deal with the stressful situations caused by the COVID-19 pandemic, on a 4-point scale (0 = not at all; 3 = a great deal) (data were transformed into a 1–4 scale). In the current study, internal consistency was 0.78 for problem-focused and 0.73 for emotion-focused coping.

**TABLE 1** | Distribution of background variables by age group ( $N = 925$ ).

		Total sample N (%)	Young N (%)	Middle N (%)	Older adults N (%)	Difference
Gender	Male	268 (29.0)	60 (31.7)	118 (24.9)	90 (34.2)	$\chi^2(2) = 7.95$ ( $p = 0.019$ )
	Female	657 (71.0)	129 (68.3)	355 (75.1)	173 (65.8)	
Family status	Married, in a relationship	656 (71.0)	70 (37.2)	373 (78.9)	213 (81.0)	$\chi^2(2) = 131.02$ ( $p < 0.001$ )
	Other (single, divorce, widower)	268 (29.0)	118 (62.8)	100 (21.1)	50 (19.0)	
Education	Secondary	194 (21.0)	63 (33.3)	66 (14.0)	65 (24.8)	$\chi^2(4) = 48.95$ ( $p < 0.001$ )
	Vocational	114 (12.4)	13 (6.9)	53 (11.2)	48 (18.3)	
	Academic	615 (66.6)	113 (59.8)	353 (74.8)	149 (56.9)	

The Bonferroni correction for multiple comparisons yields  $p = 0.017$ .

## Resilience

This measure was examined by the Connor-Davidson Resilience Scale (CD-RISC; 10), which consists of 25 statements (e.g., *able to adapt when changes occur; have close and secure relationships; belief one can deal with whatever comes and having control of one's life*). Each statement is rated by respondents in terms of the extent of their agreement with it over the previous month (0 = not at all to 4 = true nearly all the time). This scale has been used among the Israeli population and has shown good predictive validity and internal consistency (15, 22). Total CD-RISC scores representative of resilience were utilized for this study ( $\alpha = 0.89$ ).

## Psychological Symptoms

Psychological symptoms were assessed using the BSI-18 (38), which is a self-report symptom checklist measure consisting of 18 items taken from the 53-item Brief Symptom Inventory [BSI; (39)]. Each BSI-18 item describes a symptom to be rated by respondents on a five-point scale according to how much they were bothered by the symptom in the previous week. Scores on the 18 items are summarized on the Global Severity Index (GSI) ( $\alpha = 0.92$ ) and regarding three symptom scales: Somatization ( $\alpha = 0.82$ ), Depression ( $\alpha = 0.82$ ), and Anxiety ( $\alpha = 0.86$ ), each comprising six items.

## Procedure

For collecting the data, we used a cross-sectional anonymous online questionnaire. The data was collected between March 31 and April 8, 2020, a time when the Israeli government had issued a directive for citizens to isolate themselves at home and minimize face-to-face interaction. Thus, potential respondents were electronically invited by existing research respondents. The participants completed the questionnaires through an online survey platform. Then the raw data was transferred into a database. The online questionnaire offered the necessary assurances of anonymity to allow respondents to give accurate data surrounding sensitive issues, which is particularly relevant in the field of mental health. All respondents provided informed consent. The study was approved by the ethical standards of the Institutional Review Board (IRB) of the University.

## Data Analysis

Data were analyzed with SPSS v. 26. Internal consistencies were calculated for the research variables, and the research variables were computed with item means or sums. As BSI scores were positively skewed they were log transformed. Background characteristics of the respondents were described with means and standard deviations for continuous variables and frequencies and percentages for categorical variables. The three age groups were compared through analyses of variance and chi-squares, respectively. Means, standard deviations, and intercorrelations for the research variables were described. Analyses of variance with *post-hoc* estimated marginal means with the Bonferroni correction for multiple comparisons were calculated to compare the research variables across the three age groups. A multiple hierarchical regression for the total BSI score with the research variables was calculated. The first step included gender (1-males, 0-females) and the age groups (entered as two dichotomous variables: younger vs. others, and older adults vs. others). The second step included the variables of concerns, coping strategies, and the total score for resiliency. The Bonferroni correction for multiple comparisons was applied in all tables.

## RESULTS

### Coronavirus Objective and Subjective Exposure

Only one participant had contracted the virus and remained at home. Only 10 family members of the respondents (1.1%) had contracted COVID-19. **Table 2** presents the differences between the groups in objective and subjective exposure.

Participants in the three groups were mainly living with family or with their spouse during the COVID-19 epidemic. Of those who had been employed, about 43% had to stop working. Their rate was highest in the older adults group (58%), lower in the younger group (49%), and lowest in the middle aged group (35%). Most respondents had an academic education, yet to a higher extent in the middle aged group (75%) than in younger (60%) and older groups (57%).

Examination of levels of concern showed that participants were moderately concerned about their own health ( $M = 2.70$ )

**TABLE 2** | Distribution of objective and subjective exposure by age group ( $N = 925$ ).

		Total sample N (%)	Young N (%)	Middle N (%)	Older adults N (%)	Difference
Lives with (at present)	Alone	91 (9.9)	20 (10.6)	33 (7.0)	38 (14.6)	$\chi^2(2) = 10.83$ ( $p = 0.004$ )
	Family and mate	828 (90.1)	168 (89.4)	437 (93.0)	223 (85.4)	
Employment during Coronavirus	Yes- works	464 (56.9)	94 (50.8)	299 (64.9)	71 (41.8)	$\chi^2(2) = 3.58$ ( $p < 0.001$ )
	No- stopped	352 (43.1)	91 (49.2)	162 (35.1)	99 (58.2)	
	Range	M (SD)	M (SD)	M (SD)	M (SD)	
Concerned about own health	1-5	2.70 (1.16)	2.59 (1.15)	2.69 (1.17)	2.81 (1.14)	$F_{(2,919)} = 1.98$ ( $p = 0.139$ ), ( $\eta^2 = 0.004$ )
Concerned about family health	1-5	3.56 (1.14)	4.08 (0.98)	3.49 (1.15)	3.32 (1.12)	$F_{(2,920)} = 28.32$ ( $p < 0.001$ ), ( $\eta^2 = 0.058$ ) 1 > 2, 3
Concerned about financial status	1-5	2.73 (1.24)	2.84 (1.33)	2.78 (1.21)	2.58 (1.20)	$F_{(2,919)} = 2.68$ ( $p = 0.069$ ), ( $\eta^2 = 0.006$ )

The Bonferroni correction for multiple comparisons yields  $p = 0.010$ .

with no significant group difference. They were more concerned about their family's health ( $M = 3.56$ ) than about their own health ( $t_{(923)} = 26.62$ ,  $p < 0.001$ ). Concern for the family's health was highest among the younger participants ( $M = 4.08$ ), and lower among both middle aged ( $M = 3.49$ ) and older adult ( $M = 3.32$ ) participants. Further, the participants were moderately concerned about their financial state ( $M = 2.73$ ), with no significant age group differences. Concern about family members' health was the highest, compared to both concerns about own health and about participants' financial status ( $F_{(2,1840)} = 295.40$ ,  $p < 0.001$ ,  $\eta^2 = 0.243$ ). Further, the interaction between the type of concern and age group was significant ( $F_{(4,1840)} = 19.81$ ,  $p < 0.001$ ,  $\eta^2 = 0.041$ ). Interpretation revealed that for the younger group concern about the family's health was highest, then financial concerns ( $p < 0.001$ ), and lowest was the concern about their own health ( $p = 0.034$ ). In the middle aged group, concern about the family's health was higher than both financial concerns and the concern for their own health ( $p < 0.001$ ). In the older adults group, concern about the family's health was highest, followed by concerns about their own health ( $p < 0.001$ ), and lowest was financial concerns ( $p < 0.001$ ).

## Intercorrelations for the Research Variables

**Table 3** presents means, standard deviations, and intercorrelations for the research variables. Problem focused coping was moderate low, and emotion focused coping was lower ( $t_{(923)} = 21.38$ ,  $p < 0.001$ ). Resiliency was moderate high, and all BSI mean scores were low.

Significant correlations were found among the research variables. Problem focused coping was positively related with emotion focused coping, resiliency, and all BSI scores. Emotion focused coping was positively related with all BSI scores as well. Resiliency was negatively related with the BSI scores.

**Table 4** presents group differences in the research variables, controlling for gender (1-male, 0-female) and education level (1-academic, 0-less than academic). Family status was not controlled for, as it had too low a variance in two of the three groups and was thus group specific.

Problem focused coping was generally moderate low and was higher among the middle aged group than among the older adults group. Emotion focused coping was generally low and did not differ by group. Problem focused coping was generally higher than emotion focused coping ( $F_{(1,921)} = 364.40$ ,  $p < 0.001$ ,  $\eta^2 = 0.283$ ). Further, the interaction between coping style and age group was significant ( $F_{(2,921)} = 9.41$ ,  $p < 0.001$ ,  $\eta^2 = 0.020$ ). Interpretation revealed that in all age groups problem focused coping was higher than emotion focused coping, yet to a greater extent in the middle aged group ( $\eta^2 = 0.264$ ), than in the younger ( $\eta^2 = 0.088$ ) and older ( $\eta^2 = 0.067$ ) groups.

Resiliency was moderate-high and did not differ by age group. BSI mean scores were low. The total score, somatization, and anxiety were highest among the younger group, lower among the middle aged group, and lowest among the older adults group. Depression was higher among the younger group than among the middle aged and older adults groups.

## Regression

In order to assess the relationship between distress (total BSI score) and the research variables, we conducted a multiple hierarchical regression. **Table 5** presents a multiple hierarchical regression for the total BSI score. The first step included gender (1-males, 0-females) and the age groups (entered as two dichotomous variables: younger group vs. others, and older adults group vs. others) (education level was not entered as it was unrelated to distress-  $r = -0.01$ ,  $p = 0.796$ ). The second step included the research variables of concerns, coping strategies, and the total score for resiliency.

**TABLE 3** | Means, standard deviations, and intercorrelations for the research variables ( $N = 925$ ).

	<b>M (SD)</b>	<b>2.</b>	<b>3.</b>	<b>4.</b>	<b>5.</b>	<b>6.</b>	<b>7.</b>

2. Coping: emotion (0–3)	1.01 (0.36)		−0.01	0.43***	0.30***	0.44***	0.35***
3. Resiliency: total (0–100)	67.39 (13.32)			−0.34***	−0.24***	−0.29***	−0.36***
4. BSI- total score (0–4)	0.54 (0.51)				0.80***	0.93***	0.88***
5. BSI- somatization (0–4)	0.29 (0.47)					0.66***	0.55***
6. BSI- anxiety (0–4)	0.78 (0.68)						0.71***
7. BSI- depression (0–4)	0.57 (0.59)						

\*\*\* $p < 0.001$ .

The Bonferroni correction for multiple comparisons yields  $p = 0.002$ .

**TABLE 4** | Distribution of the research variables by age group ( $N = 925$ ).

	<b>Range</b>	<b>Total sample M (SD)</b>	<b>Young M (SD)</b>	<b>Middle M (SD)</b>	<b>Older adults M (SD)</b>	<b>Difference</b>	
Coping- problem focused	0–3	1.35 (0.55)	1.34 (0.53)	1.43 (0.54)	1.22 (0.54)	$F_{(2,919)} = 7.07$ ( $p < 0.001$ ) ( $\eta^2 = 0.025$ )	2 > 3
Coping- emotion focused	0–3	1.01 (0.36)	1.01 (0.32)	1.03 (0.38)	0.99 (0.35)	$F_{(2,919)} = 0.63$ ( $p = 0.534$ ) ( $\eta^2 = 0.001$ )	—
Resiliency- total score	0–100	67.39 (13.32)	67.68 (12.52)	67.70 (13.48)	66.61 (13.6)	$F_{(2,915)} = 0.48$ ( $p = 0.618$ ) ( $\eta^2 = 0.001$ )	—
BSI- total score	0–4	0.54 (0.51)	0.73 (0.63)	0.54 (0.50)	0.42 (0.39)	$F_{(2,908)} = 20.80$ ( $p < 0.001$ ) ( $\eta^2 = 0.044$ )	1 > 2 > 3
BSI- somatization	0–4	0.29 (0.47)	0.40 (0.57)	0.29 (0.46)	0.20 (0.38)	$F_{(2,908)} = 10.36$ ( $p < 0.001$ ) ( $\eta^2 = 0.022$ )	1 > 2 > 3
BSI- anxiety	0–4	0.78 (0.68)	0.95 (0.78)	0.81 (0.70)	0.60 (0.52)	$F_{(2,908)} = 14.36$ ( $p < 0.001$ ) ( $\eta^2 = 0.031$ )	1 > 2 > 3
BSI- depression	0–4	0.57 (0.59)	0.84 (0.76)	0.52 (0.53)	0.45 (0.49)	$F_{(2,908)} = 24.62$ ( $p < 0.001$ ) ( $\eta^2 = 0.051$ )	1 > 2, 3

The Bonferroni correction for multiple comparisons yields  $p = 0.007$ .

The regression model was found to be significant, with 38% of the variance explained by the total BSI score. Gender and age group were found significant, showing higher levels of psychological distress among women than men, and among the younger age group than the other groups. Higher levels of concern about the financial status was related to higher psychological distress. Greater use of emotion focused coping, as well as greater use of problem focused coping, were related to higher psychological distress. Finally, lower levels of resiliency were related to higher psychological distress as well.

## DISCUSSION

The study was conducted at the peak of the lockdown, at a time when there was a real concern that the pandemic

would get out of hand. The COVID-19 crisis had received unprecedented levels of documentation and publicity around the world. For weeks, almost every media source (newspapers, television, radio, internet) had back-to-back coverage of the coronavirus pandemic, reporting the numbers of those infected and dead and presenting frightening statistics about the hundreds and thousands of people who had died daily. Our aims were to examine psychological distress and concerns about health and about the financial implications during this unique period among different age groups. Another aim was to explore the relationship between resilience and coping on one hand and psychological distress on the other.

The research findings indicate differences between and within the groups with regard to the three types of concern explored: concern of contracting the virus, concern that a family member would contract the virus, and concern of

the financial implications. Most of the respondents expressed concern particularly with regard to their family and less regarding the financial situation. The former concern was particularly high (4.08 on a scale of 1 to 5) among the younger group, consisting of those under 30. Although this was the main concern, the regression findings indicate that it was the financial concern that was found to be associated with the respondents' level of distress.

The fact that financial concerns and not concern for the family's health was associated with psychological distress can be explained by the Israeli reality at the time the study was conducted. Most of the participants in the three groups were living with family or with their spouse at the time of this study. Israeli citizens were asked to remain at home and were in fact in a state of lockdown that protected them from contracting the virus. Indeed, as evident from the participants' reports, only one participant had contracted the virus and remained at home and only 10 family members of the participants (1.1%) had contracted COVID-19. The most significant effect of the coronavirus was the need to stop working and to remain at home during the lockdown, with no knowledge of when and even whether they would return to their jobs. Most of the government efforts were directed at preventing the pandemic from spreading and, at least in the first stage when the study was conducted, less government attention was given to the financial implications.

In our estimate the high unemployment rates following the crisis, side by side with the focus on health-related means of protection, explain how considering the lockdown and the government focus on obtaining hospital equipment the citizens felt relatively protected from a health perspective and that the government was making efforts to protect them from contracting and dying from the virus. In contrast, it was the lockdown and cessation of work, as well as the lack of government clarifications regarding the financial steps that would be taken, that led to

increasing concern of the financial implications. The post-study Israeli reality, evident at the time these lines are being written (mid-May 2020), reinforces this assumption. Despite the easing of the lockdown and the approval given to return to work, many citizens have lost their jobs and the unemployment rate is high, indicating distress that is currently manifested in protests and demonstrations against the government, in a request for massive financial assistance for those whose source of subsistence was affected by the pandemic. The association found between psychological distress and financial concerns certainly appears to indicate real distress. A similar association was found by Qiu et al. (1) who explained the high psychological distress found among Chinese citizens by concerns about delays in work time and subsequent deprivation of their anticipated income, possibly explaining the high stress level.

In contrast to the hypothesis whereby adults over 60 would report higher psychological distress than others, the current findings show that they displayed the lowest levels of distress while the younger group displayed the highest levels. Consistent with these results, previous studies have found lower reactivity to stress in older adults due to the COVID-19 pandemic [e.g., (7, 40)].

We assumed that the information publicized whereby the older adults group have the highest risk and the younger group, even if contracting the virus, are not at risk of death, as well as the reports of the very high death rates among older adults, would lead to higher distress among the older adults group compared to the younger group. Similar assumptions led to different findings in a study held in China also during the peak of the lockdown (1), where high levels of distress were found among both the older adult and younger groups. The Chinese researchers explained the high level of distress among the older adults group as due to the fact that the highest mortality rate during the epidemic occurred among older adults, adding that psychological distress levels were also influenced by the availability of local medical resources, the efficiency of the regional public health system, and prevention and control measures taken against the epidemic situation.

These explanations do not seem to have been compatible with the Israeli circumstances during the crisis. While particularly high death rates were reported in China, in Israel the death rate was very low, as was the rate of those infected. In Israel, the health system dealt with the cases discovered very successfully and managed to prevent an outbreak of the pandemic.

Another possible explanation is related to the attention and high level of care directed at older adults, both by the media and various aid organizations and by their families. Caring for older adults was emphasized in all possible media, side by side with warnings and instructions to protect mainly older adults who constitute a risk group, where the sentence "Protect grandpa and grandma—Keep a distance" became a popular motto. The media was flooded with photographic evidence showing that despite the physical isolation and the prohibition of contact between older adults and their family members, strong daily contact was maintained between them by digital means (Zoom, WhatsApp, etc.). The considerable social support provided to this age group might have moderated their sense of distress and loneliness. The association between social and family support has been found

to be a moderator of distress and a factor that helps cope with crisis situations (22, 41). Family and personal resources seem to be relevant for explaining loneliness and psychological well-being during a critical stressful period (40). Therefore, it may be that although the oldest age group had the highest risk to their physical health, they were more capable of dealing with the psychological distress that accompanied the coronavirus.

Returning to the younger group, as mentioned above younger participants were found to have the highest levels of psychological distress compared to the other age groups. Similar findings regarding young participants were found among the Chinese during the pandemic (1). The researchers explain this finding by the fact that this age group is highly interested in the media and therefore obtain more information that may result in their higher susceptibility. Other explanations may be related to the respondents' age and not necessarily to exposure to the media, as the latter was true of all ages. The higher levels of distress and concern among this age group may be due to their younger age, which meant that they had limited previous exposure to new stressors. Thus, while in the older adults age group their long life experience granted them the ability to manage new stressors, this was not so among the younger group. Support for this assumption came from other findings showing that mental health disorders are more frequent and apparent in younger age groups, and unlike physical disorders they tend to decrease as the individual matures (35). For example, in a study conducted in Singapore following the acute respiratory syndrome (SARS) epidemic (42), greater anxiety was associated with younger age. The researchers' assumption was that this is related to differences in coping styles among younger individuals.

Examination of the differences in resilience between the age groups revealed no difference in the use of resilience and that resilience was moderate high and negatively associated with psychological distress. The fact that resilience had similar distribution across age group is in line with Connor and Davidson (14) perception of resilience as a personality trait and not the result of confronting previous life experiences. The negative association between resilience and psychological distress is in line with studies indicating that resilience protects individuals from the deleterious effects of exposure to stress and trauma (13, 16).

With respect to the findings regarding coping strategies, we found more use of problem-focused coping than of emotion-focused coping, unrelated to age. This finding is indicative of a healthy coping style. The greater use of problem-focused coping in the middle age group specifically is also understandable. This age group has a greater need to cope with the reality of being at home with young children, compared to the younger group (most of whom have no children) and the older adults group.

The positive association between use of problem-focused coping and resilience supports these explanations. Resilient individuals have been found to employ greater amounts of active coping such as problem-focused coping (26). While resilience allows an individual to respond positively to adverse events (14), coping strategies may yield either positive or negative results.

As hypothesized and in line with the literature, greater use of emotion-focused coping was related to higher psychological distress (24, 28). However, the positive association between problem focused coping and psychological distress needs to be addressed. This finding contradicts research findings that indicate a reverse association between distress and problem focused coping (24, 25). However, several studies have shown that both coping strategies were positively correlated with pathogenic (e.g., PTS symptoms) as well as with salutogenic factors (e.g., resilience, post traumatic growth) (3, 22).

It was also found that emotion-focused strategies may be beneficial in situations perceived as uncontrollable or in the absence of a viable solution (e.g., exposure to terrorism and security threats) (31–34). In these cases, it may even be better to use emotion-focused coping, since this strategy may reduce the negative psychological effects of the scenario/event without confronting it directly (30). The pandemic studied here certainly fits the definition of an event perceived as uncontrollable or lacking a viable solution. It is logical for participants to use emotional (e.g., concerns about health as well as about one's financial situation) in conjunction with practical coping strategies (e.g., attempts to protect themselves as well as their family).

Finally, although at the time the study was conducted there was no indication that the coronavirus acted differently among men and women, the findings show that women had higher levels of psychological distress compared to men. This is in line with previous findings showing that women appear to be more vulnerable to internalizing symptoms, both in studies on the coronavirus (1) as well as in national studies on psychological distress levels (35, 43, 44). This tendency is well-documented and has been attributed to physiological differences (45), differences in cognitive appraisal and coping (46), socialization, and social factors (47).

To sum, due to the unusual nature of the research subject, the current study can be seen as exploratory. Psychological and coping responses following infectious disease outbreaks are relatively understudied. Thus, the findings should be approached with appropriate caution. In addition, our online survey sampling method has its benefits and drawbacks. As for the former, online surveys allow for faster data collection and access to a potentially more diverse pool of participants. However, for the latter, some degree of potential sample bias should be taken into account. This strategy was not based on a random selection of the sample, and the study population did not reflect the actual pattern of the general population. In addition, there was no measurement of prepandemic of the variables we measured in the current study. Thus, It is possible that differences reflect pre-pandemic patterns.

Online surveys can reach only those who are online and those who agree to be part of the panel, and not all those who are invited to respond. In addition, our results rely on self-report questionnaires. Self-reported levels of psychological impact may not always be aligned with assessment by mental health professionals (48). Although this type of research design

is generally a reliable source for gathering information about people's experiences, including regarding exposure to stressful events (1, 3), a multi-informant paradigm could enhance the data. Finally, only a single participant had contracted the virus. Thus, the findings could not be generalized to confirmed or suspected cases of COVID-19. However, in a time of crisis such as the current COVID-19 pandemic, there is a need to rapidly develop ways to better detect and classify those at greatest risk (49).

Overall, the research results indicate that although the coronavirus posed a higher psychological risk for older adults, it seems that this age group was better able to cope with its psychological effects, at least in Israel where the number of those infected was low. Qiu et al. (1) indicate that in regions where there seem to be better medical resources and control measures were taken against the pandemic, psychological distress was lower. We assume that knowledge that medical staff and resources in Israel are known to be on a high standard and about the drastic steps that were taken almost from the beginning of the coronavirus spread, resulted in the low psychological distress levels found among all age groups in the current study and especially among older adults. However, in the current study we have examined age as an objective variable. It may be that age should also be considered as a subjective perceived factor, which was found to be related to the mental health of older adults during the COVID-19 pandemic (50). Finally, the results of the study suggest the need to consider the younger age group as a risk group, and this needs to be addressed as the focus of an intervention program.

In 1919, following the influenza pandemic, Soper (51) wrote a paper that was published in *Science*, describing the feelings aroused by the flu:

“The pandemic which has just swept round the earth has been without precedent... never before has there been a catastrophe at once so sudden, so devastating and so universal. The most astonishing thing about the pandemic was the complete mystery which surrounded it... Nobody seemed to know what the disease was, where it came from or how to stop it. Anxious

minds are inquiring to-day whether another wave of it will come again... Nobody can now speak authoritatively upon this subject.... (p. 501)”.

Although a century has passed, the description also fits the COVID-19 crisis. Despite the relatively low rates of distress found among participants in Israel, findings from other countries (such as China) indicate extreme rates of distress and many are still in a state of uncertainty.

Any major epidemic outbreak has negative effects on individuals and on society. No country alone can prevent a global risk such as COVID-19. This shows the importance of pre-establishing community coalitions to mobilize resources efficiently and effectively and to respond successfully to the disaster-related mental health needs of affected individuals and raises the need for developing practical community mental health programs for future infectious disease outbreaks.

This study aimed to capture how the coronavirus disease 2019 (COVID-19) crisis disrupted and affected individuals' goal pursuits and self-efficacy beliefs early during the lockdown phase of COVID-19. Participants impacted by lockdown regulations accessed an online questionnaire during a 10-day window from the end of March to early April 2020 and reported a significant personal goal toward which they had been working, and then completed quantitative and qualitative survey items tapping self-efficacy beliefs for goal achievement, subjective caring about the goal during disrupted world events, and current pursuit or abandonment of the goal. The findings from both quantitative and qualitative measures demonstrated a significant drop in self-efficacy beliefs from before to during the pandemic with a large effect based on whether people thought they could still achieve their goal under current conditions. Over two-thirds of the sample was unsure or did not believe they could still carry out their goal, and over a quarter either abandoned or were uncertain they could pursue the goal. Despite this, people continued to care about their goals. Reasons for abandonment and strategies for coping with goals within the lockdown and beyond are discussed.

**Keywords:** goals, self-efficacy, COVID-19, coping, social psychology, lockdown, projects

## INTRODUCTION

Goals give meaning to life. People experience greater well-being and a higher sense of fulfillment when their days include activities structured by, and directed toward, personally significant aims (Sheldon and Elliot, 1999; Emmons, 2003). Evidence from both personality/social and clinical science attests to this (e.g., Ho et al., 2010). Even individuals experiencing severe psychopathology anticipate personal well-being when envisioning a future in which they attain self-nominated personal goals (Coughlan et al., 2017).

Many significant life goals have a quality that is well-captured by the concept of “projects” (Little, 2007). Personal projects are interrelated sets of activities organized toward an overall aim (e.g., “prepare to apply to medical school,” “find a new job so I can quit this current one”). Projects not only organize everyday actions but also foster a coherent sense of self; self-concept is reflected in and developed by the pursuit of valued personal projects (Bruner, 1990; Little, 1993).

When people commit themselves to a meaningful project, they usually pursue it over a substantial period of time. For example, Langan-Fox (1991) assessed university students' personal goals at two time periods 5 months apart. As compared with an older-adult population, one might expect that such younger adults would experience instability of goals as they consider alternate personal and professional futures. Yet, among both female and male students, goal content was highly stable. Projects persist partly as a result of becoming elements of enduring "life stories," that is, narratively structured conceptions of one's life path and personal identity (McAdams, 1996). Empirically, the themes contained in personal goals and life stories are strongly related (McGregor et al., 2006).

Little (2011) emphasizes that goals are not just mental contents stored in the head. Personal strivings are fundamentally intertwined with the social contexts in which one lives. People often can sustain their pursuit of a personal goal in "the felicitous case" in which they work toward "projects that are meaningful, manageable, and supported by the eco-setting" (Little, 2011, p. 80). But what happens in the infelicitous case, when the eco-setting withdraws its support?

One answer to this question may be found in the study of goal appraisals, that is, people ongoing evaluations of their goal-directed activity. When establishing and working toward goals, people engage in strategic evaluation of their progress, using goal appraisals and aspects of self-regulation (Bembenutty et al., 2013). One major appraisal is coping capability, or appraisals of self-efficacy, (Bandura, 1977, 1986), and the unexpected disruption presented by the coronavirus disease 2019 (COVID-19) pandemic provides a particular set of globally felt conditions in which to consider people's understanding of their capabilities, through self-efficacy, and adherence to goals. The relation between self-efficacy appraisals and goal commitments can vary from one context to another, even in ordinary times. Often, self-efficacy contributes to goal setting; people are less likely to pursue goals when they doubt their capability for success (Locke and Latham, 2006; Bardach et al., 2020). However, in some contexts, people persist on goal-directed activities even in the absence of high-efficacy expectations. This occurs, for example, when goal achievement is critical to avoiding substantial personal loss (Shah and Higgins, 1997; Senko and Freund, 2015; for a meta-analytic review, see Huang, 2016) or when the goal-directed activity is an expression of personal values and the intuitive, "integrated" self (Kuhl et al., 2015).

Basic research in personality, social, and developmental psychology establishes the causal impact of self-efficacy and goal processes on social behavior and well-being. For example, in longitudinal research, self-efficacy predicts psychosocial outcomes even after accounting for the role of personality traits (Caprara et al., 2004), goal setting predicts achievement and interest in activities (Scherrer et al., 2020), and personal goals impact subjective well-being (Brunstein, 1993) which, in turn, is found to facilitate re-engagement with meaningful life goals (Haase et al., 2020). With this basic research as our background, in the present study, we sought to portray the nature of goal pursuit and self-efficacy beliefs at a uniquely disruptive moment in recent world history, namely, the early period of the social

"lockdown" necessitated by the rapid spread of COVID-19 in the early months of the year.

The worldwide disruption created by the COVID-19 pandemic has fundamentally changed people's lives physically and psychologically (Jiang, 2020; Qiu et al., 2020; Remuzzi and Remuzzi, 2020), with several studies outlining the negative psychological impact that forced quarantine can have on the population (Brooks et al., 2020), citing reductions in positive emotions, sleep disturbances, and increased feelings of anger and anxiety (Cava et al., 2005; Roy et al., 2020). The reduction in social contact and steps taken to deal with the psychological impact of this (Bzdok and Dunbar, 2020) has added a potentially significant disruption to the populations' previous goal pursuits. Goals may now yield to new challenges such as limited access to food, financial worries, sudden need for employment, the care of isolated family members, or reductions to health (Cipolletta and Ortu, 2020; Fraenkel and Cho, 2020; Wilms et al., 2020). In addition to its vast biomedical and economic costs, there likely was a psychological cost associated with the disruption of valued personal projects by imposed social and mobility restrictions. What was the nature and magnitude of that goal disruption? How did people cope with their altered life circumstances? These are questions addressed in the present report.

## MATERIALS AND METHODS

### The Present Research

We conducted a mixed-methods survey of goals, self-efficacy beliefs, and potential goal disruptions in the early period of the lockdown in the COVID-19 crisis. Three aspects of the survey are of note. The first is its conceptual basis, which was a social-cognitive orientation (Bandura, 1986), in which self-reflection on one's capabilities, the setting of goals, and self-regulatory efforts are central to emotion, motivation, and achievement (also see Sarrazin et al., 1996; Caprara et al., 2011; Zimmerman et al., 2017). Survey items focused on three classes of thoughts and feelings about self-identified projects that are consistent with this perspective: (1) self-efficacy beliefs for goal achievement (Bandura, 1997); (2) subjective caring about the goal in light of disrupted world events (a variable associated with self-evaluative reactions to those that are central to social-cognitive analyses of self-regulation; Bandura and Cervone, 1983; Cervone et al., 1991); and (3) commitment to goals, that is, whether people saw themselves as still pursuing the projects that, prior to the pandemic, had been central to their everyday lives.

A second feature is the type of survey items we included; our use of both quantitative and qualitative measures is unique within the self-efficacy literature, which has almost exclusively relied on quantitative self-ratings of people's self-efficacy appraisals. Given the utter novelty of the COVID-19 outbreak, we judged the inclusion of open-ended qualitative measures necessary for learning about people's beliefs and experience in the midst of this pandemic. Self-efficacy researchers have continued to develop and validate questionnaires to better capture the construct within a specific domain (Bandura, 2006; Bong, 2006; Ritchie and Williamon, 2011; Axboe et al., 2016); however, the need

for a qualitative approach that moves beyond the traditional questionnaire has been suggested (Ritchie, *in press*), but no studies to date have investigated the possible comparability of qualitative and quantitative methods.

Allowing participants to speak, in their own terms, about their goals, experiences, and coping strategies enabled us to explore both the phenomenology of engagement, motivation, and processes of personal agency while navigating iterative and unforeseen challenges toward achievement. Given the mixed-methods data source, we report quantitative analyses, human-based coding of narrative text, and computational natural language processing of syntax and sentiment in that text.

The third aspect of the survey was practical. Early in a pandemic, people have a lot to do other than filling out surveys. We focused our survey exclusively on the set of variables (described above) of maximal interest, in an effort to maintain clarity while eliciting full free-text responses that captured a sense of the person, their outlook, and their investment in the goal. We also deliberately constrained the time frame of survey administration to relatively narrow time window early in the COVID-19 lockdown period when lifestyle changes were newly imposed and still unfolding. Previously, “normal” life was still within recent experience, allowing a snapshot of comparative outlooks. Had we allowed the data collection period to extend, there was a risk that people would begin to develop a catalog of adaptive behaviors in light of these new conditions. Our goal was to gain insight into people’s efforts to sustain their projects at the onset of this dramatically challenging moment in history.

## Participants

The participants ( $n = 161$ ) were aged 19–80 years,  $M = 45.70$  ( $SD = 14.86$ ), and lived in the United Kingdom ( $n = 101$ ), the United States ( $n = 31$ ), and 11 other countries ( $n = 23$ ) across five continents. Six individuals chose not to declare their location. On an 11-point bipolar measure of gender identity, 56 participants identified themselves as strongly male (1–3), 94 strongly female (9–11), nine identified with the middle (4–8), and two individuals did not identify on this scale. Participants were notified of the study *via* online academic and social media networks and voluntarily completed a “Pivotal Moments and Goals” (PMG) questionnaire, administered *via* Qualtrics<sup>1</sup>, between March 27th and April 6th, 2020. This 10-day window allowed a snapshot of views early in the COVID-19 pandemic—a period of rapid social change in which people comprehended the significance of the crisis and governments instituted lockdowns (the British Prime Minister doing so on March 23rd) (Government United Kingdom, 2020) and travel bans (the United States Centers for Disease Control and Prevention issued a strong travel advisory for New York, Connecticut, and New Jersey on March 28th) (CDC, 2020).

## Materials

### Goal Description

After a consent statement which noted the study’s ethical approval (from the University of Chichester, Approval No.

1920–25), the PMG acknowledged a (consensually recognized) pivotal moment caused by global events and stated our interest in how the social changes triggered by this event may have impacted people’s personal goals. Participants were asked to contemplate an important project they had prioritized prior to the event and to describe it in a provided text box.

### Retrospective Self-Efficacy Beliefs

Participants next rated their confidence that they could do the goal *prior to* COVID-19 events on a 1–100 sliding scale (Bandura, 1977). As a qualitative measure of prior self-efficacy beliefs, participants were asked to describe this confidence in words in two to three sentences. Responses to this and subsequent open-ended items were typed into on-screen text boxes.

The quantitative self-efficacy questionnaire adheres to common practice in the self-efficacy literature, in which self-efficacy beliefs (perceived capabilities to carry out courses of action and achieve aims) are assessed on 100-point scales and without provision of the construct name in questionnaires (Bandura, 2006; Bong, 2006). Qualitative self-efficacy reports are employed rarely (Williams, 1990), yet follow naturally from the fact that self-reflective thinking is primarily formulated through the tools of natural language (Cervone and Lott, 2007). The free prose responses gathered here supplement numerical ratings, allowing a richer, self-guided assessment of self-efficacy and step outside the limitations of traditional empirical questionnaires.

### Contemporaneous Self-Efficacy Beliefs

Current self-efficacy beliefs for goal pursuit were assessed in three steps: a multiple-choice item asking if “you can do this now” (yes, no, unsure); a 1–100 scale rating of confidence that you “can still do this”; and a two to three sentence description of this current confidence.

Before answering subsequent questions, participants were instructed to pause to consider their ideas before responding.

### Caring

Participants were next asked to indicate whether they still care about the goal (yes, no, unsure) and to describe “how and why you care” in two to three sentences.

### Contemporaneous Goal Pursuit

Participants were asked in a multiple-choice format (yes, no, genuinely undecided) whether they were still pursuing their stated goals. They next completed an open-ended report based on this multiple-choice response in which they were asked to indicate either (1) if no, why no; (2) if yes, if anything has changed in goal pursuit; or (3) if uncertain, “Can you say something about this?”

Demographic information (age, gender identity, and country of residence) was collected last so as not to distract people from essential questions. Importantly, all respondents understood that data would be published *via* open source repositories; thus, responses to demographic questions were optional, allowing respondents to preserve as much privacy as they wished.

## Exploratory Data Analysis Methods

All freely written responses were analyzed with AWS Amazon Comprehend<sup>2</sup> to confirm English as the language used and then analyze the syntax and its sentiment (positive, neutral, negative, and mixed) (Ribeiro et al., 2016). After an initial review of text-based responses, it came to light that 10 cases incorrectly completed the questionnaire, and these were removed from the sample. These participants either used negatively framed responses which produced negatively coded sentiment analysis (e.g., “I had no reason to think I couldn’t do it unless I went under a bus”) or misunderstood the directive of the questions (e.g., failed to choose a goal from before world events unfolded).

The sentiment analysis uses logistic regression to assign probability that the text sentiment is positive, neutral, negative, or mixed. For example, the first two text questions describe confidence to carry out goals; therefore, negative sentiment scores reflect the probability the text describes this confidence negatively. Thus, 1 minus the negative score provides a number representing total probability showing the text sentiment is not negative (e.g., 1 minus a negative value of 0.2 becomes 0.8). These numbers were calculated and correlated with the corresponding self-efficacy scores to ensure the text reflected the participant’s numerical confidence rating.

Goals and the reasons for pursuing or abandoning goals were qualitatively coded separately by two researchers.

## RESULTS

### Goals, Self-Efficacy, Caring, and Goal Pursuit

#### Goal Description

For descriptive purposes, we first classified the content of participants’ self-described goals into categories that were derived rationally by the investigators subsequent to the reading of all goal content. Goals could be classified into one of six categories, with varying observed frequency of response: educational ( $n = 39$ , 24.22%), professional ( $n = 36$ , 22.36%), change place of residence ( $n = 12$ , 7.45%), house repair ( $n = 6$ , 3.73%), travel ( $n = 38$ , 23.60%), and a range of projects involving personal development ( $n = 30$ , 18.63%).

#### Retrospective and Contemporaneous Self-Efficacy Beliefs

Retrospective and contemporaneous self-efficacy beliefs differed markedly. On the 100-point strength of the self-efficacy rating scale, participants reported high pre-COVID-19 self-efficacy scores,  $M = 84.6$  ( $SD = 20.8$ ,  $SE = 1.64$ ), but much lower contemporaneous, post-outbreak self-efficacy,  $M = 45.6$  ( $SD = 34.7$ ,  $SE = 2.73$ ). Retrospective and contemporaneous strength of self-efficacy differed highly significantly,  $t(160) = 11.6$ ,  $p < 0.001$ .

Complementary results resulted from the analysis of the responses to the multiple-choice item asking, “Can you still do this [goal] now?” On this item, 31.68% of people responded

yes, 35.40% unsure, and 32.92% no. These three subgroups of participants differed highly significantly in their 100-point scale rating self-efficacy beliefs, as would be expected,  $F(2, 158) = 53.6$ ,  $p < 0.001$ , and  $\eta_p^2 = 0.404$  (Cohen, 1988). See **Figure 1** for the change in mean pre-COVID-19 and current self-efficacy scores.

Strong correlations were demonstrated between the pre-COVID-19 self-efficacy scores and verbally reported confidence sentiment scores ( $r = 0.376$ ,  $p < 0.001$ ) and between the current self-efficacy and corresponding verbal confidence sentiment scores ( $r = 0.415$ ,  $p < 0.001$ ), demonstrating these verbal descriptions to be a representative measure of self-efficacy.

Results of a one-way repeated-measures ANOVA using the verbal confidence sentiment scores from the text describing current self-efficacy mirrored results achieved with the current numerical self-efficacy measure, with a highly significant result showing a very large effect with significant differences between groups [ $F(2, 158) = 14.0$ ,  $p < 0.001$ ,  $\eta_p^2 = 0.151$ ].

#### Caring About the Goal

In contrast to the considerable variability in pre- and contemporaneous self-efficacy beliefs, there was relative uniformity in caring about the goal. On the measure of caring, 89.44% of people reported yes that they still cared, 4.35% were unsure, and 6.21% no longer cared about their goal.

#### Contemporaneous Goal Pursuit

A major question was whether people were continuing to pursue their goal despite the restrictions imposed as a result of COVID-19. Notwithstanding the significance of the goals and high levels of caring, 43 participants (26.70%) indicated that they either were no longer pursuing their goal ( $n = 24$ ) or were undecided about whether they could pursue it ( $n = 19$ ). Of the 118 reporting continued pursuit of their goal, 116 confirmed they still did care and only two reported uncertainty about caring. These two had extenuating personal circumstances that rendered the goal doable but no longer of value. For example, one person reporting uncertainty about caring was planning a course that was canceled, yet they still intended to carry out the planning.

Qualitative coding of textual goal responses revealed reasons both why participants abandoned or maintained the pursuit of their goals. (For the purposes of simplifying this descriptive analysis of textual responses, we combined into a single category the participants who were not pursuing and were undecided about whether they were still pursuing their goal). Those who were no longer actively pursuing their goals ( $n = 43$ ) cited external, often physical factors ( $n = 18$ , 41.86%); general uncertainty and difficulty in making long-term plans ( $n = 12$ , 27.91%); and a shift in priorities where they had to readjust due to caring or health responsibilities ( $n = 11$ , 25.58%). Two responses were unique in their reasons and did not categorize.

Those who maintained their goals ( $n = 118$ ), despite the increased uncertainty because of lockdown and drop in self-efficacy beliefs, presented a range of perspectives and strategies. Some saw COVID-19 as not changing or impacting their goal ( $n = 27$ , 22.88%), whereas a larger group demonstrated either problem-focused coping ( $n = 47$ , 39.83%) or emotion-focused coping ( $n = 18$ , 15.25%) (Folkman and Lazarus, 1980).

<sup>2</sup><https://aws.amazon.com/comprehend/>

Others stated they intended to continue with the goal but exhibited a “holding pattern” ( $n = 16$ , 13.56%), essentially hitting pause during COVID-19. Two of these “holding” people also demonstrated aspects of problem- and emotion-focused coping strategies, for example:

“Yes, by monitoring the situation and wait for news about when we can start planning trips again so we can go. Obviously it won’t be at the same time as my partner’s birthday but at least we will go away and do what we had in mind.”

In order to better understand the qualitative responses of those who continued pursuing their goals, we established a rationally based taxonomy to analyze the text responses based on a syntax analysis. Four groups of strategic behaviors, as shown in **Table 1**, demonstrated active pursuit, engagement, and adaption in relation to goal pursuit in response to the altered conditions imposed by lockdown.

## Relations Between Self-Efficacy Beliefs and Goal Pursuits

Our cross-sectional design of course does not allow an analysis of potential causal relations between self-efficacy beliefs and goal pursuits. We analyzed the relation between these variables

for descriptive purposes, as a way of characterizing patterns of thinking about personal projects that people experienced during the early lockdown period of COVID-19.

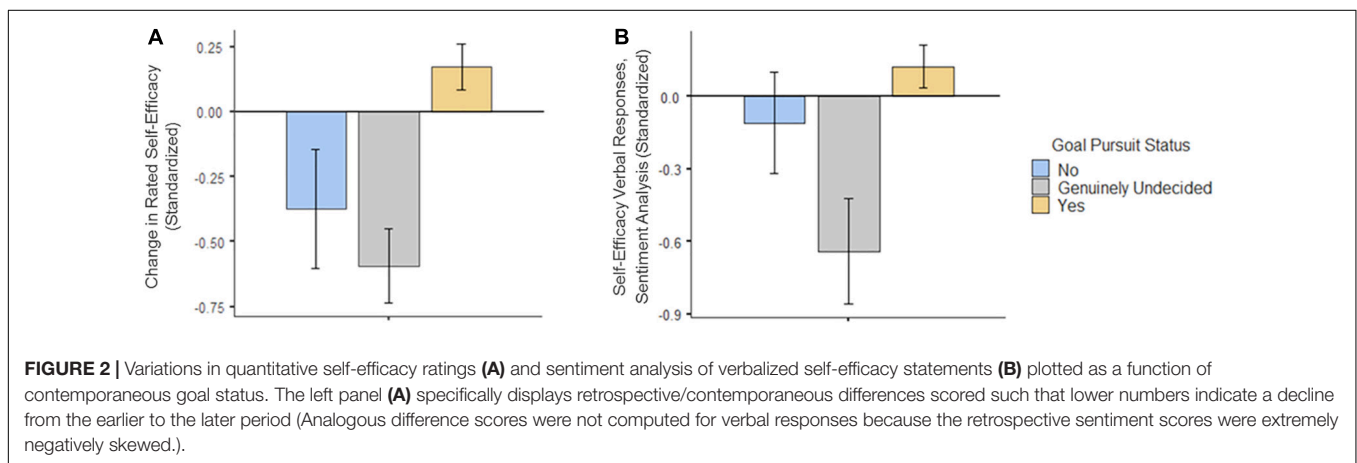

## Goal Pursuits and Self-Efficacy Beliefs

There is more than one way to describe the relations among goal pursuits and self-efficacy beliefs. One is to examine self-efficacy beliefs among three groups of participants, namely, those who were undecided about whether they were still pursuing their goal, were no longer pursuing their goal, and were pursuing their goal (i.e., the subgroups of participants who responded in these ways to the multiple-choice format question about contemporaneous goal pursuit). For these three groups, we analyzed two self-efficacy variables: (1) the magnitude of change (generally a decline) in strength of self-efficacy from pre- to during the COVID-19 lockdown and (2) AWS sentiment analysis scores obtained by coding the verbal responses from the free-response contemporaneous self-efficacy item. Both variables were standardized for ease of presentation of results.

**Figure 2** displays self-efficacy beliefs among participants with each of the three goal pursuit statuses; specifically, it displays both (a) changes in quantitative self-efficacy ratings (retrospective versus contemporaneous) and (b) qualitative

**TABLE 1** | Strategic behaviors reported by those continuing to pursue their goals.

Planning	Engaging with others	Enhanced personal awareness/engagement	Strategic thinking
For the completion of tasks	Accessing assistance with goals	Engaging in dedicated physical activity	Adapting to a new pattern of activity (at home)
For the modification of events/goals	Phoning friends	Self-care—sleep, nutrition	Navigating challenges of new media (online)
For “being ready” to do when restrictions allow (e.g., social distancing or restrictions of movement are not imposed)	Speaking with experts/professionals	New hobbies/activities	New ways to reorient the goal
Maintaining a schedule	Trading ideas	Increased focus and attention	Adaptation and implementation of new methods to circumvent the lockdown challenge
Control of personal time (daily schedules) and engagement with activity because of being at home as a result of lockdown	Collaborative working	Increased contentment, pleasure in tasks	Greater attention to detail
For the future	Using new media to maintain contact (zoom)	Internal motivation	Dedicated, analytical thinking about methods, direction, and timing of tasks
	Developing external facing materials (eBooks, websites)	More personal involvement and a sense of agency	Active monitoring of personal progress and events
			Internal reflection

analysis, namely, the sentiment analysis of contemporaneous self-efficacy verbalizations. The groups differed significantly on both the quantitative [ $F(2, 39.6) = 11.0, p < 0.001$ ] and the qualitative indices [ $F(2, 35.2) = 5.32, p < 0.01$ ]. However, that pattern of differences varied from one to another. On the quantitative self-ratings, particularly large declines in self-efficacy were observed among two subgroups: those who had abandoned and who were undecided about their project pursuit. However, in the sentiment analysis, the most negative scores were displayed by the undecided participants. Some undecided participants expressed multiple negative thoughts when verbalizing beliefs about their ability to pursue their goal, for example, “I’m not sure it’s what I want anymore because I am having a complete rethink about what is important in life. I felt in February that I had slightly overcommitted for this next year, and this has made me reconsider the extent to which I want to keep working. Maybe I have actually retired.”

A second, complementary way of examining relations between self-efficacy beliefs and goal pursuit is to explore goal pursuit status as a function of participants’ responses to the

multiple-choice self-efficacy survey items “Can you still do this?” and “Are you pursuing the task now?” Results revealed a conflict: more than double the people who answered positively to the question “Do you think you can still do this, now that current events have unfolded?” ( $n = 51$ ) confirmed that they were still pursuing their goal ( $n = 118$ ). **Table 2** relates these contemporaneous self-efficacy judgments and goal pursuit responses. As shown, almost all participants who retained confidence in their ability to achieve their goal reported that they

**TABLE 2** | Contemporaneous self-efficacy and goal pursuit.

Can you still do this [goal] now?	Still pursuing goal			Total
	Yes	Unsure	No	
Yes	46	1	4	51
Unsure	28	11	14	53
No	44	7	6	57
Total	118	19	24	161

were still pursuing it. Yet, interestingly, a great many participants who expressed a lack of confidence had *not* abandoned their goal. Factors that include, yet go beyond, reflections on self-efficacy may have influenced the continued pursuit of personal projects.

Responses from those who reported with certainty either abandonment (no) or continuation (yes) to pursuing their goals, where the goals were not travel-related, and all that had similarly low self-efficacy scores ( $\leq 40$ ) are presented in **Tables 3, 4**. Avoiding travel-related goals, which were essentially banned during this lockdown period, allowed for examination of goals that could have the possibility of strategic coping in relation to goal pursuit. The cutoff of 40 for self-efficacy scores encompassed all of those abandoning goals with low self-efficacy; those continuing to pursue their goals with similarly low self-efficacy are also represented in the table. Those who abandoned their goals and reported zero self-efficacy verbally close down the possibility of pursuing a goal. This language demonstrated a lack of strategic thinking, and in line with the self-efficacy theory (Zimmerman et al., 2017), these people quit when faced with the challenge of lockdown. In essence, they were unable or unwilling to engage in strategic behavior to find another way. However, those who confirmed they continued actively pursuing their goal, yet reported zero self-efficacy, often phrased their reasons with the future tense using words like “going to.” They acknowledged the *possibility* of pursuit exists, even if they were uncertain how this would occur.

Those who abandoned their goals yet had some self-efficacy still do not allow for the possibility of achieving the goal despite quantifying their self-efficacy beliefs. There is no use of active verbs, and they frequently use forms of “no” or “not” (e.g., “not possible”), whereas those pursuing goals with a very low self-efficacy score convey a sense of enduring, continuity, and even urgency by using “still” and “need” alongside active verbs. Those actively pursuing goals, even with low self-efficacy scores, demonstrate a noticeable sense of possibility that embraces now and the future.

## DISCUSSION

Our results provide a unique “snapshot” of how the COVID-19 crisis disrupted individuals’ pursuits of personal projects in the early period of the lockdown. Self-efficacy ratings for goal pursuit plummeted. Analysis of verbal self-efficacy reports mirrored the numerical results, showing significant differences between pre-COVID-19 and current self-efficacy beliefs for achieving valued projects. Almost all participants still cared about their goal, yet more than a quarter of the sample either had abandoned it or reported uncertainty about further goal pursuit. Given that sustained pursuit of projects enhances well-being (Little, 1993, 2007), our results highlight a potential psychological toll of the biological pandemic.

The results also, more positively, reveal ways in which people coped successfully with the constraints of the lockdown. Many participants were still working toward their goal, and among these, many reported creative problem-focused and emotion-focused coping strategies that sustained goal pursuit. Our

qualitative methods yielded a “library” of participant-provided pandemic-related coping strategies.<sup>3</sup> In future work, this library of strategies could be provided to others as one element of an intervention to enhance citizens’ well-being in the face of major social disruption (cf. Skoufias, 2003).

Although diverse in many ways, our sample was economically privileged from a global perspective. Many pursued professional and leisure projects inaccessible to lower-income persons. An implication is that our data reveal beliefs about goals people considered meaningful, even aspirational, as opposed to strictly being need-based. Also, at this early stage in the pandemic, reported strategies for understanding and approaching goals did not yet reflect crisis-type coping behavior (Ben-Zur and Zeidner, 1995). Instead, we saw the amplification of perceived limitations to achievement, and the interaction between self-efficacy beliefs and action becomes at least convoluted, and sometimes conflicted.

The initial lockdown phase of this crisis presented unexpected, tangible obstacles for people and challenged the stability of their beliefs toward goals. The imposed restrictions upset the predictable fabric of everyday engagement, and some people were not in an obvious position to enact their reported pre-COVID-19 high self-efficacy and good intentions toward their goals (Gollwitzer and Sheeran, 2006). Overwhelmingly, people still cared about these tasks, but many did not have an available repertoire of appropriate strategies. The pandemic conditions highlighted the need for adaptability to maintain and accomplish goals, and reliance on existing everyday routines may be inefficient and simply impractical under these uncertain conditions.

Creative engagement is a vehicle through which strategic development can flourish, and existing within the established confines of habit neither fosters creativity nor is an option for successfully navigating current challenges. Actively seeking to develop strategic approaches through new learning, developing the “practice of practice” (Antonacopoulou, 2006, p. 5), and the creation and adoption of disruptive innovation take vision and time (Yu and Hang, 2010). It is therefore not surprising that some people, unable to see a direct way forward, effectively put their goals on hold or abandoned tasks completely. In principle, those who abandoned their goals could adopt similar emotional and physical coping strategies used by others. Developing new strategies and perspectives is an enduring challenge for all.

The assessment of self-efficacy in this research, gathering both the quantitative (numeric) and qualitative (dialogic free text) responses, is genuinely novel in the field of self-efficacy research. Our results demonstrated that both methods produced comparable, statistically significant results, and this is a pioneering contribution to the approach of self-efficacy measurement in psychological research. The present research extended the standard questionnaire-based approach to self-efficacy research, with the novel methodological approach of including free-text descriptions of self-efficacy beliefs alongside traditional scalar measures. Anchoring these text responses to both the numerical score and sentient analyses demonstrated

**TABLE 3** | Non-travel goals abandoned and pursued for those with self-efficacy scores of 0.

Category	Score	Reason abandoned	Category	Score	Reason pursuing
E	0	It's impossible. However, now that I think about it, I am still fulfilling professional obligations that I would have done there, just without the travel, time commitment, expense, and overwhelm of a large conference.	PFC	0	I'm pursuing ways to find other opportunities for alternative musical/professional work. This has moved exclusively to an online format. The overwhelming change to life has meant that each one of us has a glimpse of how life can fundamentally change in an instant - that new uncertainty also means that deferring plans (i.e., for 6 months or 1 year) also carries with it immense uncertainty that was never present in my mind before. It means that now I'm going to try to find ways to make things work in a different way as well.
E	0	General consensus is that predicted grades will be accepted alongside evidence. As school is closed it is not possible to complete work.	PFC	0	I am planning online sessions with different groups of stakeholders during the period I have scheduled to be there
P	0	Time is precious and even if I have to suffer financial losses, I am going to spend it making things that matter to me and finding ways to share them. I will find ways to make money that require less of my soul.	H	0	Postponed to 2021. Once the COVID-19 situation is more clear
P	0	No - because this goal was very specific - I'm not dropping the overall aim of increasing cycling mileage and speed again - just need to focus on what I can currently do - and pick specific event/goal once circumstances change.	H	0	Not actively pursuing as everything on hold. Except for the plans for the kitchen. We're sitting and still planning that on paper.
U	0	The level of uncertainty in risk with regard to gathering people in the same place is simply too high to move forward.	H	0	If/when things return to a sense of normality, I will resume contact with the organizations and community groups I was working with and return to my project. However, how long this will take, if it is achievable at all, is a different kettle of fish.
			H	0	Delaying the event until after the lockdown
			NC	0	Music is the happiness in my life. So I want to make music.

Columns detail the categories for abandonment/method of pursuit (categories for abandonment reason: E, external; P, priorities; U, uncertainty; categories for pursuit explanation: H, holding; NC, no change; PFC, problem-focused coping), numerical self-efficacy score, and participant free-text reason for abandoning/pursuing their goal.

**TABLE 4** | Non-travel goals abandoned and pursued for those with self-efficacy scores of 1–40.

Category	Score	Reason abandoned	Category	Score	Reason pursued
P	1	****If there is no job to pursue, why chase it. Turn energies elsewhere.	O	5	Again, need money or I will starve to death.
E	10	The specific goal is not practical.	PFC	8	Still checking websites and employment agency web sites
E	20	Well I will try to do the French, however, Choir tour and the concert are not going to happen.	O	10	“Yes” as in “I think about it every day but I’m still procrastinating.” There’s a lot of new roadblocks now. I don’t know exactly what but I’m scared to find out.
P	25	No - These goals are now almost bottom of my priority, staying healthy, keeping my flat and re-adapting my teaching business to being completely virtual are my main goals	PFC	10	Still calling friends
E	30	It’s not physically possible due to the lock down and am reluctant to spend savings until we have a better idea of my partners ability to stay in his job/find a new one. I am unable to work.	O	11	I am still planning on going back to school, I just don’t feel that I can make any kind of financial commitment to it while I am so uncertain about my employment, my schedule, my health, medical bills, etc.
P	40	I love my job, and I wouldn’t want the fact that I wish to pursue my goals now have a major impact on my colleagues. It is a matter of timing, and once the situation we find ourselves in currently has died down and hopefully we return to normal, it will be then that I re-evaluate the situation.	EFC	15	I am still writing my book and using this time to think about priorities and redefine orientations and identities. The crisis situation is unexpected but gives me a lot to think about on a broader scale. Can we as a society step out of the crazy market system we have allowed to become total, infesting the very core of our being. The air hasn’t been so clear in as long as I can remember.
			EFC	20	I need to get in the right mindset and fit it in will other tasks that I am undertaking.
			NC	20	Nothing has changed I am just waiting to see what happens after the current situation and what state the economy and housing market is in.
			PFC	30	I will continue to work toward my assessments, even though they are not for the best part of a year. I will try and arrange extra support with my teachers to ensure I am not lacking in quality where I will no longer have that contact time after this semester. I will be asking my Academic Advisor for some kind of personal recommendation so that I am able to get a job despite not graduating this year. I do not wish to jeopardize my overall university grade by doing the alternative assessments at such short notice.
			O	30	At this current point I do not know yet.
			PFC	32	I’m still applying, though for different jobs now. I’ve applied for several “key worker” jobs like Tesco and farm roles. I’ve set up as an online tutor. I’ve signed up as a volunteer. No luck though

Columns detail the categories for abandonment/method of pursuit (categories for abandonment reason: E, external; P, priorities; categories for pursuit explanation: EFC, emotion-focused coping; NC, no change; O, other; PFC, problem-focused coping), numerical self-efficacy score, and participant free-text reason for abandoning/pursuing their goal.

that these free descriptions also produced significant results. This initial step to innovate methods opens the door for further research to explore the syntax of self-efficacy. Future research should aim to understand self-efficacy beliefs in terms of verbal expression, internal thought representation, and the expressed interrelationships between declared externalizations of self-efficacy to enacted beliefs (through tasks) to deepen the understanding of belief and achievement.

**Background and Objectives:** In order to curb the spread of coronavirus disease 2019 (COVID-19), the countries took preventive measures such as lockdown and restrictions of movements. This can lead to effects on mental health of the population. We studied the impact of COVID-19 on psychological well-being and associated factors among the Pakistani general population.

**Methods:** An online cross-sectional survey was conducted between 26th April and 15th May and included participants from all over the Pakistan. Attitudes and worriedness about COVID-19 pandemic were assessed using a structured questionnaire. A validated English and Urdu version of the World Health Organization Well-Being Index (WHO-5) was used to assess the well-being. Factor analysis was done to extract the attitude item domains. Logistic regression was used to assess the factors associated with poor well-being.

**Results:** A total of 1,756 people participated in the survey. Almost half 50% of the participants were male, and a similar proportion was employed. About 41% of the participants were dependent on financial sources other than salary. News was considered a source of fear as 72% assumed that avoiding such news may reduce the fear. About 68% of the population was worried about contracting the disease. The most common coping strategies used during lockdown were spending quality time with family, eating healthy food, adequate sleep, and talking to friends on phone. Prevalence of poor well-being was found to be 41.2%. Female gender, being unemployed, living in Sindh and Islamabad Capital Territory (ICT), fear of COVID-19, and having chronic illness were significantly associated with poor well-being. Similarly, coping strategies during lockdown (doing exercise; spending time with family; eating healthy food; having good sleep; contributing in social welfare work and spending time on hobbies) were also significantly associated with mental well-being.

**Conclusion:** We found a high prevalence 41.2% of poor well-being among the Pakistani general population. We also investigated risk factors of poor well-being which included female gender, unemployment, being resident of ICT and Sindh, fear, chronic illness, and absence of coping strategies. This calls for immediate action at population level in the form of targeted mass psychological support programs to improve the mental health of population during the COVID-19 crises.

**Keywords:** COVID-19, mental health, psychological impact, well-being, Pakistan

## INTRODUCTION

The Corona virus disease 2019 (COVID-19) emerged in Wuhan, Hubei province of China, where a large number of patients presented with pneumonia of unknown etiology (1). Later the disease spread nationwide and across the world between December 2019 to early 2020 (2). The World Health Organization (WHO) announced the outbreak of the novel corona virus disease as a public health emergency of international concern under the International Health Regulations (IHR) on January 30, 2020, and the disease was declared a pandemic on March 11, 2020, affecting 169 countries and almost all continents (3).

COVID-19 not only posed serious threats to physical health but also triggered negative impacts on the social, psychological, and mental health of the population (4). Psychological and mental health refers to the state of people in which they realize their own ability to cope with life stressors (5). Many factors affect the psychological and mental health of the population, for instance uncertainty of the illness, social distancing, self-isolation, and quarantine (6). A nationwide survey conducted in China on 31 January 2020 revealed that the mean score of the COVID-19 Peritraumatic Distress Index (CPDI) was 23.65 ( $\pm 15.45$ ) which inquired about the frequency of anxiety, depression, phobias, cognitive change, avoidance and compulsive behavior, and loss of social functioning in the population. Almost 35% of the respondents experienced psychological and mental health problems (7). Another survey conducted in China analyzed the psychological impact of COVID 19 among the elderly population which revealed that seniors of all age segments have depression and anxiety issues (8).

Pakistan has been in the state of high alert since February 2020 when the first case was notified in the country. Government and health professionals advised for preventive measures to prevent the spread of the disease (6). These measures were later intensified with the increasing number of cases and local transmission. The government implemented complete lockdown, closure of businesses and mosques, restriction of movements, and working at home to promote social distancing and curb the spread of disease. These precautionary measures such as social distancing, staying at home, and lockdown may lead to psychological and mental health problems (6). A study conducted in Karachi, Pakistan, in March 2020 highlighted psychological problems such as increase in anxiety level and fear and changes in the behavior to ensure safety (9).

Studies have confirmed that the outbreak of COVID-19 is associated with various psychological problems, and these may continue even after outbreak is over. It is therefore important to estimate the burden of psychological problems and identify the high-risk groups in the population who may need psychological support during this crisis.

This study was a nationwide survey aimed to analyze the psychological impact of the COVID-19 epidemic in the general population of Pakistan during the outbreak. Findings of this study will be helpful in targeting the vulnerable population having psychological problems and developing a better, scientifically sound and nationwide strategic plan for comprehensive psychological crisis management.

## METHODS

We conducted an online survey among the general population of Pakistan. According to the Population Census of 2017, the total population of Pakistan is 207 million with a growth rate of 2.4%. The administrative units of Pakistan consist of four provinces, i.e., Punjab, Sindh, Baluchistan, and Khyber Pakhtunkhwa, along with two autonomous territories Azad Kashmir and Gilgit-Baltistan and one federal territory, Islamabad (10).

Due to the strict lockdown all over the country to implement social distancing and to control the disease spread, it was not possible to conduct one-to-one interviews in the community. Therefore, we decided to conduct an online survey by using all possible means of contacting the general population. Convenience and snowball sampling strategy was used to enroll the general population of Pakistan. Participants were approached through a web-based self-administered questionnaire which was formulated on Google forms. We circulated the survey link to general population through WhatsApp, Facebook, and email addresses between 26th April and 15th May 2020.

## Sample Size Calculation

Sample size was calculated using open epi sample size calculator (11). We assumed a proportion of 50% of the population to have poor well-being. This 50% proportion would provide maximum variance and sample size. At 95% confidence level and 4% absolute precision, the sample size calculated was 600 participants. We used a design effect of 2.5 to inflate our sample to capture population variability which increased to a sample of 1,500. We further inflated our sample by 20% to account for

incomplete and missing data so the final sample size required was 1,800 participants.

## Data Collection Instruments, Measures, and Variables

Data was collected using a structured questionnaire in English and local language Urdu. The questionnaire was divided into three sections and had a total of 27 questions. The first two questions before the start of demographic information were about their willingness to participate and language selection. The socio-demographic information collected in section 1 included gender, age, city, education, marital status, employment, employment type, family type, and financial support.

The attitudes of the Pakistani general population related to COVID-19 were collected in section 2 and were assessed regarding the following aspects: believing in successful control against COVID-19, believing that Pakistan can win the battle against COVID-19, believing that stopping oneself from watching news will help in decreasing the fear, and believing that the unauthentic and unverified information spreading through forwarded messages is increasing panic about COVID-19. A five-point Likert scale (strongly disagree to strongly agree) was used for all these questions.

To assess the worriedness regarding COVID-19, we asked five questions in section 3 regarding the following aspects: worried about eventually contracting COVID-19 despite taking preventive measures; worried about not being able to survive if they get infected with COVID-19; worried that if they contract the infection, drugs/treatment will have no effect; worried that they will pass the virus onto their family; and not worried of contracting it because they are already old and have lived their life the best way they could. The five-point Likert scale of worriedness was used, which included “no worry at all,” “mildly worried,” “somewhat worried,” “moderately worried,” and “extremely worried.”

## WHO-5 Well-Being Index

The five-item World Health Organization Well-Being Index (WHO-5) is among the most commonly used questionnaires assessing subjective psychological well-being (12). It is a short form of the WHO-10 item and 28-item rating scales (12, 13). WHO-5 can be used as a screening tool for depressive symptoms, monitoring emotional well-being and psychological well-being (14, 15). The WHO-5 items were the following: I have felt cheerful and in good spirits, I have felt calm and relaxed, I have felt active and vigorous, I woke up feeling fresh and rested, and my daily life has been filled with things that interest me. The response alternatives were “all of the time = 5,” “most of the time = 4,” “more than half of the time = 3,” “less than half of the time = 2,” “some of the time = 1,” or “at no time = 0.” The respondents were asked to rate how well each of the five statements applies to them when considering the last 14 days. Each of the five items is scored from 5 (all of the time) to 0 (none of the time). The raw score therefore theoretically ranges from 0 (absence of well-being) to 25 (maximal well-being). The raw score ranging from 0 to 25 was multiplied by four to give the final score from 0 representing the worst imaginable possible

well-being to 100 representing the best imaginable well-being. We used official Urdu version of WHO-5 well-being scale (16).

## Statistical Analysis

Data was downloaded as Microsoft Excel sheet and then imported to IBM SPSS for Windows, v. 22.0 (IBM Corp., Armonk, USA), for analysis. Mean and standard deviations were calculated for quantitative variables such as age, attitude domains and well-being scores. Categorical variables such as gender, marital status, education, employment status, type of employment, family type, region, financial support during lockdown, and disease status were expressed as frequencies and percentages.

The proportion for the attitudes, worriedness, and coping strategies used by the participants at the time of lockdown was determined by using frequencies of individual questions. The five-point Likert scale was converted into three-point responses such as the following: “strongly disagree” and “disagree” were merged as “disagree;” “strongly agree” and “agree” were merged as “agree;” and a middle category was “don’t know.” Similarly, the five-point Likert scale of worriedness was also converted into three-point responses; that is, “No worry at all” and “Mildly worried” and “Somewhat worried” were merged as “Somewhat worried,” and a last category was “Extremely worried.” Factor analysis was done to explore the attitude questions and give them a factor solution. Construct validity for attitude domain items was analyzed using exploratory factor analysis (EFA). To find the best fit to the data, orthogonal (varimax) rotation was used in our factor analysis. Factor loadings of more than 0.40 were considered satisfactory.

Prevalence of poor well-being was determined using a cutoff of  $\leq 50$  score on the 100-point WHO-5 well-being scale (17). Univariate and multivariate logistic regression models were developed to explore the factors associated with poor well-being among general population. Variables were included in the multivariate model based on contribution in the overall model assessed by  $-2$  log likelihood ratios. Crude and adjusted odds ratio (aOR) along with associated 95% confidence intervals (CI) were calculated.

## Ethical Approval

The ethical approval of the study was sought from the Ethics Review Committee of Women Medical College, Abbottabad (20204-2 CMD-ERC-20). The first page of the online form described the purpose of the study and consent was taken on that page from all the participants.

## RESULTS

A total of 1,756 individuals participated in the survey. The mean age of the participants was  $31.5 \pm 10.8$  years, and half (49.9%) were male. More than half (58%) had post-graduation or a professional degree. About 50% were employed, 32% were students, and 6.2% were unemployed. Among the employed, majority (48%) had a private job. The highest proportion of participants was from Khyber Pakhtunkhwa (KPK) 37% followed by Sindh 32%. The most common financial support during

**TABLE 1** | Socio-demographic characteristics of the study participants ( $n = 1,756$ ).

Characteristic	$n$ (%)
<b>Age (<math>n = 1,728</math>)</b>	
Mean (SD)	31.5 (10.8)
<b>Gender (<math>n = 1,730</math>)</b>	
Male	863 (49.9)
Female	876 (50.1)
<b>Marital status (<math>n = 1,745</math>)</b>

Ever married	917 (52.6)
<b>Education (<math>n = 1,733</math>)</b>	
Postgraduate	1,010 (58.3)
Graduate	405 (23.4)
Intermediate	259 (14.9)
Other	59 (3.4)
<b>Employment status (<math>n = 1,746</math>)</b>	
Employed	880 (50.4)
Student	556 (31.8)
Housewife	178 (10.2)
Retired	23 (1.3)
Unemployed	109 (6.2)
<b>Type of employment (<math>n = 871</math>)</b>	
Private job	419 (48.1)
Government job	340 (39.0)
Business	73 (8.4)
Small business/vendor	21 (2.4)
Part time work	10 (1.1)
Laborer	8 (0.9)
<b>Family type (<math>n = 1,745</math>)</b>	
Joint	905 (51.9)
Nuclear	840 (48.1)
<b>Region (<math>n = 1,728</math>)</b>	
Punjab	287 (16.6)
Sindh	553 (32.0)
Khyber Pakhtunkhwa	641 (37.1)
Baluchistan	53 (3.1)
Islamabad Capital Territory	136 (7.9)
Other	58 (3.7)
<b>Financial support during lockdown (<math>n = 1,724</math>)</b>	
Salary	1,013 (58.8)
Savings	266 (15.4)
Business earning	218 (12.6)
Support from friends and family	120 (7.0)
No source	62 (3.6)
Loan	29 (1.7)
Pension	16 (0.9)
<b>Disease status</b>	
Any chronic illness	418 (23.8)
Cardiac disease	38 (2.2)
Hypertension	191 (10.9)
Diabetes	88 (5.0)
Others	206 (11.7)

lockdown was salary (59%), followed by savings (15.4%). The most common chronic disease was hypertension (10.9%) while prevalence of any chronic illness was 23.8% (Table 1).

Table 2 presents the attitude and worries related to COVID-19 among the Pakistani population. About 69% and 73% participants believed that COVID-19 will be controlled globally and in Pakistan, respectively. Seventy-two percent assumed that avoiding news may help reduce the fears of COVID-19. A high proportion (90%) believed that unauthentic information through social media is adding to the panic about COVID-19. About two-thirds (68%) of the population was somewhat worried about contracting the disease even with preventive measures. Six percent were worried about surviving after the infection and no effects of treatment. A little less than half (43%) were extremely worried about transmitting infection to family members.

Prior to factor extraction for attitude domain items, sampling adequacy was checked to ensure suitability for factor analysis. The Kaiser–Meyer–Olkin (KMO) test and the Bartlett test of sphericity (BTS) showed adequate sampling. The number of factors was assessed using eigenvalues  $>1$  and a scree plot which suggested a three-factor solution and explained 57.41% of the total variance. We named the factors as controllability, misinformation, and fear related to the attitude domains of COVID-19. One item was eliminated because it did not contribute to a simple factor structure and failed to meet a minimum criterion of having a primary factor loading of 0.4 or above (Table 3). Descriptive statistics of these domains were run. Mean score was computed as the following: for the controllability domain ( $7.65 \pm 1.80$ ), for the misinformation domain ( $8.07 \pm 1.69$ ), and for the fear domain ( $16.03 \pm 4.61$ ), respectively, with higher scores suggesting higher degree of believability related to items of specific domains.

The most common coping strategies to counter the effects of lockdown and home confinement used by the participants included spending quality time with family (83%), eating healthy food (79%), adequate sleep (77%), and talking to friends on the phone (73%). Other strategies included watching TV/movies, seeking spiritual support, working on hobbies, and reading (Table 4).

The mean score of well-being as measured by the WHO-5 well-being scale was  $55.0 \pm 24.6$  out of a total of 100 points. The prevalence of poor well-being was 41.2%. Detailed results of individual items of WHO-5 are presented in Supplementary Table 1.

We found that being female, being a student, being a housewife, being unemployed, having a nuclear family, living in Sindh and Islamabad Capital Territory (ICT), and having a chronic illness were significantly associated with poor well-being in the univariate analysis. Regarding the attitude domains, the controllability and fear domains were also significant in the univariate analysis. Coping strategies were also analyzed for having an association with poor well-being among the population. In the univariate analysis, individuals who were exercising; spending time with the family; reading; taking healthy food; having a good sleep; participating in social welfare work; spending time on their hobbies; seeking spiritual support; and taking to family & friends on the phone were significantly

**TABLE 2 |** Attitudes and worriedness of Pakistani general population related to COVID-19 (n = 1,756).

Variable	n (%)
<b>ATTITUDES</b>	
<b>COVID-19 will be controlled (n = 1,744)</b>	
Agree	1,207 (69.2)

well-being compared to males, aOR 1.35 (95% CI: 1.04–1.75). The unemployed were at about 60% higher risk of having a poor well-being compared to employed individuals, aOR 1.62 (95% CI: 1.02–2.59). Those living in the Sindh province and ICT were also at a higher risk of having a poor well-being compared to Punjab province, aOR 1.54 (95% CI: 1.10–2.16) and 1.82

(95% CI: 1.13–2.93), respectively. Similarly, individuals with any chronic illness were also at a higher risk of poor well-being, aOR 1.71 (95% CI: 1.31–2.23). Similarly, those who believed in controllability were less likely to have mental well-being, aOR 0.88 (95% CI: 0.83–0.94). Those who had fear were more likely to have poor well-being, aOR 1.06 (95% CI: 1.03–1.08). In the multivariate analysis, we also found that persons who were exercising; spending time with the family; taking healthy food; having a good sleep; participating in social welfare work; and spending time on their hobbies were significantly associated with better mental well-being. Other factors such as age, marital status, education status, and family type did not show any significant association with well-being (Table 5).

## DISCUSSION

We conducted a rapid survey to determine the psychological impact of COVID-19 pandemic and its associated factors among the Pakistani general population. This pandemic, apart from the obvious morbidity and mortality, resulted in psychological distress and adverse mental consequences to the population, who are in a constant state of lockdown and quarantine for the last few months (18). The lockdown and curfew measures in Pakistan have affected the lives of common people and as a result triggered psychological problems. Therefore, the estimation of this psychological impact among the general population is crucial in guiding policies and interventions to maintain their psychological well-being. We employed a web-based survey to access the participants throughout Pakistan; it was the first web survey of its kind to assess the psychological impact of the COVID-19 pandemic and its associated factors among the general population of Pakistan.

The finding of our study showed that around 59% of the participants depended on their salary for financial support during the lockdown period. This indicates that 41% of the population depends on sources which can be affected by lockdown. This is important to document that Pakistan is a lower middle income country with limited resources and the major proportion of the population generally struggles to make their ends meet. In this crisis time, when the whole country is shut down, the people living below the poverty line are at high risk of getting affected as they mostly rely on daily wage informal work. There is no effective safety net for the vulnerable population, and therefore, there is an immediate need for the federal and provincial governments to launch the mechanism and programs for the survival of our disadvantage population. On 2nd May 2020, the federal government has launched the Ehsaas program, which promised to provide financial assistance to the unemployed population (19).

Regarding coping strategies adopted by our participants, higher responses were reported for spending quality time with family at home (83%), eating healthy food (79%), taking adequate sleep (77%), and talking to family & friends on the phone (77%). Around two-thirds of the participants reported seeking spiritual support as a coping strategy and 42% of the respondents

contributed in social welfare activities. A study from Karachi, Pakistan, reported that religious coping is a common behavior in patients presenting with symptoms of anxiety and depression (20). One recent study in Italy found that people increased the usage of digital media near bedtime during this COVID-19 lockdown (21). As the uncertainty is high regarding the period of this pandemic, the coping strategies during these depressing times are of utmost importance (22). Our population in general is utilizing this lockdown time with useful activities. However, we think that as the closure of work and other activities would continue, the vulnerable population specifically would be requiring psychological support.

In our study, two-thirds of the respondents were hopeful that the COVID-19 pandemic would be successfully controlled in the world, while three-fourths believed that Pakistan would also be able to control this pandemic through mitigation and prevention efforts. A higher proportion was reported in a recent Chinese study, where 90.8% believed that COVID-19 will finally be successfully controlled and 97.1% had confidence that China can win the battle against the virus (23). In our study, more than two-thirds of the respondents (72%) thought that stopping oneself from watching news would help in decreasing the fear related to COVID-19 during this lockdown. It was alarming that a high majority (91%) also believed that unauthentic information through social media is increasing panic about COVID-19. Balkhi et al., in a recent study in Karachi, also reported that a high proportion (84%) believed that fake news surfacing through social media regarding COVID-19 is causing panic (9). As there is an overflow of unconfirmed information related to COVID-19 on social media and there is a tendency of forwarding these types of posts or videos to the social media circle (24), there is a need to strengthen official channels of communication to educate the masses. People should rely on only official resources from the official account of the Ministry of National Health Services Regulations & Coordination, Pakistan, that would help in decreasing the fear and panic related to the pandemic. One third of the participants also thought that social distancing would become the new norm and it would be difficult to meet people in the future like before. This links to the fear and anxiety related to the lockdown and curfew environment, as the pandemic is continuously rising in all parts of the world.

Regarding concerns and worriedness, more than two-thirds of the respondents (72%) were afraid of getting the disease despite preventive measures. This proportion is higher than that reported among the Chinese population (54%) (25). Another recent study from Karachi, Pakistan, reported that around 42% fear for the safety of their health even when they are at home (9). Our study also reported that around 63% of our participants were worried that they would not be able to survive if contracting COVID-19, which is more than in the China study (30%) (25). Around 90% thought that they would transmit the infection to their family members, if they got the infection. This is supplemented by Balkhi et al. (9), who reported that 94% of the respondents fear for the health of their family members in Karachi. Contrastingly, a lower proportion at 75% was reported in a Chinese population related to family members' susceptibility (25). The worriedness and susceptibility about contracting and

–Not included in multivariate model.

transmitting infection to oneself and family members was higher in our population. A possible explanation could be that there was no complete compliance by the population to the mitigation measures taken by government, which resulted in fear related to spread of COVID-19.

The prevalence of poor well-being in our study was 41.2%. This finding was similar to one of the large Chinese surveys, which reported 35% of the respondents' experienced psychological distress during this pandemic (7). On the contrary, a recent online survey from Malaysia reported 72.1% moderate to severe anxiety (26), while a study from Egypt found 82% mild to moderate anxiety symptoms during this pandemic (27). The difference observed among different countries regarding psychological well-being could be explained by different healthcare infrastructures, the variability in responsiveness of the health system, and the prevention and control measures taken against the pandemic. The use of different tools to assess psychological well-being during this pandemic also makes it difficult to compare the findings. Regarding risk factors, we found that being a female, being unemployed, residing in Sindh & ICT, fear of COVID-19, and having any chronic illness were significant predictors of poor well-being in our population. Studies conducted in China, Iraq, and Spain reported that female gender was found to be an important predictor of depression, anxiety, and stress as compared to males during the COVID-19 pandemic (7, 28, 29). Another systematic review also reported that female gender was found to be more related to psychiatric

disorders (30). Wang et al. also reported that male gender was significantly associated with lower scores in the Impact of Event Scale-Revised (IES-R) as compared to females. Similarly, history of chronic illness was significantly associated with higher IES-R (25, 31), which is also significantly associated with poor well-being in our study. The possible explanation of these findings would be that females as primary caregivers in the households were overburdened with routine household work. In addition, they were also taking care of the responsibilities related to children and male members of the family, who are stuck at home due to lockdown. This made them more vulnerable to poor well-being. Unemployment is also considered as an important factor related to poor well-being, and presence of chronic illness makes the individual vulnerable for psychological issues. People residing in the Sindh & ICT regions were more likely to have poor well-being as compared to the Punjab region. This could be due to differences in socio-political situations and extent of lockdown compliance. However, this needs further exploration. Fear of having COVID-19 and believing that it can be passed to other family members were also significantly associated with poor well-being. Recent studies conducted among the different population groups have also reported that anxiety and fears related to COVID-19 had a significant association with psychological distress and mental health issues (32–35).

We also found that coping strategies; exercise during lockdown; spending time with the family; taking healthy food; having a good sleep; participating in social welfare work; and

spending time on their hobbies were significantly associated with better mental well-being. There were few studies conducted on a sample of university students in Poland and China (36, 37), which have reported that certain coping strategies had a positive effect on mental well-being during COVID-19.

We used a standardized and validated Urdu version of the WHO well-being scale for assessing the well-being of the population. As our questionnaire was in both languages (English & Urdu), we were able to include those people who were not comfortable in responding in the English language. We also did factor analysis to extract domains of attitude items, which enabled the use of a standardized tool. Our respondents were from all provinces, and we took the data from all the major cities of Pakistan. Also, there was a fair distribution of respondents from every region of the country. However, there are some limitations that need consideration. The online web survey was able to capture mostly the urban population of Pakistan, so we cannot generalize our findings to the rural population of Pakistan. As it was an online survey, we used all our possible contacts to invite the population through means of phone calls, messages, and one-to-one interactions. There was an oversampling of a particular characteristic (e.g., younger age group, postgraduate, and participants from KPK), leading to selection bias. However, it may serve as an important resource of psychological assessment for the educated and younger population living in Pakistan. Also, we were not able to include those segments of the population who were non-users of social media applications and those who were illiterate. Nevertheless, this is the first study in Pakistan that focused on the impact of the COVID-19 pandemic on psychological well-being of the Pakistani general population from respondents across all regions in the country. Lastly, with the help of our findings, policymakers can develop psychological interventions that can minimize the psychosocial impact of COVID-19 and also help the most vulnerable groups that are at a higher risk of experiencing poor well-being as a result of this pandemic. These findings may also be applicable to other countries with similar socioeconomic profiles as COVID-19 is affecting all the countries and measures of social distancing are more or less similar globally.

## CONCLUSION

In summary, prevalence of poor well-being due to the COVID-19 pandemic was 41.2% in our population. We reported the initial data pertaining to the psychological impact of the COVID-19 pandemic in the Pakistani population. The predictors of poor well-being were being a female, being unemployed, being a resident of Sindh & ICT, fear of COVID-19, having any chronic illness, and absence of coping strategies. This calls for the development of psychological support and interventions by the policymakers, for the general population as well as for the high-risk groups.

# COVID-19 Pandemic as the Beginning of a Golden Era for Telepsychiatry in Poland's Healthcare System

Łukasz Zadka<sup>1,2\*†</sup> and Marcin Olajossy<sup>2,3†</sup>

**Keywords:** telepsychiatry, telehealth, e-health, COVID-19, Poland

## BACKGROUND

The COVID-19 pandemic has had a tragic impact on the health and economy sectors of many countries in the world. The deepening social isolation resulting from limited interpersonal contact, the need for quarantine, overloaded healthcare professionals, and the increasing feeling of global fear, may lead to long-term deterioration in the mental health of societies and outweigh the losses of the current crisis (1).

The new coronavirus has also become an attractive topic for mass media outlets that are outdoing each other in informing the public about the current infection and death rates. At the beginning of March (2), a media campaign was launched in Poland against some patients with COVID-19. The published articles emphasized the fact that infected persons had returned from foreign travels to the country, which caused strong public outrage and accusations of deliberately bringing the virus to Poland. Stigmatization of infected people by mass media particularly affected unaware doctors returning to Poland after a vacation during that time period (3, 4). An avalanche of negative online comments caused by the published articles has led to threats against those physicians, and consequently even to suicide (5, 6). The hate wave is a well-known phenomenon that increases the risk of aggression and the percentage of committed suicides, that requires the use of appropriate strategies to prevent the spread of these adverse social impacts (7).

## FEAR OF THE UNKNOWN

Telepsychiatry is a term first introduced in 1973 by Dwyer (8), that in the current definition is a broad issue and refers to activities carried out with information and communications technology (ICT) for the provision or support of psychiatric services at a distance (9). Despite numerous reports of beneficial effects of e-platforms on mental health (9–11), in the Polish medical community it was a topic of little interest. One possible reason was the later acceptance of this therapy method, that emphasizes the fact that the Polish equivalent of the English definition “telepsychiatry” was first defined in 2003 and until that time remained a widely unknown issue (12). Wojtuszek et al. found, that two-thirds of patients had never heard of this term, and yet half of the respondents saw the usefulness of applying telepsychiatry. In relation to physicians, 84% of respondents have never dealt with the practice of telepsychiatry and 64% would not like its broader implementation in routine medical practice. The article points to administrative difficulties, the lack of relevant legal regulations, technological limitations, no payment for e-services, and security issues as major obstacles to the practice of telepsychiatry (13).

## THE SNOWS OF YESTERYEAR

One of the restrictions on the use of telemedicine in Poland was also the Medical Code of Ethics (*Kodeks Etyki Lekarskiej – KEL*). Its 9th Article indicates that a physician may only start the treatment thorough a physical examination of the patient. This article allows the possibility of distance treatment, but only in the case of an urgent need (14). The interpretation of that term remains controversial and may be interpreted differently by the physician giving the services, and otherwise by the medical court.

For Poland, the most common reasons for e-consultations are emergency incidents of mental health deterioration most often associated with anxiety disorders, followed by mood disorders (15). Moreover, e-interventions have also been shown to be beneficial to patients with schizophrenia and the therapeutic approach itself was positively evaluated by these patients (12). However, the 6th Article of KEL mentions the physician's freedom to choose the methods of follow-up that are considered most effective. It should be noted that e-services allow patients a significant reduction in travel costs (16). Here, we should refer to the 57th Article of the 2nd Act of KEL, which clearly states that the physician is responsible for choosing the form of diagnosis or therapy without putting the patient at an unreasonable expenditure (14). Therefore, there are no premises preventing the provision of telepsychiatry with regard to ethical concerns.

## THE METAMORPHOSES

The position of the Polish government on the latest changes in the Law of December 5, 1996 on the profession of physicians and dentists should be considered as positive. The Act allows clinicians to carry out diagnostic and therapeutic activities through ICT (17). The law as a valid legal act dispels any doubts about the application of telemedicine in Poland. The positive impact on the position of these services in the Polish healthcare system has also the obligation to provide e-prescriptions using the recently introduced IT platform, which has been in place since January 8, 2020 (18). These changes contribute to the better understanding of the digitization of medical systems, that should lead to increased trust in the use of ICT services.

Before the most recent pandemic, Polish psychiatrists highlighted the lack of places for patients who required hospitalization in mental health units, which resulted in the inability to provide medical benefits in line with current needs. Child and adolescent psychiatry has been particularly hit by this problem, where the needs were greatest, and the level of underfinancing remained high. The pandemic crisis caused concern associated with the obvious determinative state of the health status of patients who were in remission and the expected acceleration of mental health problems in the general population. The Polish Psychiatric Association (PTP) and the national psychiatry consultant took the initiative by making appropriate statements addressed to both the Ministry of Health and the National Health Fund of Poland. National consultants are appointed by the Minister of Health from among specialists in particular fields and their duties include but are not limited to: the initiation of national epidemiological research,

**TABLE 1** | Characteristic of telepsychiatric services available in Poland.

Subject	Description
Service definition	A remote visit (e-visit, tele-visit, online visit)
Customer	Patient identification required (identity card), the need to provide patient's personal data (first and last name, address, national identification number (PESEL) or the guardian's data (for patients with intellectual disabilities or if incapacitated)
Service provider	Physician, psychologist, psychotherapist
Recommended form of service provision	Telephone conversation or video consultation that ensures encrypted transmission; video communicators are the preferred form ( <i>empathic patient-physician relationship; possible observation of facial expressions, reactions and patient behavior</i> )
Requirements	Past medical history, current medical documentation, including the results of laboratory tests and/or neuroimaging findings the physician may ask the patient to send scans of documentation by an email or via SMS/MMS.
Responsibility	The consequences of providing incorrect, incomplete, false, misleading or otherwise incorrect data are the sole responsibility of the patient.
Restrictions	The examination cannot fully replace a direct medical or psychological examination; teleconsultation is allowed only if a direct examination cannot take place
Important reasons allowing the patient to be examined at a distance	Epidemiological threat, forced isolation of the patient or unavailability for other reasons
Conditions for refunding benefits	Provision of services using ICT systems at the place of providing benefits

ICT, Information and communications technology; SMS, Short message service; MMS, Multimedia messaging service.

Based on recommendations of the Scientific Section of Telepsychiatry of Polish Psychiatric Association (19); Regulation of the Minister of Health of 16th March, 2020 (20).

the forecast of health needs in their specific field, advising on the implementation of important tasks in the Polish healthcare system, and giving opinion and advice on tasks related to the training program of medical specialists. Adequate action by the PTP contributed to an immediate change in Polish legislation for the provision of on-line services. The latest PTP recommendations are summarized in **Table 1**.

## THE REVOLUTION - TELEMEDICAL SERVICES ARE JUST AS IMPORTANT AS AN IN-PERSON VISIT

The Polish Chamber of Physicians and Dentists (*Naczelna Izba Lekarska - NIL*) at a meeting on July 24, 2020 adopted an act on the recognition of guidelines for the provision of

telemedicine services along with the recommendation of its use by physicians and dentists as part of their profession. As highlighted, a significant contribution in the legislative work should be attributed to the statements made by Polish medical societies and recently implemented changes to the legal norms (21). Moreover, the Presidium of NIL called on the Minister of Health to undertake prompt steps leading to the introduction of proposed guidelines as an existing standard for the Polish healthcare system (22, 23). The appeal took into account the benefits of implementing telemedicine services into routine medical practice, as well as the negative impact of the COVID-19 pandemic which required adequate action, justifying the immediate use of ICT services.

Obviously, the provision of telemedicine services must be consistent with the Polish legal system. The emphasis was placed on the issue of the security of the patient's personal data and medical data, emphasizing the need to maintain medical confidentiality when performing e-services. Healthcare institutions providing e-services in the field of telemedicine are required to secure data transmission and enable optimal accessibility to such services for every recipient. This means ensuring appropriate system requirements, securing the network, and providing facilities with all electronic tools needed to enable e-consultation with a patient. With regard to medical practitioners, the appropriate amendments to professional liability related to the provision of telemedicine services have been taken into account, in light of which the use of telemedicine is not only highly recommended, but also mandatory when the patient's condition requires it. If a physician fails to provide e-services, when available and required, they could be held legally liable for malpractice. The healthcare entities employing medical staff are now responsible for their mistakes resulting from given e-services, if the employee was hired under an employment contract. In case of a contract physician, the liability rules will be enforced individually on the basis of the concluded contract.

A need to use telemedicine services during the COVID-19 pandemic was noticed, which was emphasized in the prepared guidelines as well as in the written communication to the Minister of Health. An additional interpretation was also introduced in relation to the previous rules of medical ethics, which previously limited the implementation of e-services, thus a physical examination of the patient is currently recommended only in cases where it is necessary to perform it. The following NIL directives, included in the guidelines, are particularly worth emphasizing:

- Telemedicine is a recognized method of patient care, and thus it can be treated as one of the standards of medical treatment.
- The medical practitioner should use the potential of telemedicine to realize the patient's rights.
- Telemedicine enables the implementation of individual patient rights in a new, digital way.
- Telemedicine advice should not be disregarded due to its remote form. The rules of professional, civil, and criminal liability for telemedicine services are the same as in the case of other services, and the recipient receives all rights pertaining to a patient.

The adopted guidelines constitute a decisive and important turnaround to the previously discussed limitations of the implementation of telemedicine services resulting from some articles of KEL.

## IT IS TOO SOON FOR THE EPILOG

The updates incorporated into the Polish healthcare sector are moving in the right direction. In our opinion, previously hospitalized patients on long-term treatment will benefit the most. Many of them are often in contact by phone to provide expert support. There are still doubts to first-time treated patients, where the diagnosis, often in psychiatry, is based on medical history and may be difficult, thus actions taken will be at risk. However, it should be noted that in the face of the current pandemic, special care is required for patients with anxiety disorders. Panic and behavioral change due to the necessity of wearing gloves and medical masks to protect against the contamination by the new coronavirus may increase anxiety and polarize the current problems in the direction of a "coronaphobia" (24). The increased availability of e-services will also intensify the phenomenon of the deinstitutionalization of Polish psychiatry, will help patients gain access to medical specialists, and it will reduce the difficulties included with a limited number of hospital beds. Therefore, we look forward to the future with optimism.

The coronavirus disease 2019 (COVID-19) pandemic has strongly affected oncology patients. Many screening and treatment programs have been postponed or canceled, and such patients also experience fear of increased risk of exposure to the virus. In many cases, locus of control, coping flexibility, and perception of a supportive environment, specifically family resilience, can allow for positive emotional outcomes for individuals managing complex health conditions like cancer. This study aims to determine if family resilience, coping flexibility, and locus of control can mitigate the negative affect caused by the pandemic and enhance positive affect in breast cancer patients. One hundred and fifty-four female patients with breast cancer completed the Walsh's Family Resilience Questionnaire, the Perceived Ability to Cope With Trauma Scale, the Positive-Negative Affect Schedule, and the Mini Locus of Control Scale. Family resilience and internality of locus of control contribute significantly to positive affective responses. Family resilience is responsible for mitigating the negative affect perceived during the pandemic and is enhanced by external locus of control. Evidence suggests that clinical psychologists should develop and propose programs to support oncology patients' family resilience, coping flexibility, and internal locus of control, allowing for decreased stress and improved adaptability for effectively managing cancer treatment during the pandemic.

**Keywords:** breast cancer, coronavirus, COVID-19, locus of control, coping flexibility, family resilience, breast cancer patients

## INTRODUCTION

Since late February 2020, Italy has been drastically affected by the coronavirus disease 2019 (COVID-19) pandemic, resulting in approximately 229,300 positive cases and 33,000 deaths (World Health Organization, 2020). The pandemic has required a restructuring of the hospital system and suspension of all non-essential health services to better manage the influx of COVID-19 patients while also reducing potential exposure to uninfected patients (Curigliano et al., 2020; van de Haar et al., 2020). The pandemic has also necessitated the implementation of a countrywide

lockdown – effective at the beginning of March 2020 – including the closure of places previously open to the public, suspension of all non-essential activities, telecommuting requirements for the workforce, and a stay-at-home order for the general population.

Many COVID-19 patients have presented with comorbidities like cardiovascular disease, liver disease, or malignant tumors (Guan et al., 2020; Thakur, 2020; Yang et al., 2020). However, evidence remains unclear if oncology and other immunosuppressed patients are at an increased risk of severe complications from the virus as compared with healthy individuals among the general population (D'Antiga, 2020; Desai et al., 2020). Oncology patients have been more strongly impacted by the pandemic, not only because of the fear and panic of increased risk of infection (Casanova et al., 2020; Mark and Lewis, 2020; Romeo et al., 2020) but also because many treatment and screening programs have been postponed or canceled until the spread of the virus is stabilized, potentially compromising the affective states of these patients. Donovan stated that when traumatic events like cancer diagnoses or emergency situations arise, personal outcomes – adaptation versus maladaptation – are affected by family response (Donovan, 1998). Additionally, the Double ABC-X model (McCubbin and Patterson, 1983) explains that the interaction between the traumatic event and subsequent life stressors is determined by perceptions of family support, coping strategies, and locus of control.

Family resilience is defined as the perceived ability of a family to withstand a crisis which disrupts their normal course of life and can be a protective factor against stress and negative affect (Walsh, 1996). Perceptions of family's role, system of beliefs, values, and behaviors are essential in helping a family member overcome traumatic events (Patterson, 2002). For example, if one family member has been diagnosed with cancer, perceived high levels of family resilience can significantly influence personal outcomes such as medication compliance, rehabilitation, and social or occupational reintegration (Faccio et al., 2018). These resources may also offer support in overcoming challenges like negative emotions linked to heightened perception of risk, mandatory quarantine, and possible postponement of treatments presented by the COVID-19 pandemic (Killgore et al., 2020; Prime et al., 2020; Russell et al., 2020).

Another protective factor is coping flexibility. A literature review by Kashdan and Rottenberg (2010) identified coping flexibility as a vital component of health and adjustment to stressors across a variety of settings. Since the early 1990s, coping flexibility has been associated with improved well-being and success in confronting stress (Lester et al., 1994). Additionally, it is associated with decreased anxiety and depression as well as symptom severity, ultimately increasing overall quality of life (Cheng, 2003; Kato, 2012, 2015). These studies demonstrate that coping flexibility contributes to improved psychological well-being, further confirmed by individuals' reports of decreased levels of depression and increased abilities in managing work-related stress following completion of a coping flexibility intervention (Cheng et al., 2012).

When assuming a situational perspective, a cross-situational view of coping flexibility supports that coping-flexible individuals can adjust their strategies across stressful events (Westman and Shirom, 1995; Murphy, 2001; Thompson et al., 2007). Oncology

patients, for example, have already experienced a severe adverse traumatic event – cancer diagnosis and prognosis – which can introduce important emotional consequences (Williams, 2002) and coping challenges (Nipp et al., 2016). Coping flexibility (Oliveri et al., 2019a) is therefore considered a valuable tool that allows such patients to reduce distress (Bonanno et al., 2011) during stressful circumstances (Roussi et al., 2007) like the COVID-19 pandemic. Coping flexibility remains especially vital in reconciling the need to both elaborate the trauma and maintain a positive outlook toward the future after the event has subsided (Bonanno et al., 2008). Oncology patients who can access these coping resources are more likely to endure the pandemic and subsequent lockdown with adequate emotional response (Kaliampou and Roussi, 2018). Examining emotional responses of breast cancer patients during the pandemic can therefore be a preliminary approach to understanding its impact.

Patients' affect during the COVID-19 pandemic is also influenced by locus of control (Romeo et al., 2019), which determines if individuals perceive the events they are experiencing to be driven by external (e.g., circumstances) or internal (e.g., individuals' personality, abilities, etc.) factors (Rotter, 1966). These beliefs influence individuals' cognition, behavior, and affect (Wallston et al., 1978). Evidence has shown that having an internal locus of control is a strong predictor of better psychological adjustment to cancer: behavioral scientists have long been interested in understanding how an individual's locus of control relates to coping and adjustment (Knappe and Pinquart, 2009; Galvin et al., 2018). Recent research highlights that internal locus of control generates positive emotions and lessens negative ones (Crisson and Keefe, 1988; Gupta et al., 2018). Thus, internal locus of control lowers the perceived level of distress (Ryan and Deci, 2008), threat, and depression (Arraras et al., 2002; Goldzweig et al., 2016) while improving the quality of life (Sharif and Khanekharab, 2017; Toscano et al., 2020) among patients.

The literature therefore highlights the role of these variables in reducing the levels of distress and in promoting psychological adjustment. At the moment, there is no empirical evidence on their impact on Italian cancer patients' affects during the first month of the 2020 lockdown. Therefore, the purpose of this paper is to determine if family resilience, coping flexibility, and locus of control can mitigate the negative affect and enhance positive affect in Italian oncology patients during the first month of the COVID-19 pandemic.

## MATERIALS AND METHODS

The study was reviewed and approved by the IEO (Istituto Europeo di Oncologia) Ethic Committee. The patients/participants provided their informed consent to participate in this study.

### Procedure

Participants were eligible for the study if the patient (a) was female, 40–70 years of age at the time of recruitment diagnosis; (b) had a breast cancer diagnosis requiring surgery; (c) is receiving any type of systemic treatment for breast cancer

regardless of treatment type; and (d) could both read and speak Italian. All patients received their diagnosis in 2019 or later, and all the patients had cancer in stages I–III. Participants were recruited using a convenience sampling method during the COVID-19 quarantine. Participants were a pool of IEO patients who at the time of the admission gave their availability to participate to research studies and were at the time enrolled in other research projects. All eligible patients were contacted through email or telephone, on the preferred method of contact they gave for the study. A message was included to invite them to take part to the study and an anonymous link to the survey was included.

The survey was hosted by Qualtrics, and an anonymous link was made available to the patients. Participation in the study was voluntary, and patients could withdraw from the study at any time. Participants signed consent forms and completed questions regarding sociodemographic characteristics as well as questions regarding family resilience, coping flexibility in trauma, locus of control, and positive and negative affect. The questionnaire was available from March 19th to March 31st, 2020, starting 4 weeks after the partial lockdown (school closure) and 10 days after the full lockdown (closure of all non-essential businesses and movement restrictions) in Italy.

## Participants

Out of a total of 250 women with breast cancer, 181 started the questionnaire, and 154 completed the questionnaire. Mean age was 51.07 (SD = 7.93). Thirty-seven (20.4%) were single and 146 (79.6%) were in a stable relationship (married or cohabiting), and 127 (70.2%) had children. Regarding educational levels, 40.3% ( $n = 73$ ) of the participants possessed a high school diploma, 7.2% ( $n = 13$ ) achieved a bachelor's degree, and 26% ( $n = 47$ ) achieved a higher specialization. One hundred and twenty-five participants (69.1%) were still receiving systemic treatment that included chemotherapy, radiotherapy, and/or endocrinological treatment at the time of the survey. All percentages were calculated for total available cases for each demographic variable.

## Measures

After completing the sociodemographic form, participants were asked to fill the following sections:

Family resilience (FR) was measured with the Italian version of the Walsh's Family Resilience Questionnaire (Rocchi et al., 2017), a 26-item questionnaire, on a five-point Likert scale (1 = "not at all"; 5 = "completely agree") assessing the three dimensions of family resilience: shared beliefs and support, family organization and interaction, and utilization of social resources. Shared beliefs and support (FR\_SBS) includes values, beliefs, and attitudes, establishing a set of shared suppositions that activate emotional responses, form decisions, and orientate action (15 items). Family organization and interaction (FR\_FOI) is the perceived family capacity to adapt and identify collaborative solutions to manage crises and avoid conflicts (eight items). Utilization of social resources (FR\_USR) indicates individuals' perceived ability of the family to harness support from social and institutional organizations (three items).

Coping flexibility (CF) was measured with the Italian version of the Perceived Ability to Cope With Trauma Scale (PACT) (Saita et al., 2017), which examines the broad categories of coping behaviors in response to potentially traumatic experiences. The Italian version of the PACT differs from the original one for the number of items and dimensions: The questionnaire was composed of 14 items which asked participants to rate their ability to use different coping strategies on a seven-point scale (1 = "not at all able"; 7 = "extremely able"). Forward focus (CF\_FF, nine items) is the component that assesses coping abilities related to maintaining plans and goals, attending to the needs of others, thinking optimistically, remaining calm, reducing painful emotions, and laughing. The trauma focus subscale (CF\_TF, five items) explores the ability to fully experience the emotional and cognitive significance of a stressful, and potentially traumatic, event.

Locus of control (LOC) was measured with the Italian version of the six-item Mini Locus of Control Scale (MLCS) (Perussia and Viano, 2008). It is a self-reported scale that investigates locus of control based on three factors: chance (LOC\_C, two items), powerful of others (LOC\_PO, two items), and internality (LOC\_I, two items). The questionnaire is composed of six items on a four-point Likert scale (1 = "not at all"; 4 = "completely agree").

Affect was measured through the Positive-Negative Affect Schedule (PANAS) (Terraciano et al., 2003). This scale is comprised of two 10-item mood scales and was developed to provide brief measures of positive and negative affect. Subjects are asked to rate each peculiar emotion experienced within a specified time period, with reference to a five-point scale (1 = "very slightly or not at all"; 5 = "very much"). The specified time period in this case was 15 days before the questionnaire was completed, taking place during the COVID-19 pandemic in Italy.

## Statistical Strategy

Demographic variables were described using descriptive statistics. Before proceeding with the regression analyses, assumptions were checked and the data met the requirement for the analysis. Two stepwise regression analyses (forward method with removal test for the least useful predictor) were conducted with dimensions of family resilience, dimensions of locus of control (chance, powerful others, internality), and coping flexibility as predictors, with positive and negative affect as outcome variables. Variance inflation factors (VIF) revealed acceptable values of collinearity between independent variables and are included in **Table 2**.

## RESULTS
